- Increased pulmonary arterial pressures also cause intracardiac shunting across any patent foramen ovale, ductus arteriosus, or atrioseptal or ventriculoseptal defect that may be present. This shunting causes more deoxygenated blood to go to the left heart and to be pumped to the body. The oxygen saturations postductally are lower than preductally.
- Deoxygenated blood in the left heart can lead to ischemic damage to the heart and right or left ventricular failure.
- If there is no shunting of blood, or the blood cannot get from the right to left heart because of a lack of persistent fetal pathways, a neonate may develop poor systemic perfusion, severe acidosis, shock, right ventricular failure, and even death.
- Any hypoxia, acidosis, or stress that occurs after birth further increases pulmonary vascular resistance.

ETIOLOGY

- Abnormal persistence of pulmonary vasculature constriction after birth secondary to underlying disease: infection, pneumonia, or meconium aspiration
- Secondary to an anatomic abnormality that has caused hypoplastic vasculature: congenital diaphragmatic hernia, oligohydramnios and pulmonary hypoplasia, or alveolar capillary dysplasia
- Idiopathic: The pulmonary vasculature is remodeled due to chronic in utero stress or hypoxia or the maternal use of nonsteroidal anti-inflammatory drugs (NSAIDs) near term. Data is unclear on maternal use of selective serotonin reuptake inhibitors (SSRIs) in the 2nd trimester and PPHN.

COMMONLY ASSOCIATED CONDITIONS

Related to the underlying disease or as a complication of treatment

- Pneumothorax or air leak syndrome
- Chronic lung damage
- Long-term developmental delays
- Cerebral palsy
- Sensorineural hearing loss

DIAGNOSIS

HISTORY

- Pregnancy history
 - Congenital diaphragmatic hernia, congenital pulmonary airway malformation, and congenital heart disease can all be diagnosed with a prenatal ultrasound.
 - History of oligohydramnios, which may be associated with pulmonary hypoplasia in the neonate
- Problems during labor and delivery
 - Events that can cause fetal distress and/or hypoxia: maternal chorioamnionitis, group B streptococcal infection, difficult delivery, or meconium aspiration
- Initial clinical course
 - Infants with PPHN usually present with mild respiratory distress that worsens in the 1st minutes to hours of life, progressing to respiratory failure, labile oxygenation with pre- and postductal saturation differences $>5\%$, hypoxia, and poor perfusion.
- Infants with cardiac disease, congenital pulmonary airway malformation, or congenital diaphragmatic hernia are usually cyanotic and in significant distress from birth.

PHYSICAL EXAM

- The following physical exam findings suggest a diagnosis of PPHN:
 - Significant respiratory distress with tachypnea, nasal flaring, grunting, and retractions and cyanosis
 - Lung sounds may be clear or coarse.
 - Pale, gray color with poor perfusion

- Tricuspid regurgitation murmur heard at the left lower sternal border or prominent S2
- The following physical exam findings suggest diagnoses other than idiopathic PPHN:
 - Barrel chest shape suggests a pneumothorax or meconium aspiration.
 - Scaphoid abdomen suggests congenital diaphragmatic hernia.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential: leukocytosis, leukopenia, bandemia, or neutropenia suggests bacterial infection
- Blood culture: should be performed in all cases of PPHN to rule out infection
- Frequent arterial blood gases
 - Help to determine degree of hypoxia, hypercapnia, acidosis, and illness
 - Help manage ventilator support
 - Determine need for extracorporeal membrane oxygenation (ECMO) by calculating the oxygenation index (OI)
- OI
 - $OI = (\text{mean airway pressure} \times FiO_2 / PaO_2) \times 100$
 - Used to express severity of respiratory distress and to determine if neonate is a candidate for ECMO
 - Should be calculated with every blood gas: 3 OIs >40 suggest the need for ECMO.
- Hyperoxia test: While exposed to FiO_2 of 100% oxygen, a $PaO_2 >250$ mm Hg almost completely rules out cyanotic heart disease.

Imaging

- Chest radiograph
 - In idiopathic disease, usually shows clear lungs
 - Will help diagnose pneumothorax, hyperinflation, meconium aspiration, and atelectasis
 - Assessing cardiac silhouette and pulmonary vascular markings may help rule out some congenital heart disease.

- Echocardiogram (very important)
 - To exclude congenital heart disease
 - To diagnose PPHN with right to left blood flow in the patent ductus arteriosus (PDA) and can estimate pulmonary artery pressure by septal positioning and tricuspid regurgitation
 - To follow cardiac output and function

DIFFERENTIAL DIAGNOSIS

- Congenital
 - Cyanotic congenital heart disease
 - Total anomalous pulmonary venous return
 - Congenital diaphragmatic hernia
 - Congenital pulmonary airway malformation
 - Alveolar capillary dysplasia
- Infectious
 - Pneumonia
 - Sepsis
- Pulmonary
 - Meconium aspiration syndrome
 - Blood or amniotic fluid aspiration
 - Pneumothorax or air leak syndrome
 - Surfactant deficiency (respiratory distress syndrome [RDS])
 - Pulmonary hypoplasia
 - Idiopathic pulmonary hypertension

TREATMENT

GENERAL MEASURES

- All infants should be transferred to a level III neonatal intensive care unit where high-frequency ventilation (HFV) and inhaled nitric oxide (iNO) are available. If the neonate meets or nearly meets criteria for starting ECMO (OI >40 on 3 different blood gases), then ECMO should be available at the receiving institution.
- Support respiratory status
 - Conventional ventilation or HFV to improve oxygenation and

- ventilation while minimizing lung damage
- No set guidelines for ventilator management
- Most institutions feel that HFV minimizes lung damage when high mean airway pressures (>15 cm H₂O) are needed.
- Frequent monitoring to keep PaO₂ between 60 and 90 mm Hg, PCO₂ >35 –45 mm Hg, and OI below ECMO criteria (OI >40 times 3)
- Avoid hyperventilation, which has been associated with poor neurodevelopmental outcome.
- Lower the pulmonary vascular resistance and thus promote pulmonary blood flow:
 - Give 100% oxygen.
 - Keep blood gas pH normal (7.3–7.4) while keeping PaCO₂ >35 –45 mm Hg by ventilator manipulation.
 - Keep systemic BP high (mean BP >45 –50 mm Hg) with volume, transfusions, or medications.
 - Treat acidosis with fluid, blood, or bicarbonate infusion.
- Improve O₂ saturation and O₂ tissue delivery:
 - Initially, 100% O₂ should be used to keep the PaO₂ >60 –90 mm Hg and the O₂ saturation around $>97\%$. The O₂ can be weaned very slowly (2% per hour).
 - iNO, a pulmonary vasodilator, should be used if the infant is on 100% (FiO₂) O₂ and the OI is >20 on two blood gases.
 - Has been shown to decrease the need for ECMO in term neonates with hypoxic respiratory failure secondary to PPHN, except for those babies with congenital diaphragmatic hernia
 - Wean slowly: If oxygen and iNO are weaned too quickly, the infant can become critically ill because PPHN is a very labile condition.
 - 30% of infants with PPHN do not respond to iNO and will need ECMO.
- Reduce oxygen demand:
 - Sedatives and paralytics may be given to prevent fluctuations in oxygenation during care. Minimize the use of paralytics because

they have been shown to increase mortality.

- Minimize stimulation
- Treat any underlying lung disease with the following, if applicable:
 - Antibiotics
 - Surfactant (especially in meconium aspiration)

ALERT

- Can be difficult to differentiate cyanotic congenital heart disease from PPHN. Infants who fail to improve should be reevaluated for an underlying disease process.
- PPHN is a very labile condition. Neonates can change from being stable to being very sick and emergently needing ECMO.
- ECMO, although lifesaving and with a good survival rate, is not without problems. Side effects include the following:
 - Repeated exposure to blood products
 - Risk of bleeding
 - Potential for long-term neurologic sequelae
 - Long-term risk of having only one patent carotid artery

ONGOING CARE

PROGNOSIS

- PPHN usually resolves either spontaneously or as the underlying parenchymal lung disease improves.
- Survival rate is good even for neonates who receive ECMO. Survival rate and incidence of long-term sequelae depend on underlying disease and severity of illness.
- Survival rate for all causes of PPHN in patients not requiring ECMO is >90%. ~10–20% has sensorineural hearing loss or an abnormal neurologic exam at follow-up.
- For those requiring ECMO, survival rate is 80% for idiopathic disease, 90% for meconium aspiration syndrome, 80% for disease secondary to sepsis, and 50–60% for patients with congenital diaphragmatic hernia. Roughly 20% of these survivors have sensorineural hearing loss or abnormal neurologic examinations at follow-up.

COMPLICATIONS

- Myocardial dysfunction
- Congestive heart failure (CHF)
- Hypoxic ischemic insult

CODES

ICD10

P29.3 Persistent fetal circulation

FAQ

- Q: Does iNO improve outcome in newborns with severe PPHN?
- A: Yes. iNO has been shown to decrease the need for ECMO by 40%. Recommended starting dose is 20 ppm. Follow-up studies have shown no difference in long-term disabilities between those babies treated and not treated with iNO. Long-term outcome is mainly determined by the underlying disease and the severity of illness.
- Q: Are there any other potential therapies for treating PPHN?
- A: Yes. Inhaled tolazoline, other smooth muscle relaxants

(dipyridamole, zaprinast, and E4021), iloprost, and bosentan have been studied and have been shown to be effective in enhancing the vasodilatory effects of iNO. Sildenafil has been shown to be beneficial but is being used in select cases under special guidance due to concerns for increased mortality in children with pulmonary artery hypertension.

PERTHES DISEASE

Harry K.W. Kim

BASICS

DESCRIPTION

Childhood femoral head osteonecrosis of unknown etiology, which can weaken the femoral head and produce a permanent femoral head deformity in some patients, predisposing them to early arthritis

EPIDEMIOLOGY

- Prevalence varies depending on the region: 0–15 per 100,000 children <15 years of age.
- In the United States and Canada, about 5 per 100,000
- Rare in African Americans
- Most frequent in children 4–8 years old
- 3–5 times more common in boys than girls
- 10–15% develop bilateral disease in asynchronous fashion.

PATHOPHYSIOLOGY

- A partial or complete disruption of blood supply to the femoral head produces a partial or total femoral head osteonecrosis.
 - The greater the femoral head involvement, the worse the prognosis.
 - Bone necrosis and subsequent resorption of necrotic bone weaken the femoral head.
 - Weight bearing worsens the femoral head deformity.
- Chronic hip joint synovitis also develops producing pain and restriction of motion.
- Necrotic femoral head goes through 4 stages of healing over 3–5 years:
 - 1. Stage of avascular necrosis
 - Smaller femoral head epiphysis with increased radiodensity
 - 2. Stage of fragmentation
 - Necrotic epiphysis shows fragmentation.
 - Necrotic bone is resorbed, weakening the head.
 - Most deformity occurs during this stage, which lasts 1–2 years.

- 3. Stage of reossification
 - New bone begins to fill the epiphysis.
 - Longest stage, lasting up to 3 years
- 4. Healed
 - Femoral head is completely reossified.
 - Not all heal back in round shape, and deformed femoral heads are at risk for developing arthritis later.

ETIOLOGY

- Unknown
- Unlikely genetic transmission, as <5% have family history
- Many theories:
 - Multifactorial (genetic predisposition with environmental trigger)
 - Hyperactivity and subclinical trauma
 - Type II collagenopathy
 - Thrombophilia (factor V Leiden)
 - Tobacco smoke exposure

COMMONLY ASSOCIATED CONDITIONS

- Delayed bone age
- Hyperactivity
- Genitourinary anomalies (hypospadias, undescended testis, and inguinal hernia)

DIAGNOSIS

HISTORY

- Age at onset of symptoms, location, duration, patient's activity level, and risk factors for osteonecrosis are important.
- Age at onset before 6 years has better prognosis than after 6 years.
- Most common symptoms are limping and pain.
 - Insidious, relatively mild, able to ambulate (unlike septic hip)
 - Commonly complain of knee or thigh pain and NOT hip or groin pain, which may mislead an unsuspecting physician and delay the diagnosis
 - Weeks' to months' duration with waxing and waning of pain and

limping

- Worse during or after sports activities
- Participation in high-impact activities that involve running and jumping may produce greater symptoms and synovitis.
- Known causes of osteonecrosis must be ruled out through history:
 - Previous hip surgery
 - Corticosteroid use
 - Sickle cell disease
 - Neonatal hip sepsis
 - Coagulopathy
 - Gaucher disease
- Obtain family history for Perthes disease, skeletal dysplasias, and early arthritis.

PHYSICAL EXAM

- Because pain can be nonspecific (such as knee or thigh pain), careful exam is required to localize the source of pain.
- Gently check hip and knee passive range of motion with patient recumbent:
 - Patients with Perthes will have limited hip internal rotation and abduction. Knee exam should be normal.
 - The loss of motion may be mild in the early stage and becomes worse during the stage of fragmentation.
 - In severe cases, hip flexion and adduction contractures may be found.
- Assess walking for limping and Trendelenburg gait: head and trunk leaning over to the affected leg as it takes stance.
- Positive Trendelenburg test
 - Have the patient lift one leg off the ground while standing straight.
 - When the weight is on the normal hip, the pelvis is maintained in a horizontal position.
 - When the weight is on the affected hip, the pelvis drops due to the hip abductor muscle weakness.
- Atrophy of thigh muscles and slight shortening of the affected side are late findings.
- Check face, hands, feet, chest, and spine for signs of skeletal dysplasia.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Labs are not required.
- May be helpful if infectious, inflammatory, or metabolic conditions mimicking Perthes are being considered.

Imaging

- Diagnosis of Perthes requires imaging.
- Anteroposterior (AP) pelvis and frog-leg lateral views are primarily used.
- Radiographic findings vary depending on the duration and the stage of the disease.
 - Early stage: smaller femoral epiphysis, increased radiodensity, and a widened space between the epiphysis and the medial acetabulum compared to the normal side. In some patients (30%) subchondral fracture or crescent sign can be seen.
 - Fragmentation stage: slight to severe flattening of the epiphysis, which is best seen on a lateral view; fragmented appearance of the epiphysis with radiolucent areas (bone resorption); and lateral extrusion or subluxation of the epiphysis
- MRI, especially gadolinium-enhanced MRI, maybe helpful in the early stage of the disease when the diagnosis is questionable.

DIFFERENTIAL DIAGNOSIS

Perthes is a diagnosis of exclusion. Known causes of osteonecrosis along with other conditions that mimic Perthes must be ruled out.

- Transient or toxic synovitis
- Infection
 - Septic arthritis
 - Subacute osteomyelitis
 - Tuberculosis of hip
- Chondrolysis
- Juvenile rheumatoid arthritis
- Traumatic osteonecrosis secondary to hip fracture or dislocation
- Corticosteroid-associated osteonecrosis: for treatment of leukemia and inflammatory conditions

- Sickle cell disease–induced osteonecrosis
- Iatrogenic osteonecrosis: hip surgery for DDH, hip pinning
- Tumor or tumorlike conditions affecting the proximal femoral epiphysis or acetabulum
 - Osteoid osteoma
 - Chondroblastoma
 - Bone cyst
- Skeletal dysplasias
 - Multiple epiphyseal dysplasia
 - Trichorhinophalangeal syndrome
 - Spondyloepiphyseal dysplasia
- Gaucher disease
- Hypothyroidism
- Hemophilia

TREATMENT

- Treatment principles
 - Restore and maintain good hip motion, especially abduction.
 - Prevent the collapse and lateral extrusion of the femoral epiphysis.
- Initial treatment for symptomatic patients include rest, activity restriction, weight-relief using crutches, walker or wheelchair, gentle range of motion exercises, and NSAIDs.
- In general, patients should be referred and followed by a pediatric orthopedic surgeon with expertise in managing Perthes.
- Early recognition and treatment may prevent or minimize the development of the femoral head deformity.

MEDICATION

- NSAIDs should only be used for a short duration (few days to a week), as prolonged use may inhibit bone formation.
- Supplemental calcium and vitamin D if poor diet and/or inadequate sun exposure.

ADDITIONAL TREATMENT

General Measures

- Based on the age at onset of the disease, the stage of disease, and the extent of head involvement
- Patients with the onset of disease before age 6 years are treated with nonoperative means:
 - Bed rest for few days if motion is severely limited
 - Weight relief of the affected limb using crutches, walker, or wheelchair during the stages of avascular necrosis and fragmentation if severe disease
 - Range of motion exercises
 - Petrie casts (long leg casts with abduction bar) and abduction bracing if unresponsive to aforementioned
- Surgery to keep the femoral head contained within the acetabulum in older age group of patients

ISSUES FOR REFERRAL

Patients with Perthes disease should be referred to a pediatric orthopedic surgeon.

SURGERY/OTHER PROCEDURES

- Surgical treatments such as femoral varus osteotomy or pelvic osteotomy are recommended for patients with the onset of disease after age 8 years and greater than 50% head involvement.
- For 6–8-year-old age group, unclear whether surgical treatment is beneficial.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patient should be seen every 3–4 months to assess disease progression and compliance to treatment during the active phase of disease.
- Activity and weight-bearing restrictions generally continue until patient enters the reossification stage.

Patient Monitoring

Examine for the following:

- Worsening of limping and pain
- Loss of hip motion, especially hip abduction
- Radiographic changes: progression of femoral head collapse, lateral extrusion of the femoral epiphysis, and subluxation

PROGNOSIS

- Depends on the following:
 - Age at onset of the disease (onset before age 6 years is better than after age 6 years)
 - Extent of femoral head involvement; poorer prognosis if >50% head involvement
 - Development of poor prognostic radiographic signs: flattening of the lateral part of the epiphysis (lateral pillar C hip), subluxation of the epiphysis, growth disturbance of the proximal femoral physis producing short, broad femoral neck
- Long-term prognosis depends on the shape of the femoral head at skeletal maturity and how well it fits the acetabulum.

COMPLICATIONS

- 1–2 cm limb length discrepancy
- Restricted hip range of motion
- Residual femoral head deformity
- Overriding greater trochanter with lateral impingement and abductor weakness
- Femoroacetabular impingement and labral disease
- Early osteoarthritis

CODES

ICD10

- M91.10 Juvenile osteochondrosis of head of femur, unspecified leg
- M91.11 Juvenile osteochondrosis of head of femur, right leg
- M91.12 Juvenile osteochondrosis of head of femur, left leg

FAQ

- Q: When should I obtain radiographs?
- A: Diagnosis of Perthes requires radiographic confirmation. AP pelvis and frog-leg lateral radiographs should be obtained when a child presents with intermittent thigh, knee, or groin pain that has been present for weeks and has the finding of decreased hip range of motion but normal knee exam.
- Q: Why do patients with Perthes complain of knee or thigh pain instead of hip pain?
- A: Knee, thigh, and hip regions share the same sensory nerve. Thus, pain originating from one site (for instance hip) can be felt by a child as if it is originating from another site (for instance knee). This can cause confusion in localizing the correct source of pain and obtaining appropriate radiographs. Some patients get knee x-rays and MRI before getting hip x-rays because of this. Thus, it is important to examine both the hip and the knee even if a child complains only of knee pain.

PERTUSSIS

Camille Sabella

BASICS

DESCRIPTION

Pertussis (whooping cough), classically caused by *Bordetella pertussis*, is a protracted illness characterized by spasms of cough.

EPIDEMIOLOGY

- Pertussis is one of the most highly communicable diseases with attack rates close to 100% in susceptible individuals exposed at close range.
- Humans are the only hosts of *B. pertussis*.
- Route of spread is via large aerosolized respiratory droplets.
- Spread most commonly occurs during the catarrhal stage and first 2 weeks of cough onset.
- Incubation period 5–21 days.
- Pertussis occurs with seasonal peaks (late summer-autumn) and 3–5-year cycles of increased incidence of disease.
- Adolescents and adults serve as major reservoirs and source of pertussis for infants.

Incidence

- Pertussis infection rates have steadily risen since the early 1980s.
 - This is due to the combination of imperfect vaccines, waning immunity, incomplete vaccination, low transplacental protection for infants, and increased detection and reporting.
- Infants younger than 2 months of age have the highest age-related incidence.
- Rates in adolescents have been steadily increasing and now approach rates in infants.
- Studies have indicated that 10–30% of adolescents and young adults with prolonged cough have pertussis.

GENERAL PREVENTION

- Infection control

- Isolation of hospitalized patient: droplet precautions for 5 days after starting appropriate antimicrobial therapy or for 3 weeks after the onset of cough, if antibiotics were not given
- Care of exposed people: Exposed individuals (all household contacts, other close contacts, other children in child care) should receive chemoprophylaxis (same agents and doses as treatment; see the following discussion) to limit secondary transmission, regardless of immunization status. Immunization should be given to all unimmunized and underimmunized children and to adolescents and adults who have not yet received the Tdap booster vaccination.
- Immunizations
 - All pertussis vaccines available in the United States are acellular vaccines in combination with diphtheria and tetanus toxoids.
 - Universal immunization of all children <7 years of age with DTaP vaccine is recommended as per CDC and AAP guidelines.
 - Undervaccinated children ages 7–10 years, all adolescents ages 11–18 years, adults ages 19–64 years, as well as certain adults ages 65 years and older should receive a single dose of Tdap vaccine to help control the rate of infection in infants and young children.

PATHOPHYSIOLOGY

- Tropism and replication are limited to the ciliated epithelium of the respiratory tract.
- Biologically active substances such as pertussis toxin (PT), filamentous hemagglutinin, tracheal cytotoxin, adenylate cyclase, and pertactin are responsible for virulence of the organism, including attachment, ciliostasis, impaired leukocyte function, and local epithelial damage.

ETIOLOGY

- *B. pertussis*, a small, nonmotile, fastidious, gram-negative coccobacillus, causes classic pertussis.
- *Bordetella parapertussis* causes a less protracted cough illness.

DIAGNOSIS

HISTORY

- History of a cough illness in other family members, including older siblings, parents, and grandparents, is important to elicit.
- 3 clinical stages
 - Catarrhal stage (1–2 weeks) with symptoms of an upper respiratory infection
 - Paroxysmal stage (≥ 2 –4 weeks) characterized by paroxysmal cough with increased severity and frequency producing the characteristic whoop during the sudden forceful inspiratory phase; posttussive vomiting is also observed during this stage.
 - The convalescent stage begins and lasts 1–2 weeks, but cough can persist for several months. In the adolescent or adult, long-standing cough of 2–3 weeks is the hallmark symptom. Most patients report a paroxysmal or staccato quality to the cough.
- Apnea is a common manifestation in infants < 6 months. The characteristic whoop is typically absent. Short catarrhal stage, gasping, and choking are other manifestations in young infants.
- History of fever is typically absent.

PHYSICAL EXAM

- Normal physical examination between paroxysms is supportive of the diagnosis.
- Conjunctival hemorrhage and petechiae on the upper body may be present.
- Cyanosis, apnea, and bradycardia can be observed during the paroxysmal stage in young infants.
- Fever and signs of lower respiratory tract disease are uncommon.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Leukocytosis ($15,000$ – $100,000$ cells/mm³ with predominant lymphocytosis is commonly observed at the end of the catarrhal stage and throughout the paroxysmal stage of illness in infants and children; not commonly observed in adolescents and adult
- Culture of *B. pertussis*
 - Achieved using calcium alginate or Dacron swabs of the

nasopharynx and plated onto selective media such as Regan-Lowe and incubated for 10 days

- Most frequently successful during the catarrhal or early paroxysmal stages and is rarely found beyond the 3rd week of illness
- Specificity 100%; overall sensitivity is 60–70% but can be lower in previously vaccinated individuals if antibiotics have already been given or if beyond the 3rd week of illness.
- Polymerase chain reaction (PCR)
 - Increasingly used; higher sensitivity and more rapid diagnosis than culture in the detection of *B. pertussis* from nasopharyngeal specimens
 - There is no FDA-licensed PCR test available, and there are no standardized protocols or reagents.
- Direct immunofluorescent assays (DFA) of nasopharyngeal specimens are no longer recommended for the diagnosis of pertussis.
- Serology
 - Can be helpful later in the course of the illness
 - No commercially available FDA-approved test available and difficult to interpret in previously immunized individuals
 - In the absence of recent immunization, an elevated serum IgG antibody to PT after 2 weeks of onset of cough is suggestive of recent infection. An increasing titer or a single IgG anti-PT value of approximately 100 IU/mL or greater can be used for diagnosis.

Imaging

Chest radiograph: may reveal perihilar infiltrates, interstitial edema, and atelectasis

DIFFERENTIAL DIAGNOSIS

- *B. parapertussis*
- Adenoviruses
- *Mycoplasma pneumoniae*
- *Chlamydia trachomatis*
- Bronchiolitis
- Bacterial pneumonia
- Cystic fibrosis

- Tuberculosis
- Foreign body aspiration
- Reactive airway disease

TREATMENT

MEDICATION

- Azithromycin (PO)
 - 10 mg/kg as a single dose on day 1, then 5 mg/kg/24 h as a single daily dose on days 2–5 is recommended for ages ≥ 6 months.
 - For infants < 6 months of age, dosage is 10 mg/kg/24 h as a single daily dose for 5 days.
 - For adolescents and adults, dosage is 500 mg as a single dose on day 1, followed by 250 mg as a single daily dose on days 2–5.
- Erythromycin PO (40 mg/kg/24 h) in 4 doses for 14 days
 - Erythromycin in infants < 4 weeks of age is associated with hypertrophic pyloric stenosis. Thus, azithromycin is the drug of choice for treatment or prophylaxis of pertussis in that age group.
- Clarithromycin PO (15 mg/kg/24 h divided b.i.d for 7 days) can be used in children ≥ 1 month of age.
- Trimethoprim/sulfamethoxazole in children ≥ 2 months of age, is an alternative agent, although its efficacy is unproven.

GENERAL MEASURES

- Patients with more severe disease manifestations (apnea, cyanosis, feeding difficulties) or other complications require hospitalization for supportive care:
 - Infants < 6 months of age may develop apnea from fatigue secondary to excessive coughing. They need close observation, preferably in the hospital.
- Antibiotics have little effect on the clinical course unless begun early in the disease process (catarrhal phase) but should always be given to prevent spread of the infection.

INPATIENT CONSIDERATIONS

Admission Criteria

- Young infant (<6 months of age) with concern for apnea or fatigue with coughing
- Patients with severe disease manifestations or complications

Discharge Criteria

- No evidence of cardiorespiratory instability
- Able to self-recover from coughing spells

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

The paroxysmal stage can last up to 4 weeks and the convalescent stage up to several months.

PROGNOSIS

Directly related to patient age

- Highest mortality is observed in infants <6 months of age, with a 0.5–1% risk of death.
- In the older child, prognosis is good.

COMPLICATIONS

- The complications of pertussis are more likely to occur in infants <6 months of age:
 - Apnea
 - Pneumonia, which may be primary or secondary to viruses (adenovirus, respiratory syncytial virus) or bacteria (*Streptococcus pneumoniae*, *Staphylococcus aureus*), occurs in 13–25%; the presence of fever or respiratory symptoms in between cough episodes should raise the possibility of secondary bacterial pneumonia.
 - Other pulmonary complications include atelectasis, pneumothorax, pneumomediastinum, and subcutaneous emphysema.
 - Seizures (2%) and encephalopathy (0.5%) have also been observed in infants with pertussis.
- Complications of pertussis in adolescents and adults include cough syncope, incontinence, rib fractures, and pneumonia.

- A37.00 Whooping cough due to Bordetella pertussis without pneumonia
- A37.01 Whooping cough due to Bordetella pertussis with pneumonia

FAQ

- Q: Why is the transmission of pertussis difficult to control in the young infant?

- A: Unfortunately, many physicians do not consider pertussis in adolescents or adults because the symptoms can be nonspecific and often are not severe. They also assume that childhood immunization will protect adults against pertussis. Therefore, delays in antimicrobial treatment are common in adults, owing to the lack of index of suspicion of pertussis by their providers. Finally, there was not a universal recommendation for adolescents and adults to receive pertussis boosters until 2005, even though the immunity protection by pertussis vaccination is limited. It is largely adolescents and adults with pertussis who then spread the disease to young infants and children.
- Q: What is the best way to diagnose pertussis in the young infant?
- A: The diagnosis can be made clinically but requires a high index of suspicion. The diagnosis should be considered based on a history of severe cough in any young infant. At the time of presentation, infants usually appear well and have a normal exam. So, the history provided by the parents of the paroxysmal and severe nature of the course, often associated with gagging, posttussive emesis, and exhaustion, should be taken seriously.

PHARYNGITIS

Daniel E. Felten

BASICS

DESCRIPTION

Pharyngitis specifically refers to inflammation of the pharynx as indicated by erythema and swelling of the structures in the posterior portion of the oral cavity including the tonsillar pillars, the tonsils, the inferior soft palate, the uvula, and the posterior wall. Pharyngitis is usually caused by viral or bacterial infections.

EPIDEMIOLOGY

- Prevalence and etiology of pharyngitis vary based on age of patient and time of year.
- In preschool-aged children, viral agents are most common and exhibit seasonal variation depending on the specific virus.
- Group A Streptococcus (GAS) pharyngitis is most common in children between the ages of 5 and 15 years, is very rare in children younger than the age of 3 years, and may occur in outbreaks affecting up to 20% of children at risk.
- Pharyngitis caused by *Neisseria gonorrhoeae* occurs primarily in sexually active adolescents.

ETIOLOGY

- Viral
 - Common causes: adenovirus, Epstein-Barr virus (EBV), influenza A and B, enteroviruses (specifically, coxsackievirus A), herpes simplex virus (especially in adolescents), and echoviruses
 - Uncommon: measles, rubella, cytomegalovirus, human immunodeficiency virus (HIV)
 - Rhinovirus, coronavirus, parainfluenza virus, and respiratory syncytial virus (RSV) may cause sore throat but not usually pharyngitis.
- Bacterial

- Common: *Streptococcus pyogenes* (group A β -hemolytic *Streptococcus*)
- Uncommon: *Mycoplasma pneumoniae*, group C or G streptococci, *N. gonorrhoeae* (more likely in sexually active adolescents), *Arcanobacterium haemolyticum*, *Fusobacterium necrophorum* (Lemierre syndrome), *Corynebacterium diphtheriae* (diphtheria), *Chlamydophila pneumoniae*, *Chlamydophila psittaci*, *Yersinia enterocolitica*, *Treponema pallidum* (syphilis), *Francisella tularensis* (tularemia), oral anaerobes (Vincent angina or trench mouth)
- Fungal: *Candida* species (oral thrush)

GENERAL PREVENTION

- Most infectious agents that cause pharyngitis are spread through contact with respiratory droplets or other body fluids, although many can live for some time outside of the body.
- Careful hand washing and avoiding respiratory secretions are key to minimizing transmission.
- Return to school/child care
 - Children diagnosed with GAS pharyngitis should be kept at home for 24 hours after starting antibiotics.
 - Children with pharyngitis due to presumed viral etiology should be fever-free for 24 hours and have symptoms under control prior to return.

RISK FACTORS

- Children who are immunocompromised and children on chronic inhaled corticosteroids who are otherwise immune competent are at risk for candidiasis of the pharynx.
- Adolescents or sexually abused children engaging in oral sex are at risk for pharyngitis due to gonorrhea or HSV.
- Unvaccinated patients or travelers from certain areas are at risk for vaccine-preventable diseases: diphtheria and measles.

DIAGNOSIS

HISTORY

- Typical: sore throat, fever
- Variable
 - Headache, nausea, vomiting, abdominal pain (suggest GAS pharyngitis)
 - Rhinorrhea, cough, hoarseness, stridor, conjunctivitis (suggest viral etiology)
- Rash: scarlatiniform or nonspecific viral
- Sudden onset of fever and sore throat with difficulty swallowing, headache, stomach pain, nausea, vomiting, or scarlatiniform rash support diagnosis of GAS pharyngitis.
- Pharyngitis associated with rhinorrhea, cough, hoarseness, conjunctivitis, diarrhea, or nonspecific rash is more likely to have a viral cause.
- Significant systemic complaints such as fever and malaise are characteristic of EBV or HIV (acute retroviral syndrome).
- History of oral sex suggests possibility of *N. gonorrhoeae* infection.

PHYSICAL EXAM

- Pharynx and oral cavity
 - Exudative tonsillitis suggestive of GAS but also present in EBV, *N. gonorrhoeae*, *Arcanobacterium*, HSV, adenovirus
 - Palatal petechiae suggest GAS.
 - Ulcers on tonsils or tonsillar pillars seen in coxsackievirus, HSV, echovirus
 - Ulceration or inflammation of buccal mucosa or gums seen in HSV, coxsackievirus
- Lymph nodes
 - Tender anterior lymphadenopathy more common in GAS pharyngitis
 - Diffuse LAD, splenomegaly suggests EBV.
- Rash
 - Scarlatiniform rash (diffuse, erythematous, fine-papular, “sandpapery” rash) key feature of scarlet fever from GAS pharyngitis but can be seen with *Arcanobacterium haemolyticum* and in Kawasaki disease
 - Nonspecific, diffuse rash can be associated with viral infection; may

- be seen shortly after starting antibiotic if underlying etiology is EBV
- Vesicular lesions on hands, feet, and/or buttocks characteristic of coxsackievirus

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Rapid antigen detection test (RADT)
 - The diagnosis of GAS pharyngitis should not be made based on clinical features alone but should be confirmed by laboratory testing.
 - Sensitivity varies (55–90%) based on quality of sample obtained. Specificity is more consistent in 95–98% range. Therefore, a good test to rule in GAS, but culture or DNA probe should be used to confirm negative RADTs. Confirmation of positive RADTs is not needed.
 - RADT is not recommended when patients present with symptoms that strongly suggest viral etiology (cough, rhinorrhea, hoarseness, oral ulcers).
 - Testing children <3 years old is not indicated, as those children are at very low risk for acute rheumatic fever (ARF). Testing may be considered in this age group if other risk factors are present such as an older sibling with GAS.
 - Testing of asymptomatic household contacts is not recommended.
- Monospot (heterophile antibody) test
 - Detects presence of IgM for EBV, which appears during the first 2 weeks of illness and gradually disappears over 6 months
 - Atypical lymphocytes may also be seen on WBC differential during the 2nd week of EBV infection. >10% atypical lymphocytes plus a positive heterophile antibody test is diagnostic of acute infection.
 - Heterophile antibody is often negative in children <4 years of age with EBV, so it should not be used in this age group.
- Testing for certain bacteria (*N. gonorrhoeae*, *A. hemolyticum*, *F. necrophorum*) requires special handling and processing, so must confirm appropriate collection medium and alert the laboratory performing the test if any of these agents is suspected.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Peritonsillar or retropharyngeal abscess or cellulitis
 - Lemierre syndrome
 - Epiglottitis
 - Kawasaki disease
 - Tularemia
- Ingestions
 - Caustic or irritant ingestions
 - Inhaled irritant
- Tumors
 - Leukemia
 - Lymphoma
 - Rhabdomyosarcoma
- Trauma: vocal abuse from shouting
- Allergy: postnasal drip from allergic rhinitis
- Miscellaneous
 - PFAPA syndrome (periodic fever, aphthous ulcers, pharyngitis, and cervical adenitis)
 - Psychogenic pain (globus hystericus)
 - Vitamin deficiency (A, B complex, C)
 - Dehydration

TREATMENT

GENERAL MEASURES

Treatment is largely supportive for most viral causes of pharyngitis, including pain control and hydration.

MEDICATION

First Line

- Penicillin-resistant GAS has never been documented. Apparent treatment failure (recurrent episode of acute pharyngitis with positive lab tests for GAS) most likely indicates repeat intercurrent viral infection in GAS carrier.

- Oral penicillin V
 - Children: 400,000 U (250 mg) b.i.d. or t.i.d. for 10 days
 - Adolescents/adults: 800,000 U (500 mg) b.i.d. for 10 days or 400,000 U (250 mg) 3–4 times per day for 10 days
- Amoxicillin: 50 mg/kg (max dose 1 g) daily divided b.i.d. for 10 days
 - Once-daily dosing may increase adherence.
- Intramuscular (IM) penicillin G benzathine: ensures compliance, useful in outbreaks
 - Children (>1 month and <27 kg): 600,000 U IM \times 1
 - Children (>27 kg) and adults: 1,200,000 U IM \times 1
 - Procaine penicillin combinations are less painful.

Second Line

- A 10-day course of a 1st-generation oral cephalosporin is indicated for most penicillin-allergic patients. However, 5–10% of penicillin-allergic patients may also be allergic to cephalosporins, so patients with a type I hypersensitivity to penicillin should not be given a cephalosporin.
- Oral clindamycin 20 mg/kg/24 h (max 1.8 g/24 h) divided t.i.d. may be given to patients with type I hypersensitivity to penicillin.
- Oral azithromycin, clarithromycin, or erythromycin are also acceptable alternatives in penicillin-allergic patients, although cases of ARF have been reported after treatment with these drugs.
 - Azithromycin 12 mg/kg (max 500 mg) daily for 5 days
 - Clarithromycin, 15 mg/kg/24 h divided q12h for 10 days or 500 mg extended-release tablets given once a day for 5 days (studied in adolescents ≥ 12 years of age)
 - Erythromycin ethylsuccinate, 40–50 mg/kg/24 h in 2–4 divided doses. Resistance is rare in the United States (<5% of isolates).
- Tetracyclines and sulfonamides should not be used due to high rates of resistance.
- In patients with *N. gonorrhoeae* infection
 - 250 mg ceftriaxone IM (>45 kg); 125 mg ceftriaxone IM (<45 kg)
 - Coinfection with *C. trachomatis* is unusual in pharyngitis caused by *N. gonorrhoeae*; however, treatment is recommended: azithromycin 1 g PO in adolescents. In younger children, should confirm infection
- In patients with EBV

- Antibiotics should not be given; in particular, if amoxicillin or ampicillin is given, a high proportion of patients will develop a nonallergic rash.
- Short-course corticosteroids may be beneficial but can also have significant adverse effects; should only be used in patients with marked tonsillar inflammation and impending airway obstruction. Usual prednisone dose is 1 mg/kg/24 h for 7 days with subsequent tapering.

SURGERY/OTHER PROCEDURES

Tonsillectomy for recurrent pharyngitis is not recommended but may be considered in the rare patient who has frequent symptomatic episodes of pharyngitis in whom no alternative explanation to GAS pharyngitis is found (e.g., recurrent viral infections in a GAS carrier). Benefit is relatively short-lived.

ONGOING CARE

PATIENT MONITORING

- Most cases of pharyngitis are self-limited; however, patients are at risk for dehydration if PO intake is limited by pain.
- Caregivers should be cautioned to monitor fluid intake and urine output and to return for reassessment if oral intake and/or urine output drops significantly.

COMPLICATIONS

- Streptococcal pharyngitis
 - Suppurative complications include peritonsillar abscess, cervical lymphadenitis, and mastoiditis.
 - Most significant nonsuppurative complication is ARF. This can be prevented if adequate antibiotic treatment is provided within 10 days.
 - Another nonsuppurative complication is poststreptococcal glomerulonephritis.
- Lemierre syndrome: spread of *F. necrophorum* from peritonsillar abscess caused by GAS to jugular vein causing thrombophlebitis,

bacteremia, and thromboembolism

- Pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS): controversial association that has not been demonstrated in prospective studies

CODES

ICD10

- J02.9 Acute pharyngitis, unspecified
- J02.0 Streptococcal pharyngitis
- B08.5 Enteroviral vesicular pharyngitis

FAQ

- Q: Is there any benefit to starting therapy while waiting for culture results?
- A: Immediate therapy probably shortens the symptomatic period. However, waiting for culture is appropriate because the goal of treatment is to minimize progression to ARF, and treatment within 10 days of onset of symptoms is effective.
- Q: Should all patients with sore throat be swabbed for RADT and/or strep culture?

- A: No. Most cases of sore throat are not due to GAS. However, clinical exam alone is insufficient to diagnose strep throat. Patients with symptoms that highly suggest a viral etiology (rhinorrhea, congestion, cough, conjunctivitis) should not be tested for GAS, as a positive result would most likely indicate carrier status rather than GAS pharyngitis.
- Q: Should contacts of patients with documented GAS pharyngitis be tested for GAS?
- A: Contacts who have recent or current clinical symptoms of GAS infection should undergo appropriate testing. However, carrier rates of contacts are quite high, up to 50% for siblings and 20% for other contacts, so routine testing of asymptomatic contacts is usually not indicated except during outbreaks or when contacts are at increased risk of developing sequelae of infection.

PHIMOSIS AND PARAPHIMOSIS

Kara N. Saperston • Michael DiSandro

BASICS

DESCRIPTION

- Phimosis is the inability to retract the prepuce (foreskin) after puberty due to a narrow preputial opening.
- Infants and prepubertal children rarely have true phimosis but rather a normal physiologic phimosis.
- Paraphimosis is the entrapment of the prepuce in a retracted position.

EPIDEMIOLOGY

- The incidence of phimosis is 0.4 cases per 100 boys per year.
- Phimosis affects 0.6 boys prior to their 16th birthday.

RISK FACTORS

- Phimosis
 - Forced retraction of the prepuce
 - Lichen sclerosis
- Paraphimosis
 - Prolonged retraction of the prepuce

PATHOPHYSIOLOGY

- Phimosis
 - As the constriction of the phimosis worsens, urine is trapped in the foreskin and ballooning of the prepuce occurs. In severe cases, urine will fill the entire prepucial space and extend down the shaft.
- Paraphimosis
 - Prolonged retraction of the prepuce around the glans causes edema of the prepuce and the glans. The edema makes it harder to correct the phimosis and causes significant pain for the child.

GENERAL PREVENTION

Boys should be instructed to return the foreskin to covering the glans after cleaning to prevent paraphimosis.

DIAGNOSIS

HISTORY

- Phimosis
 - Parent may report ballooning of the prepuce during voiding.
 - Parent may report having to squeeze the prepuce to clear all the trapped urine.
- Paraphimosis
 - Parent will report cleaning the penis during a diaper change, pulling the foreskin back, and then being unable to return it to its normal position covering the glans.
 - Child may pull the foreskin back and then be unable to return the foreskin to its normal position.

PHYSICAL EXAM

- Phimosis
 - Gentle attempt to retract the foreskin to evaluate the size of the preputial opening
 - A child who cannot retract foreskin after onset of puberty has phimosis.
 - Dry, white patchy areas of the foreskin indicate lichen sclerosis and seen with phimosis 50% of the time.
- Paraphimosis
 - Tender penis with marked edema of the prepuce (foreskin)
 - Tight collar around the glans
 - Long duration of the retracted skin will compromise the blood supply of the prepuce and glans.
 - There are case reports of gangrene.
 - Consider calling child protective services if there is gangrene.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Not needed

Imaging

Not needed

Diagnostic Procedures/Other

Not needed

DIFFERENTIAL DIAGNOSIS

- Physiologic phimosis
 - A child who has not gone through puberty will have a normal physiologic phimosis. This will change as he nears puberty and the foreskin will be easier to retract over time.
 - There may be small lumps of white material under the glans that are desquamated skin cells that are not infection and slowly work their way out of the preputial cavity. This desquamated skin helps with skin separation.

ALERT

Early (before puberty), forced retraction of the foreskin before the foreskin is naturally ready to retract may cause phimosis.

TREATMENT

MEDICATION

- Phimosis
 - Topical steroids t.i.d. for 6 weeks; use a small bead size amount
 - Fluticasone propionate, 0.05%
 - Betamethasone propionate, 0.1%
 - Triamcinolone cream
 - This also treats lichen sclerosis.
 - Topical tacrolimus is 2nd-line treatment for lichen sclerosis.
- Paraphimosis
 - Should be considered an emergency
 - Sedation and reduction by applying pressure to the glans and prepuce

ADDITIONAL THERAPIES

- Phimosis
 - Circumcision
 - Performed when medical treatment fails

- Paraphimosis
 - Dorsal slit is performed if compression fails.
 - Dorsal incision of the prepuce: under sedation

GENERAL MEASURES

- Phimosis
 - Refer to pediatric urologist if patient fails 2 months of medical management.
- Paraphimosis
 - Refer to pediatric urologist immediately if unable to return the foreskin to covering the glans without sedation.
 - Keep the patient in the ER, as sedation will most likely be necessary.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Phimosis
 - Follow-up in 2 months after use of steroids
- Paraphimosis: If foreskin is back in normal position:
 - Follow up with pediatric urologist in 2 weeks.
 - There should be no retraction of the foreskin in that time frame.
 - Consider use of topical steroids to avoid development of severe phimosis.

PROGNOSIS

- Phimosis
 - Use of steroids is successful 70–90% of the time.
- Paraphimosis
 - High risk of development of severe phimosis
 - May require circumcision in the future

CODES

ICD10

- N47.1 Phimosis
- N47.2 Paraphimosis

FAQ

- Q: Can a child have phimosis as a newborn?
- A: Physiologic phimosis (inability to retract the foreskin) is normal in prepubertal children. It occurs because of incomplete separation of skin between the glans and the inner prepuce. It does not require treatment.

PHOTOSENSITIVITY

Leslie Castelo-Soccio

BASICS

DESCRIPTION

Adverse or abnormal reaction of the skin to sunlight

EPIDEMIOLOGY

- Variable for each disorder
- Photosensitivities with onset in childhood include albinism, hydroa aestivale, hydroa vacciniforme, the porphyrias (e.g., erythropoietic, erythropoietic protoporphyria, hepatoerythropoietic), and genetic disorders (e.g., xeroderma pigmentosa, Hartnup disease, poikiloderma congenitale, Bloom syndrome, and Rothmund Thomson and Cockayne syndromes).
- Photosensitivities that occur frequently in adults but can occur in childhood are vitiligo, chemically induced photosensitivities, polymorphous light eruption, connective tissue disease, and pellagra.

RISK FACTORS

- Family history
- Disease
- Exposure to toxins

Genetics

- Genetic disorders include the porphyrias and others as previously listed:
 - The various porphyrias have variable inheritance patterns, whereas most of the other genetic disorders are inherited in an autosomal recessive pattern.
 - There is a positive familial history in many cases of polymorphous light eruption.

PATHOPHYSIOLOGY

Findings are diverse for the different disorders and rarely diagnostic.

ETIOLOGY

- Combination of sunlight with some abnormality in the skin such as loss of pigment, a chemical agent, a metabolic product, another skin disorder, a genetic disease, or an unknown factor produces a cutaneous abnormality.
- Specific wavelengths of the radiant energy emitted by the sun and reaching the earth are usually responsible for each photosensitivity disorder, most commonly ultraviolet B (UVB, 290–320 nm), ultraviolet A (UVA, 320–400 nm), and visible light (400–800 nm).

DIAGNOSIS

HISTORY

- Age of onset of rash
- Occurrence
 - Season: spring and summer
 - Relation to sun exposure: time frame, effect of sun through glass
- Oral medications
 - May be related to oral contraceptives, tetracyclines (doxycycline in particular), sulfa drugs, iodines/bromides, or phenytoin
- New topical agents (e.g., perfumes, lemons, limes, sunscreens, etc.):
 - Photosensitivity may occur on neck or places where agents were placed on skin.
- Rash
 - Accentuation of the rash on the nose, cheeks, and forehead with sparing of the eyelids and the submental portion of the chin
 - There is often a sharp cutoff in the nuchal area at the collar line.

PHYSICAL EXAM

- Distribution
 - Distribution of lesions is the main sign of photosensitivity reactions.
 - Lesions are prominent on sun-exposed skin such as the face, pinnae of the ears, the V of the neck, the nuchal area, and the dorsa of the hands.
 - Often, sparing of the philtrum, the area below the chin, the eyelids,

and other covered areas is seen.

- In phytophotodermatitis, linear or bizarre shapes can occur, including, as an example, hand prints if a caregiver has been squeezing limes and then picks up a child and the child is then exposed to sunlight.
- Lesion characteristics
 - Vary with the particular disease and can include the following:
 - Papules
 - Vesicles
 - Plaques (polymorphous light eruption)
 - Sunburn (chemical reaction to a systemic agent)
 - Linear areas of hyperpigmentation (chemical reaction to a topical agent)
 - Skin cancers (xeroderma pigmentosum)
 - Vesicles (porphyria)
 - In some cases, scarring can also be seen related to severe burns (porphyria).

DIAGNOSTIC TESTS & INTERPRETATION

- Phototesting
 - Using an artificial source of light can confirm the presence of certain photosensitivities. Procedures are of 2 types:
 - The 1st is exposure of skin to increasing doses of UVA and UVB to determine the erythema response (present at lower exposures than usual) and possibly reproduce lesions in certain diseases.
 - The 2nd is photopatch testing in which photoallergic chemicals are applied under patches in duplicate, and 1 set is subsequently exposed to UVA. Patients who have photoallergic contact dermatitis develop a reaction under only the exposed patch of the agent causing the problem.

Lab

Initial lab tests

- Genetic tests (optional): Find labs that perform genetic tests at www.genetests.org and enter disease name:
 - Cell culture: evaluates DNA repair for xeroderma pigmentosum or

- shows chromosomal breaks in Bloom disease
- Measurement of specific amino acid and indole excretion patterns in Hartnup disease
- Measurements of antinuclear antibodies are helpful in connective tissue diseases.
- Biochemical tests
 - Helpful for the diagnosis of the porphyrias, with elevated levels of various porphyrins specific to each type in the urine, blood, or stool
- Screening for connective tissue diseases should be done where appropriate.
- Screening for niacin deficiency

DIFFERENTIAL DIAGNOSIS

- Photosensitivity resulting from pigment loss
 - Albinism
 - Vitiligo
- Idiopathic photosensitivity
 - Polymorphous light eruption
 - Solar urticaria
- Chemically induced reactions
 - Topical agents
 - ▢ Perfumes
 - ▢ Plant-associated phytophotodermatitis (e.g., lemons, limes, celery, parsnips, carrots, dill, parsley, figs, meadow grass, giant hogweed, mangos, wheat, clover, cocklebur, buttercups, shepherds purse, and pigweed)
 - ▢ Blankophors (e.g., optical brighteners in detergents)
 - ▢ Sunscreens
 - ▢ Topical retinoids (e.g., tretinoin, adapalene, tazarotene)
 - Systemic agents
 - ▢ Tetracyclines, sulfonamides, nalidixic acid, griseofulvin, phenothiazines, oral hypoglycemic agents, amiodarone, quinine, isoniazid, and thiazide diuretics
- Metabolic disorders
 - Porphyrias: disorders of hemoglobin synthesis producing various porphyrins that are photosensitizers

- Genetic disorders: see “[Genetics](#)”
- Cutaneous diseases aggravated by sunlight
 - Connective tissue diseases

TREATMENT

GENERAL MEASURES

- Protection against sun exposure
 - Avoiding the sun, particularly between 10 a.m. and 3 p.m., and wearing protective clothing is important.
 - Sunscreens are helpful for those sensitive to UVB.
 - Sunscreens should be water resistant and reapplied q2h.
 - Sun protection factor (SPF; ratio of minimal erythema dose of sunscreened skin to minimal erythema dose of unprotected skin) >30
 - Sunscreens are less effective for blocking UVA and therefore less effective in helping patients with sensitivities to longer wavelengths.
 - Sunscreens that contain both UVA- and UVB-blocking capabilities offer better protection than most. These include sunscreens containing avobenzone, titanium dioxide, and zinc oxide.
 - Avobenzone has a relatively short lifespan but is now available in a chemically stabilized form known by the trade names Helioplex and Active Photobarrier Complex.
 - Mexoryl is another long-acting broad-spectrum sunscreen that has especially good UVA protection.
 - Opaque formulations such as zinc oxide and titanium dioxide block UV and visible light but may be less cosmetically appealing; however, new formulations made from microfine particles of titanium dioxide or zinc oxide make it more appealing.
 - Patients with severe photosensitivities may have to avoid any significant light exposure.
 - Most patients require chronic protection against sun exposure. However, the problem is generally more acute in spring and summer months.

- Removal of the offending agent is necessary in chemically induced photosensitivities:
 - Any severe and acute eruptions may require a short course of oral prednisone.
- Antimalarial agents have been used for polymorphous light eruption, lupus erythematosus, solar urticaria, and porphyria cutanea tarda and require the experience of a specialist.

ISSUES FOR REFERRAL

If possible, it is important to accurately document the specific wavelength of light and the degree of photosensitivity to accurately advise the patient. This requires phototesting by a specialist.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Skin exams for skin cancers routinely with frequency dependent on type of photosensitivity; for example, more monitoring for genetic causes such as xeroderma pigmentosa

PATIENT EDUCATION

Education regarding significance of using sunscreen

PROGNOSIS

With the exception of chemically induced photosensitivities, most of the conditions are chronic.

CODES

ICD10

- L56.8 Oth acute skin changes due to ultraviolet radiation
- L59.8 Oth disrd of the skin, subcu related to radiation

FAQ

- Q: What is the best sunscreen to use?
- A: It depends on your particular problem. If you are sensitive to UVB, use a sunscreen with the highest SPF. If you are sensitive to UVA, sunscreens containing avobenzone, titanium dioxide, or zinc oxide are best.
- Q: I have heard that sunscreens with an SPF >15 are not necessary. Is this true?
- A: This is definitely not true for patients with photosensitivities who have abnormal responses to light and require excessive protection. Even for the healthy person, it is often not true. An SPF of 15 suggests that someone may receive 15 times more sun exposure with the sunscreen applied than without and not become sunburned. Some physicians have suggested that this is more than anyone should need. However, this number is calculated by testing in a controlled laboratory. Normal outdoor conditions, such as wind, reflection from water and sand, perspiration, and water exposure can significantly decrease the effectiveness of the sunscreen.
- Q: What is “sun allergy”?
- A: This is a lay term for polymorphous light eruption, one of the most common photosensitivities, presenting with papules, vesicles, and plaques 1–2 days after sun exposure. It usually recurs every spring, and

most patients learn to avoid sun exposure. However, ironically, it can improve with slow, gradual sun exposure.

- Q: Can I become allergic to sunscreens?
- A: Certain active agents in sunscreens can produce an allergic response in rare individuals. If the rash recurs with each use, switch to another sunscreen with different ingredients. If the problem continues, consult a specialist for evaluation.

PINWORMS

Terry Kind • Hope Rhodes

BASICS

DESCRIPTION

- Infection by a small, white nematode (roundworm), typically *Enterobius vermicularis*
- Pinworms may also be caused by *Enterobius gregorii* in Europe, Africa, and Asia.

EPIDEMIOLOGY

- Considered the most common helminthic infection of humans (the only known natural host) and the most common worm infection in the United States.
- Occurs in school-aged children (5–10 years) and preschool children predominantly
- Does occur in adults, usually in those caring for infected children. Some individuals may be predisposed to having either heavy or light worm burdens.
- Independent of socioeconomic status

Prevalence

- U.S. infection rates: 5–15%
- Among children, people caring for infected children, and people who are institutionalized, prevalence can reach 50%.
- Occurs worldwide but is more prevalent in temperate climates

GENERAL PREVENTION

- Decontaminate the environment by washing underclothes, bedclothes, bedsheets, and towels.
- Maintain good hand hygiene, including hand washing and proper toileting.
- Keep fingernails short and avoid nail biting.
- Treat family members and close contacts.

PATHOPHYSIOLOGY

- *E. vermicularis* eggs are ingested and hatch in the human's stomach and duodenum. Then the larvae migrate to the ileum and cecum. Adult worms copulate in the cecum.
- The pregnant female pinworm migrates from the cecum to the anus ~5 weeks later and deposits eggs on the perianal skin (at which point the female pinworm usually dies). Thousands of eggs are laid, which may result in hundreds of worms.
- Pruritus is caused by the perianal deposition of eggs and a mucosal mastocytosis response. Other GI symptoms, such as anorexia or abdominal pain, may occur because of the mucosal inflammatory response.
- Granulomas may form if dead worms and eggs invoke an inflammatory response in ectopic locations such as the peritoneal cavity, vulva, cervix, uterus, and fallopian tubes.

ETIOLOGY

- Ingestion of organism via fecal–oral transmission
- Can be spread directly, hand-to-mouth, or via fomites found on toys, bedding, clothing, toilet seats, and baths

DIAGNOSIS

HISTORY

- Prior pinworms or sibling with pinworms
 - Eggs can survive for several days in the environment, and the incubation period can be 1–2 months.
 - Spread can occur between family members.
- Daytime itching
 - Pinworm infections usually cause perianal itching during the night or just before waking in the morning.
 - Daytime perianal or perivulvar itching or irritation is likely due to other causes.
- Fevers, diarrhea, or vomiting
 - Pinworms are highly unlikely to cause systemic symptoms (except

in rare cases where they migrate aberrantly).

- Visible worms at night
 - Pinworms may be seen 2–3 hours after the child has gone to sleep. Female worms are 8–13 mm, and males are 2–5 mm.
 - They may be visible as small, white worms in the perianal area at night.

PHYSICAL EXAM

- Exam may be normal, and the child may be well-appearing.
- May have self-inflicted, perianal excoriation
- Pinworms may be visible perianally.
- Infection is characterized by perianal pruritus that occurs at night or just before waking.
- Difficulty sleeping, decreased appetite, and/or abdominal pain may occur.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool or urine samples for ova or parasites
 - Generally not helpful or recommended
 - Very few ova present in stool (even more rare in urine)
- Blood count for eosinophilia
 - Generally not helpful or recommended
 - Eosinophilia is not observed because usually there is no tissue invasion.

Diagnostic Procedures/Other

- Transparent tape, Scotch tape test
 - In the morning, prior to the child awakening and before defecation or washing, the adhesive side of transparent tape is applied to the perianal area.
 - After removal, the tape is applied to a glass slide and examined under light microscopy for pinworm ova. Several samples may be necessary to see the pinworms.

DIFFERENTIAL DIAGNOSIS

- Infection

- Other parasites (e.g., *Strongyloides stercoralis*)
- Nonparasitic vulvovaginitis (due to bacterial, fungal, or viral causes)
- Dermatologic
 - Contact or irritative diaper dermatitis
 - Hidradenitis suppurativa
 - Irritative vulvovaginitis secondary to soaps, bubble baths, or lotions
 - Anal fissures (usually cause pain rather than itching)
- Miscellaneous
 - Behavioral: self-stimulation (normal)
 - Sleep disorders not owing to nocturnal pruritus
 - Hemorrhoids

TREATMENT

MEDICATION

Single-drug and single-dose therapy with one of the following agents:

- Mebendazole, 100 mg (available as a chewable tablet) PO once, may repeat in 2 weeks if symptoms still present
- Pyrantel pamoate, 11 mg/kg (maximum 1 g) PO once, may repeat in 2 weeks
- Albendazole, 400 mg PO once, may repeat in 2 weeks
- Experience is limited in children <2 years of age. Consider risks and benefits before use.
- Caution in treating pregnant individuals with anthelminthic medications because mebendazole, pyrantel pamoate, and albendazole are all category C and are not recommended in pregnancy.

ADDITIONAL TREATMENT

General Measures

- Reinfection is common especially if not all close contacts are treated.
- Treat all symptomatic contacts, and consider treating close household contacts, especially if repeated infections have occurred.
- Reinfection can occur if eggs remain on bed linen or clothing.
- Infection may be asymptomatic and transmitted to others.

- Autoreinfection can occur if eggs remain under the nails.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Watch for signs of reinfection.

PATIENT EDUCATION

- National Library of Medicine's health information site:
<http://www.nlm.nih.gov/medlineplus/pinworms.html>
- Centers for Disease Control and Prevention site:
<http://www.cdc.gov/healthywater/hygiene/disease/pinworms.html>

PROGNOSIS

- Reinfection is common.
- With appropriate treatment, symptoms resolve within a few days.
- Any chronic symptoms are likely due to recurrence rather than chronic infection because the life cycle of the adult worm is short, with eggs being laid by the adult worm within 5 weeks.

COMPLICATIONS

- Intestinal
 - Appendicitis (uncommon)
 - Bacterial superinfection of perianal excoriations
 - Granuloma formation
- Extraintestinal
 - Urethritis
 - Vulvovaginitis
 - Pelvic inflammatory disease

FAQ

- Q: Could the child have acquired pinworms from a pet dog or cat?
- A: No. Household pets are not involved in the life cycles of pinworms.
- Q: When can an infected child return to day care?
- A: After receiving the 1st treatment dose, the child can return to school or day care. It is prudent to bathe the child and to trim and scrub his or her nails prior to school reentry.
- Q: Is it necessary to reevaluate and retest a child once treated?
- A: No. However, reinfection is common.
- Q: Can pinworm eggs survive on bedding, toilet seats, or clothing?
- A: Yes. Eggs can remain infectious in an indoor environment for up to 3 weeks.
- Q: Does pinworm infection cause nocturnal bruxism?
- A: There is no proof of any causal relationship.
- Q: How do the anthelmintic medications work?

- A: They inhibit microtubule function and cause glycogen depletion in the adult worms.

PLAGUE

Gordon E. Schutze

BASICS

DESCRIPTION

Plague is an enzootic disease transmitted by fleas from wild rodents and caused by *Yersinia pestis*. Humans and their pets can enter this cycle, resulting in human plague. Human plague has 3 main forms: bubonic, septicemic, and pneumonic; rarely presents as meningeal, pharyngeal, ocular, or gastrointestinal (GI) plague

EPIDEMIOLOGY

- Worldwide: enzootic in Africa, Asia, and Americas. Since 2000, 95% of the 22,000 cases reported to the World Health Organization have been from countries in sub-Saharan Africa.
- In the United States, most cases occur in Arizona, New Mexico, California, Colorado, Oregon, and Nevada.
- In the United States, most cases occur in spring/summer.
- 51 cases of plague occurred in the United States from 2004 to 2011.
- 20% of U.S. cases with identified mode of transmission are acquired through direct contact with *Y. pestis*-infected animals, not via flea bite.
- No cases of person-to-person transmission of pneumonic plague have been reported in the United States since 1924.
- Untreated bubonic plague: >50% fatal
- Untreated pneumonic plague: nearly 100% fatal

GENERAL PREVENTION

- Reduce rodent shelter and food sources in the immediate vicinity of the home by storing grain and animal food in rodent-proof containers.
- Flea disinfestation of cats and dogs, especially in endemic areas
- Hospital isolation precautions
 - Patients with bubonic or septicemic plague and no evidence of pneumonia: standard precautions; add droplet precautions for first

- 24 hours of therapy until chest radiograph persistently clear.
- Patients with pneumonic plague: standard and droplet precautions. Continue droplet precautions until patient has completed 48 hours of appropriate antimicrobial therapy.
- Postexposure management
 - All persons with exposure to known or suspected plague source in last 6 days
 - ▢ Daily surveillance for fever or symptoms of disease for 7–10 days
 - ▢ Offer prophylaxis.
 - ▢ Initiate treatment if becomes ill
- Persons with close (<2 m) contact with a patient with pneumonic plague should receive antimicrobial prophylaxis, but isolation is not necessary.
- Chemoprophylaxis ≥ 8 years
 - Doxycycline (PO), OR
 - Ciprofloxacin (PO) at treatment doses for 7 days from last exposure (see “[Medications](#)” for dosing)
- Chemoprophylaxis <8 years: ciprofloxacin (PO)
- Notify state public health authorities of cases of suspected and proven *Y. pestis* infection.
- Vaccination is no longer available and is not considered useful to prevent plague from an enzootic source.

PATHOPHYSIOLOGY

- Skin portal of entry
 - *Y. pestis* is transmitted from fleas to humans via the regurgitation of the organism into the bite during the flea’s blood meal (*Y. pestis* blocks foregut, causing regurgitation).
 - Rodents, ground squirrels, cats, prairie dogs, marmots, rabbits, and occasionally dogs harbor infected fleas and are reservoirs of infection (enzootic).
 - Direct skin inoculation of organisms from infected animal tissue or blood occurs through breaks in the skin (e.g., cat scratch, skinning quarry).
 - Lymphatic spread of infection to the regional lymph nodes creates a

- localized inflammatory response (bubo, bubonic).
- Subsequent hematogenous spread of the organism to other organs results in high levels of circulating bacterial endotoxin (septicemic plague).
- By hematogenous spread to lungs, both bubonic and septicemic plague can cause secondary pneumonic plague.
- Respiratory portal of entry
 - Primary pneumonic plague: acquired via inhalation of respiratory tract droplets from a human or animal (e.g., cat) with pneumonic plague
- Incubation period
 - 2–8 days for bubonic or septicemic plague
 - 1–6 days for pneumonic plague

ETIOLOGY

Plague is caused by *Y. pestis*, a pleomorphic, bipolar-staining, gram-negative coccobacillus.

DIAGNOSIS

HISTORY

- A thorough travel history (especially to enzootic areas) is imperative to raise the index of suspicion for diagnosing plague.
- Environmental history should include epizootic deaths (die-offs) of rodents, ground squirrels, or prairie dogs in the patient's locale.
- In enzootic areas, a sick household cat or dog is an additional risk factor.
- Signs and symptoms
 - Bubonic plague
 - Initial symptom: pain in the groin or axillae prior to lymph node swelling
 - Lymphadenitis (usually inguinal > axillary > cervical)
 - Fever, chills, prostration
 - Septicemic plague
 - Tachycardia and hypotension

- Abdominal symptoms
 - Hemorrhage
 - Fever, chills, prostration
- Bubonic or septicemic plague may progress to secondary pneumonic plague.
- Pneumonic plague
 - Cough, dyspnea
 - Systemic manifestations
 - Fever, chills, shock
 - Rapidly progressive and often fatal

PHYSICAL EXAM

- Tachycardic, hypotensive, tachypneic, and toxic-appearing
- Flea bite lymphadenitis classically affects inguinal nodes; cat-associated plague affects mostly axillary or cervical nodes secondary to handling infected cat.
- GI: Abdominal pain, nausea, and diarrhea are common, secondary to inflammatory mediators.
- Neurologic: weakness, delirium, and coma, owing to the effects of the endotoxin of *Y. pestis*
- Heme: disseminated intravascular coagulation
- Renal: glomerular parenchymal damage
- Rare: meningitis, endophthalmitis, endocarditis, and pleuritis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Total WBC count
 - Usually 10,000–20,000, but may be as high as 100,000, with immature neutrophils.
- Perform Gram, Wayson, Giemsa, or fluorescent antibody staining on specimen (blood, bubo, CSF, sputum) to look for gram-negative, bipolar-staining organisms.
- *Y. pestis* culture (Notify receiving lab.)
 - Suspect bubonic plague: needle aspiration of the bubo for stain and culture. Puncture center of bubo with a sterile syringe and inject 1 mL of nonbacteriostatic, sterile saline. Withdraw aspirate vigorously

- until blood-tinged liquid appears in syringe.
 - Suspect pneumonic plague: sputum for stain and culture
 - Blood cultures are usually positive, even with bubonic plague, and should always be done prior to therapy.
 - Slow-grower; may be misidentified as *Yersinia pseudotuberculosis* or *Acinetobacter* sp.
- Serology
 - Single positive acute serology OR
 - At least a 4-fold increase in antibody titers by passive hemagglutination test between acute and convalescent sera taken 4–12 weeks apart
- Comprehensive testing and notification to state public health lab and CDC

Diagnostic Procedures/Other

Pitfalls

- Patients who present with a nonspecific febrile illness, tachycardia, and tachypnea, rather than lymphadenitis, are at higher risk for delayed diagnosis and serious sequelae (e.g., septicemic plague, death).
- Failure to consider septicemic plague in the appropriate epidemiologic setting and withholding appropriate antibiotics or using an empiric β -lactam regimen
- Failure to treat suspected bubonic plague with antibiotics while awaiting culture results when needle aspiration of the bubo shows no organisms on direct stain.

DIFFERENTIAL DIAGNOSIS

- Diagnosis of plague follows a high index of suspicion and a thorough review of the patient's lifestyle, travel history, and recent activities. The appearance of septicemia and endotoxin-mediated shock includes a large differential diagnosis that includes sepsis owing to other bacteria or viruses as well as distributive shock resulting from toxic ingestion or anaphylaxis.
- Infection
 - Streptococcal and staphylococcal infections (especially between the toes) can result in tender inguinal lymph nodes, fever, shock.

- Cat-scratch fever (*Bartonella henselae*) can present with a history of cat scratch or bite, regional lymphadenitis, and fever.
- Hantavirus in humans has a clinical presentation similar to septicemic and pneumonic plague and occurs in many of the plague-enzootic areas.
- Rickettsial diseases: *Rickettsia*, *Orientia*, *Coxiella*, *Ehrlichia*, *Anaplasma* (e.g., Rocky Mountain spotted fever [*Rickettsia rickettsii*] and relapsing tick fever due to *Borrelia* sp. may mimic septicemic or pneumonic plague)
- Recent reports of plague-like illnesses have been associated with infections by other organisms such as *Burkholderia pseudomallei* (melioidosis) and *Francisella tularensis* (tularemia).

TREATMENT

MEDICATION

- Use IV/IM forms for acute disease.
- For children, gentamicin or streptomycin administered intramuscularly or intravenously appear to be equally effective.
- Gentamicin, equally effective as streptomycin in recent study (IV):
peds: 2.5 mg/kg/dose q8h. Adult: 5 mg/kg/dose q24h
- Streptomycin traditionally has been the drug of choice (IV/IM): peds: 20–30 mg/kg/24 h divided q12h. Adult: 15 mg/kg/dose q12h to max 1 g q12h
- Meningitis or severe disease: Consider adding chloramphenicol (IV): 12.5–25 mg/kg/dose q6h (max 4 g/24 h). Monitor for toxicity.
- Alternatives
 - Doxycycline: peds (IV/PO): 2.2 mg/kg q12h up to adult dose as the max dose. Adult: 200 mg IV \times 1, then 100 mg IV/PO q12h. Some experts recommend adding it to gentamicin for severe disease.
 - Ciprofloxacin: peds (IV/PO): 30 mg/kg/24 h (max 1 g/24 h) divided q12h. Adults: 400 mg IV q12h; 500 mg PO q12h
- Continue antibiotic therapy for 7–10 days or until several days after lysis of fever.
- Severely ill patients may require a substantially longer course of

therapy.

- Foci (e.g., abscess) are infectious until sufficient appropriate antimicrobial therapy is given.

ADDITIONAL TREATMENT

General Measures

For septic patients in shock, initial attention should be given to airway management and fluid resuscitation, then antibiotics.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Resolution of symptoms should begin in the first 3 days after initiation of therapy; however, the rate of clinical improvement depends on the initial severity of illness.

Patient Monitoring

None; most recover without sequelae.

COMPLICATIONS

- Hematologic (disseminated intravascular coagulation)
- Renal (glomerular and parenchymal damage)

- A20.0 Bubonic plague
- A20.7 Septicemic plague

FAQ

- Q: Can one determine the risks of being exposed to plague during international travel?
- A: Yes. The CDC provides a service that contains updated information for international travel exposures at www.cdc.gov/travel.
- Q: Does persistent fever during treatment for plague warrant altering the antibiotic regimen?
- A: No. Fever can persist for up to 2 weeks despite appropriate 1st-line antibiotic therapy for *Y. pestis*. However, an evaluation for a focus of infection requiring drainage is recommended under these circumstances.
- Q: What is a bubo?
- A: “Bubo” (plural: buboes) comes from the Greek word for groin. A bubo is a painful, swollen lymph node.

PLEURAL EFFUSION

Richard M. Kravitz

BASICS

DESCRIPTION

Accumulation of fluid in the pleural cavity

PATHOPHYSIOLOGY

- Normally 1–15 mL of fluid in the pleural space
- Alterations in the flow and/or absorption of this fluid lead to its accumulation.
- Mechanisms that influence this flow of fluid:
 - Increased capillary hydrostatic pressure (i.e., congestive heart failure [CHF], overhydration)
 - Decreased pleural space hydrostatic pressure (i.e., after thoracentesis, atelectasis)
 - Decreased plasma oncotic pressure (i.e., hypoalbuminemia, nephrosis)
 - Increased capillary permeability (i.e., infection, toxins, connective tissue diseases, malignancy)
 - Impaired lymphatic drainage from the pleural space (i.e., disruption of the thoracic duct)
 - Passage of fluid from the peritoneal cavity through the diaphragm to the pleural space (i.e., hepatic cirrhosis with ascites)
- 2 types of pleural effusion:
 - Transudate: Mechanical forces of hydrostatic and oncotic pressures are altered, favoring liquid filtration.
 - Exudate: Damage to the pleural surface occurs that alters its ability to filter pleural fluid; lymphatic drainage is diminished.
- Stages associated with parapneumonic effusions (infectious exudates):
 - See Appendix, [Table 3](#).
 - Exudative stage
 - Free-flowing fluid
 - Pleural fluid glucose, protein, lactate dehydrogenase (LDH) level,

- and pH are normal.
- Fibrinolytic stage
 - Loculations are forming.
 - Increase in fibrin, polymorphonuclear leukocytes, and bacterial invasion of pleural cavity are occurring.
 - Pleural fluid glucose and pH falls while protein and LDH levels increase.
 - Organizing stage (empyema)
 - Fibroblasts grow.
 - Pleural peel forms.
 - Pleural fluid parameters worsen.

DIAGNOSIS

HISTORY

- Underlying disease determines most systemic symptoms.
- Patient may be asymptomatic until the amount of fluid is large enough to cause cardiorespiratory compromise/distress.
- Dyspnea and cough are associated with large effusions.
- Fever (if infectious etiology)
- Pleuritic pain (pneumonia may cause irritation of the parietal pleura, causing pleural pain; as the effusion increases and separates the pleural membrane, the pain may disappear)

PHYSICAL EXAM

- Decreased thoracic wall excursion on the ipsilateral side
- Fullness of intercostal spaces on the ipsilateral side
- Trachea and cardiac apex displaced toward the contralateral side (may produce a mediastinal shift that can reduce venous return and compromise the cardiac output)
- Dull or flat percussion on the ipsilateral side (suggesting the presence of consolidation of pleural effusion)
- Decreased tactile and vocal fremitus
- Decreased whispering pectoriloquy
- Pleural rub during early phase (may resolve as fluid accumulates in the

pleural space)

- Decreased breath sounds

DIAGNOSTIC TESTS & INTERPRETATION

- Cytologic exam of pleural fluid
 - Fresh and heparinized specimen should be refrigerated at 4°C (39.2°F) until it can be processed.
 - Fixatives should not be added.
- Pleural fluid parameters to be routinely measured include the following (Appendix, [Table 4](#)):
 - pH
 - LDH
 - Protein
 - Glucose
 - Note: Glucose of <40 mg/dL suggests a para-pneumonic, tuberculosis, malignant, or rheumatic etiology to the effusion.

Lab

Initial lab tests

Serology values to follow the degree of inflammation and the response to therapy:

- Erythrocyte sedimentation rate (ESR)
- C-reactive protein (CRP)

Imaging

- Chest radiograph
 - Anteroposterior projection can show >400 mL of pleural fluid.
 - Lateral projection can show <200 mL of pleural fluid.
 - Lateral decubitus film to evaluate for free-flowing pleural fluid can show as little as 50 mL of pleural fluid.
- Ultrasound
 - Reveals small (3–5 mL) loculated collections of pleural fluid
 - Useful as a guide for thoracentesis
 - Aids in distinguishing between pleural thickening and pleural effusion
- CT scan
 - Clearly reveals effusions/empyemas, abscess, or pulmonary

consolidations

- Useful for defining the extent of loculated effusions

Diagnostic Procedures/Other

- Thoracentesis
 - Indicated whenever etiology is unclear or if the effusion causes symptoms (e.g., prolonged fever or respiratory distress)
- Pleural biopsy
 - If thoracentesis is nondiagnostic
 - Most useful for diseases that cause extensive involvement of the pleura (i.e., tuberculosis, malignancies)
 - Confirms neoplastic involvement in 40–70% of cases

DIFFERENTIAL DIAGNOSIS

- Transudate
 - Cardiovascular
 - CHF
 - Constrictive pericarditis
 - Nephrotic syndrome with hypoalbuminemia
 - Cirrhosis
 - Atelectasis
- Exudate
 - Infection
 - Staphylococcus aureus (increasing incidence of methicillin-resistant species)
 - Streptococcus pneumoniae (increasing incidence of penicillin-resistant species)
 - Haemophilus influenzae (decreasing incidence since introduction of H. influenzae type b [Hib] vaccine)
 - Group A Streptococcus
 - Anaerobes
 - Gram-negative enterics
 - No identified organisms (all cultures sterile)
 - Tuberculous effusion
 - Viral effusions (adenovirus, influenza)
 - Fungal effusions: most not associated with effusions; Nocardia

and Actinomyces are most commonly seen.

- Parasitic effusions
- Neoplasm: seen mostly in leukemia and lymphoma; uncommon in children
- Connective tissue disease
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
 - Wegener granulomatosis
- Pulmonary embolus
- Intra-abdominal disease
 - Subdiaphragmatic abscess
 - Pancreatitis
- Sarcoidosis
- Esophageal rupture
- Hemothorax
- Chylothorax
- Drugs
- Chemical injury
- Postirradiation effusion

TREATMENT

MEDICATION

- Antibiotics
 - Used when effusion is caused by a bacterial infection
 - Specific antibiotics dictated by organism identified
 - If effusion is sterile, broad-spectrum antibiotics are indicated to cover for the usually seen organisms.
 - Clinical improvement usually begins within 48–72 hours of therapy.
 - Continue IV antibiotics until afebrile.
 - Complete remainder of therapy on oral antibiotics.
- Duration of antibiotic therapy depends on the infectious organism and the degree of illness:
 - Total duration is controversial.
 - Usually, at least 2–4 weeks of total IV and PO

ADDITIONAL TREATMENT

General Measures

- Supportive measures:
 - Maintain adequate
 - Oxygenation
 - Fluid status
 - Nutritional balance
 - Antipyretic agents when febrile
 - Pain control
- Treat the underlying disease:
 - Antibiotics for infections
 - Cardiac medications for CHF
 - Chemotherapeutic agents for malignancies
 - Anti-inflammatory agents (i.e., steroids) for connective tissue diseases
 - Medium-chain triglycerides and low-fat diet for chylothorax
- Effective drainage of pleural fluid
 - Thoracentesis
 - Chest tube drainage
 - Surgical drainage
- Duration of chest tube drainage
 - Discontinue when patient is asymptomatic (afebrile, no distress) and drainage <50 mL/h
 - Thick, loculated empyema requires prolonged drainage (and possibly a video-assisted thoracic surgery [VATS] procedure if effusion not improving).

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Thoracentesis
 - For diagnosis purposes
 - To distinguish between a transudate and an exudate
 - For culture material (if infection is suspected)
 - For cytology (if malignancy is suspected)
 - For relief of dyspnea or cardiorespiratory distress
- Chest tube thoracostomy
 - Reduce reaccumulation of fluid.

- Drain parapneumonic effusion (before loculations develop which will prevent fluid drainage).
- Intrapleural fibrinolytics
 - Adjunct to aid in drainage of complicated (i.e., multiloculated empyema) pleural effusions
 - Streptokinase, urokinase, and tPA are the agents of choice.

SURGERY/OTHER PROCEDURES

- VATS
 - Alternative to more invasive procedures (e.g., open thoracotomy/decortication)
 - Debridement through pleural visualization and lysis of adhesions/loculations
 - Useful when
 - Initial drainage is delayed
 - Loculations prevent adequate drainage by chest tube alone
 - Patient is failing more conservative therapy
- Pleurectomy
 - Chylothorax
 - Malignant effusions
- Pleurodesis
 - For recurrent effusions
 - Chemical agents frequently used include talc, tetracycline, doxycycline, and quinacrine.
 - Surgical methods include the following:
 - Mechanical abrasion
 - Pleurectomy via VATS
 - Open thoracotomy route
 - In cases of malignant effusion:
 - Sclerosing procedures are usually ineffective.
 - Chest tube drainage can create a pneumothorax because the lung is incarcerated by the tumor.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Clinical improvement usually within 1–2 weeks
- With empyemas, the patient may have fever spikes for up to 2–3 weeks after improvement is noted.

DIET

When the effusion is a chylothorax:

- Medium-chain triglycerides
- Nutritional replacement
- At least 4–5 weeks on this regimen

PROGNOSIS

Depends on underlying disease process:

- Properly treated infectious cause: excellent prognosis
- Malignancy: poor prognosis

COMPLICATIONS

- Hypoxia
- Respiratory distress
- Persistent fevers
- Decreased cardiac function
- Malnutrition (seen in chylothorax)
- Shock (secondary to blood loss in cases of hemothorax)
- Trapped lung

CODES

ICD10

- J90 Pleural effusion, not elsewhere classified
- J86.9 Pyothorax without fistula
- J91.0 Malignant pleural effusion

FAQ

- Q: When will the chest radiograph findings become normal?
- A: They may take up to 6 months (or longer) to return to normal appearance.
- Q: When will the pulmonary function tests normalize?
- A: Depending on extent of effusion, they may take up to 6–12 months.

PNEUMOCYSTIS JIROVECI (PREVIOUSLY KNOWN AS PNEUMOCYSTIS CARINII PNEUMONIA)

Danna Tauber

BASICS

DESCRIPTION

Opportunistic lung infection caused by *Pneumocystis jiroveci* (PJ). This organism is currently considered a primitive fungus based on DNA sequence analysis. It has two developmental forms (the cysts contain sporozoites that become trophozoites when excised).

- Although previously known as *Pneumocystis carinii* pneumonia (PCP), the acronym PCP is still in use and refers to *Pneumocystis* pneumonia.
- PCP occurs almost exclusively in the immunocompromised host.
- PCP is an AIDS-defining illness. It is the most common opportunistic life-threatening lung infection in infants with perinatally acquired human immunodeficiency virus (HIV) disease.
- PJ causes a diffuse pneumonitis characterized by fever, dyspnea at rest, tachypnea, hypoxemia, nonproductive cough, and bilateral diffuse infiltrates in the roentgenogram. It is a severe condition frequently leading to respiratory failure, necessitating intubation and mechanical ventilation.
- Chemoprophylaxis against this microorganism has proven successful. Therefore, early identification of the HIV-infected mother becomes essential.
- Despite advances in therapy, the infection continues to be associated with significant morbidity and mortality.

EPIDEMIOLOGY

- Ubiquitous in mammals worldwide, particularly rodents
- Growth on respiratory tract surfaces
- Mode of transmission is unknown:
 - Airborne person-to-person transmission is possible, but case

contacts are rarely identified.

- Environmentally acquired
- Asymptomatic infection appears early in life; >70% of healthy individuals have antibodies by age 4 years.
- Primary infection is likely to be the mechanism in infants. Reactivation of latent disease with immunosuppression was proposed as an explanation for disease later in childhood; however, animal models of PCP do not support this proposition.
- PCP in the HIV patient can occur at any time but usually presents during the 1st year of life. The highest incidence is between 3 and 6 months of age.

RISK FACTORS

- Immunocompromised host
 - Children with congenital or acquired immunodeficiency syndrome (AIDS) and recipients of suppressive therapy in the treatment of malignancies or after organ transplantation are at high risk.
 - In leukemic patients, the incidence of PCP has been directly related to the degree of immunodeficiency resulting from chemotherapy.
 - Epidemics of PCP were reported in premature and malnourished infants and children in resource-limited countries and during times of famine.

PATHOPHYSIOLOGY

- In the immunodeficient child, the pathologic changes occur predominantly in the alveoli. Cysts and trophozoites are seen adhering to the alveolar lining cells or in the cytoplasm of macrophages.
- As infection progresses, the alveolar spaces are filled with a pink, foamy exudate containing fibrin, abundant desquamative cells, and a large number of organisms. Alveolar septal thickening with mononuclear cell infiltration is also seen.

DIAGNOSIS

HISTORY

- In malnourished host

- Subacute onset with nonspecific manifestations
 - Poor feeding, weight loss, and restlessness
 - Chronic diarrhea
 - Usually without fever
 - After 1–2 weeks, the patient develops progressive tachypnea, respiratory distress, and cough.
- In sporadic or immunocompromised host
 - This form has a more abrupt onset, sometimes even fulminant:
 - Fever ($>38.5^{\circ}\text{C}$)
 - Nonproductive cough
 - Dyspnea at rest
- These subtypes are characterized by general clinical guidelines. Symptoms may be superimposed and can be seen in infants, children, and adolescents.

PHYSICAL EXAM

- Fever and significant tachypnea are characteristic.
- Hypoxemia: early in the course of disease and disproportionate to the auscultatory findings
- Rapidly progressive respiratory distress with cyanosis: respiratory failure early in course
- Absence of crackles is a common initial finding.
- Chest auscultation can reveal decreased breath sounds, crackles, and rhonchi.
- Coryza and wheezing have infrequently been reported.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Arterial blood gas
 - pH is usually increased.
 - Reduced PaO_2 in room air (<70 mm Hg)
 - Alveolar–arterial oxygen gradient (>35 mm Hg)
- Chest radiograph
 - Most common radiologic presentation is diffuse bilateral alveolar infiltrates:
 - Initially a perihilar distribution that spreads to the periphery

- Apices are the least affected.
 - Interstitial infiltrates and air bronchograms can be seen.
 - Rapid progression to whole lung consolidation
- Presence of hilar or mediastinal adenopathy may indicate another process such as Mycobacterium tuberculosis, Mycobacterium avium-intracellulare, fungal infections, cytomegalovirus, or lymphoma.
- Other tests:
 - Lactate dehydrogenase (LDH) can be elevated in patients with AIDS and PCP, but this finding is nonspecific.
 - WBC count is usually normal.

Pathologic Findings

- Definitive diagnosis can be obtained by demonstration of PJ in pulmonary specimens:
 - Induced sputum
 - Bronchoalveolar lavage (BAL) usually through flexible bronchoscopy (90% sensitivity)
 - Open lung or transbronchial biopsy
- Staining
 - Cysts stain with methenamine-silver, toluidine blue-O stains, calcofluor white, and fluorescein monoclonal antibody
 - Sporozoites and trophozoites are identified with Giemsa stain, modified Wright-Giemsa stain, and fluorescein-conjugated monoclonal antibody stain.
 - Polymerase chain reaction assays of BAL fluid or induced sputum is available and more sensitive for detecting PJ than microscopic methods but is not USFDA approved for diagnosis.

DIFFERENTIAL DIAGNOSIS

- Viral infections
 - Common viral respiratory pathogens
 - Cytomegalovirus
 - Epstein-Barr virus
- Bacterial infections
 - M. tuberculosis
 - M. avium-intracellulare

- Other:
 - Lymphocytic interstitial pneumonitis

TREATMENT

MEDICATION

First Line

- Minimum duration of therapy is 2 weeks; 3 weeks of therapy recommended in patients with AIDS.
- Antibiotics
 - Trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice:
 - TMP (15–20 mg/kg/24 h) and SMX (75–100 mg/kg/24 h) IV/PO divided q6h
 - Oral therapy is reserved for patients with mild illness who do not have malabsorption or diarrhea.

Second Line

- Minimum duration of therapy is 2 weeks; 3 weeks of therapy recommended in patients with AIDS.
- Pentamidine isethionate
 - 3–4 mg/kg/dose IV (or IM) given in a single daily dose
 - Used in patients who cannot tolerate TMP-SMX or are unresponsive after 5–7 days of therapy
 - If clinical improvement is seen after 7–10 days of IV pentamidine, consider oral regimen to complete the 21-day course.
- Atovaquone
 - 1–3 months and >24 months of age: 30 mg/kg/24 h PO divided into 2 doses
 - 4–24 months of age: 45 mg/kg/24 h PO divided into 2 doses
 - Maximum dose: 750 mg b.i.d.
- Dapsone plus trimethoprim
 - Dapsone: 2 mg/kg PO daily to a maximum of 100 mg daily
 - Trimethoprim: 15 mg/kg/24 h PO divided into 3 doses
- Primaquine plus clindamycin
 - Primaquine: 0.3 mg/kg PO daily to a maximum of 30 mg PO daily

- Clindamycin: 40 mg/kg/24 h PO divided into 4 doses to a maximum of 600 mg q6h

ADDITIONAL TREATMENT

General Measures

- Supply oxygen as necessary to keep $\text{PaO}_2 > 70$ mm Hg.
- Mechanical ventilation must be considered if PaO_2 is < 60 mm Hg on FiO_2 of 0.5.
- Corticosteroids
 - May be beneficial in HIV patients with moderate to severe PCP
 - Not systematically evaluated in children
 - Consider when PaO_2 is < 70 mm Hg or the alveolar–arterial oxygen gradient is > 35 mm Hg.
 - In patients > 13 years of age, suggested dose is prednisone 40 mg PO b.i.d. for days 1–5, 40 mg PO once daily for days 6–10, and 20 mg PO once daily for days 11–21 with tapering. Doses of methylprednisolone or prednisone at 1 mg/kg given b.i.d.–q.i.d. for 5–7 days with a taper over the next 5 days have been suggested.

ADDITIONAL THERAPIES

- Chemoprophylaxis indications: During high-risk periods, PCP can be effectively prevented in the immunodeficient host by chemoprophylaxis in the following groups:
 - HIV exposed: 4–6 weeks to 4 months
 - HIV infected or indeterminate: 4–12 months
 - HIV infected: 1–5 years if CD4^+ T-lymphocyte count is < 500 cells/ μL or $< 15\%$
 - HIV infected: ≥ 6 years if CD4^+ T-lymphocyte count is < 200 cells/ μL or $< 15\%$
 - Severely symptomatic HIV patients or those with rapidly declining CD4 counts
 - HIV patients who have had previous PCP illness
 - Children who have received hematopoietic stem cell transplants (HSCTs)
 - All HSCT recipients with hematologic malignancies (e.g., leukemia, lymphoma)

- All HSCT recipients receiving intense conditioning regimens or graft manipulation
 - Prophylaxis is initiated at engraftment and administered for 6 months; longer than 6 months in children receiving immunosuppressive therapy or with chronic graft-versus-host disease
- Drug regimen for prophylaxis
 - TMP-SMX is the drug of choice.
 - 150 mg/m² body surface area per day of TMP or 750 mg/m² body surface area per day of SMX PO divided into 2 doses on 3 consecutive days per week
 - TMP-SMX can also be given 7 days a week when prevention against other bacterial infections is sought.
 - For patients who cannot tolerate TMP-SMX
 - Dapsone (>1 month of age): 2 mg/kg (maximum 100 mg) PO daily or 4 mg/kg (maximum 200 mg) PO weekly
 - Aerosolized pentamidine (>5 years of age): 300 mg via Respirgard II nebulizer inhaled monthly
 - Atovaquone at age 1–3 months and >24 months: 30 mg/kg (max 1,500 mg/dose) PO daily; at age 4–24 months: 45 mg/kg (max 1,500 mg/dose) PO daily

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- After 5–7 days of treatment
- If no improvement, TMP-SMX should be replaced with pentamidine.
- Standard precautions are required. Isolation from other immunodeficient patients is recommended.

PROGNOSIS

- 5–40% mortality in treated patients
- Near 100% mortality if patient is untreated
- ~35% of patients will have recurrence unless lifetime prophylaxis is instituted.

COMPLICATIONS

- High rate of respiratory failure necessitating intubation and mechanical ventilation (~60%)
- HIV-infected patients have a higher rate (40%) of adverse reactions to TMP-SMX than the general population. Rash is most common, with fever, neutropenia, anemia, renal dysfunction, nausea, vomiting, and diarrhea occurring as well.
- Prophylactic medication protects the patient as long as the drug is administered. However, this does not eradicate PJ.

FAQ

- Q: Which are the most common side effects of pentamidine?
- A: They include hypoglycemia, impaired renal or liver function, anemia, thrombocytopenia, neutropenia, hypotension, and skin rashes. These side effects can be expected in 50% of patients.

- Q: How frequently is prophylaxis failure seen?
- A: Adequate TMP-SMX treatment has only a 3% failure rate.
- Q: How are adverse reactions to TMP-SMX during PCP therapy managed?
- A: Continuation of treatment, if the reactions are not severe, is recommended.

PNEUMONIA—BACTERIAL

Erica S. Pan • Shannon Thyne

BASICS

DESCRIPTION

Pneumonia is an infection of the lungs involving the alveoli and distal airways.

EPIDEMIOLOGY

Incidence

- Highest incidence in children <5 years of age (annual incidence 3–4%)
- Viral pneumonias still generally comprise a large proportion of pediatric pneumonia.

RISK FACTORS

- Immune deficiency
 - Immunocompromised status
 - Sick cell anemia
- Increased aspiration risk
 - Altered mental status
 - Tracheoesophageal fistula
 - Cerebral palsy
 - Seizure disorder
- Compromised lung function/anatomy
 - Cystic fibrosis
 - Congenital pulmonary malformations
 - Bronchopulmonary dysplasia
 - Asthma

ETIOLOGY

- Etiology of bacterial pneumonia differs by age:
 - Neonates: group B Streptococcus, enteric gram-negative rods (e.g., *Escherichia coli*), *Listeria monocytogenes*, *Haemophilus influenzae*, *Bordetella pertussis*

- 1–3 months: neonate organisms + *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Chlamydia trachomatis*
- 4 months to 4 years: *Streptococcus pneumoniae*, *Staphylococcus aureus*, *H. influenzae*
- >5 years of age: *Streptococcus pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, *Mycoplasma pneumoniae*, *Mycobacterium tuberculosis*
- Etiology can also differ based on risk factors:
 - Aspiration as etiology increases the risk for oral flora including anaerobes such as *Bacteroides* and *Peptostreptococcus*.
 - Ventilator-dependent patients are at increased risk for *Pseudomonas* or *Klebsiella* infections and infection with other gram-negative rods.
 - Cystic fibrosis increases the risk for *Pseudomonas* and other more unusual organisms.

DIAGNOSIS

HISTORY

- Fever and/or chills
- Rapid breathing is a sensitive but nonspecific finding in bacterial pneumonia.
- Difficulty breathing or shortness of breath is common (can be associated with difficulty feeding in infants).
- Poor feeding or apnea in young infants
- Cough is often seen in bacterial pneumonia. *B. pertussis* pneumonia often presents after a catarrhal phase with a paroxysmal cough and posttussive vomiting.
- Pleuritic chest pain
- Abdominal pain and/or vomiting: most often seen with lower lobe pneumonia.
- Irritability, lethargy, and/or malaise
- Birth history, including maternal infections (e.g., *C. trachomatis* can be transmitted to an infant through a mother's genital tract at delivery)
- Immunization status: In a fully immunized child, *H. influenzae* type b, *B. pertussis*, and *S. pneumoniae* infections are less common.

- Recent history of upper respiratory tract infection (URI) or RSV can predispose to bacterial pneumonia.
- History of repeated bacterial infections may suggest immunodeficiency or cystic fibrosis (both are risk factors for bacterial pneumonia).
- Exposure to contacts with pertussis, tuberculosis, or history of recent travel
- Travelers, health care workers, and persons working in prisons or institutional settings are at greater risk for tuberculosis.

PHYSICAL EXAM

- Most common findings: oxygen saturation <95%, elevated respiratory rate, nasal flaring, fever, and ill appearance
- General examination can range from mildly ill appearing to toxic in appearance.
- Infants may have a paucity of exam findings disproportionate to their appearance and tachypnea.
- Patients may be dehydrated or in shock.
- Most children with bacterial pneumonia have fever.
- Patients with atypical bacterial pneumonia and pertussis are sometimes afebrile.
- Tachypnea or increased work of breathing: nasal flaring, grunting, and/or retracting
- Decreased oxygen saturation; therefore, oxygen saturation should be obtained by pulse oximetry in children with tachypnea or other signs of distress.
- Localized rales, crackles, rhonchi, decreased breath sounds, or wheezing
- With increasing consolidation, dullness to percussion and decreased breath sounds may be noted.
- In patients who are actively wheezing, it may be difficult to distinguish rales from other auscultated sounds.

DIAGNOSTIC TESTS & INTERPRETATION

- Not indicated for patients with uncomplicated pneumonia
- In toxic-appearing infants, blood, urine, and CSF cultures (i.e., a sepsis workup) should be considered.

- Viral testing for RSV, influenza, and other respiratory viruses if readily available can help exclude viral diagnoses in children who are candidates for outpatient therapy.

Lab

- Blood culture
 - Not indicated in healthy, immunized children with uncomplicated pneumonia
 - Rarely leads to identification of pathogen causing pneumonia
 - Should be obtained in children not responding to antibiotic therapy or moderate to severe pneumonia requiring hospitalization
 - Bacteremia has been noted in up to 30% of patients with pneumococcal pneumonia.
- Elevated peripheral WBC or range 15,000–40,000/mm³ is associated with bacterial pneumonia or even higher WBC in pertussis but should not be relied upon to distinguish etiology of pneumonia.
- Testing for *M. pneumoniae* may be considered to guide antibiotic therapy if with signs or symptoms of atypical bacteria.
- Acute-phase reactants such as ESR, CRP, or others may provide useful information for clinical management in serious disease but cannot distinguish between viral and bacterial etiologies
- Purified protein derivative (PPD) test or an interferon-gamma release assay (e.g., quantiFERON) should be obtained in all patients in whom *M. tuberculosis* is suspected.

Imaging

- Chest radiograph (CXR), upright
 - A CXR is not required for diagnosis if clinical symptoms and examination findings are consistent with uncomplicated pneumonia.
 - A CXR (PA and lateral) is recommended if pneumonia is suspected but clinical findings are unclear, if the patient has hypoxemia or significant respiratory distress, if a pleural effusion is suspected, or if the patient is not responding to treatment.
 - Characteristic CXR patterns include “alveolar or lobar infiltrate” with air bronchograms. “Round” infiltrates may be seen with *S. pneumoniae*. “Diffuse” interstitial infiltrates and hyperinflation may be seen with atypical pneumonia such as *M. pneumoniae* or

chlamydial pneumonias.

- More commonly, CXR cannot be reliably used to distinguish between viral and bacterial disease.
- An infiltrate may not be seen (negative CXR) if the disease is diagnosed early or if the patient is dehydrated.
- CXR, lateral decubitus: more sensitive than an upright radiograph in detecting pleural effusions or foreign body aspiration
- CT scan: not recommended as 1st-line imaging for suspected pneumonia. CT is mainly used as adjunct imaging for patients who are worsening (not improving) despite treatment or have complications.

Diagnostic Procedures/Other

If diagnosis is unclear, consider the following:

- Tracheal aspirates for Gram stain and culture if intubation necessary
- In immunocompetent children, bronchoscopy, bronchoalveolar lavage, percutaneous lung aspiration, or lung biopsy should be reserved for severe pneumonia if initial tests are not diagnostic.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Sepsis
 - Viral pneumonia
 - ▢ Infants: cytomegalovirus (CMV), metapneumovirus, herpes simplex virus (HSV)
 - ▢ From 1 to 3 months: CMV, respiratory syncytial virus (RSV), metapneumovirus
 - ▢ From 4 months to 4 years: RSV, adenovirus, influenza, metapneumovirus
 - Bronchiolitis
 - URI
 - Croup (laryngotracheobronchitis)
 - Fungal infection (if immunodeficiency or exposure history)
 - Parasitic infection (if immunodeficiency or exposure history)
- Pulmonary
 - Asthma
 - Atelectasis

- Pneumonitis (i.e., chemical)
- Pneumothorax
- Pulmonary edema
- Pulmonary hemorrhage
- Pulmonary embolism
- Congenital
 - Pulmonary sequestration
 - Congenital pulmonary airway malformation
- Genetic: cystic fibrosis
- Tumors
 - Lymphoma
 - Primary lung tumor
 - Metastatic tumor
- Cardiac: CHF
- GI: gastroesophageal reflux disease
- Miscellaneous
 - Foreign body aspiration
 - Sarcoidosis

TREATMENT

MEDICATIONS

Outpatient: empiric treatment

- Nontoxic, uncomplicated pneumonias in patients older than 3–6 months of age and anticipated to comply with antibiotic therapy may be managed as outpatients.
- Infants and preschool children (<5 years old)
 - Amoxicillin 80–100 mg/kg/24 h (max 3 g/24 h) PO divided q8–12h
- School-aged children (≥5 years old)
 - Amoxicillin 80–100 mg/kg/24 h (max 3 g/24 h) PO divided q8–12h
- Consider for additional coverage of atypical bacterial pathogens
 - Azithromycin 10 mg/kg/dose (max 500 mg) PO × 1 day then 5 mg/kg/dose (max 250 mg) PO once daily × 4 days
 - May consider clarithromycin 15 mg/kg/24 h (max 1 g/24 h) PO divided q12h or doxycycline 4.4 mg/kg/24 h (max 200 mg/24 h) PO

divided by 2 doses in patients 7 years of age or older.

- If specific pathogen is known or suspected, use appropriate antibiotic therapy.
- For patients with more severe disease, may consider combining β -lactam antibiotic and macrolide

INPATIENT CONSIDERATIONS

- Patients with moderate to severe pneumonia as defined by respiratory distress and hypoxemia (<90%), infants younger than 3–6 months of age, children and infants with pneumonia caused by a pathogen with increased virulence (e.g., community-associated MRSA), and failed outpatient therapy should be hospitalized
- Intubation and positive pressure ventilation, if clinically indicated
- Empiric antibiotic treatment
- All ages
 - Ampicillin 200–400 mg/kg/24 h (max 12 g/24 h) IV divided q6h (or penicillin 250,000 U/kg/24 h [max 24 million U/24 h] IV divided q6h)
 - Ceftriaxone 50–100 mg/kg/24 h (max 2 g/24 h) IV divided q12–24h or cefotaxime 200 mg/kg/24 h (max 12 g/24 h) IV divided q8h
- If atypical pathogens suspected, may add macrolide or use as alternative: azithromycin IV or PO using the same initial empiric dosage regimen from above
- For seriously ill patients, add vancomycin 15 mg/kg/dose IV q6–8h.
- For antistaphylococcal coverage, add vancomycin 15 mg/kg/dose IV q6–8h or clindamycin 30 mg/kg/24 h IV/PO divided q8h.
- May also consider macrolides or clindamycin as alternative for cephalosporin-allergic patients

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Children on appropriate therapy should show improvement within 48–72 hours.

- If worsening or not responding to treatment, consider repeated or additional diagnostic studies. For example, persistent fever may be due to loculated pleural fluid or an empyema.
- For additional antibiotic guidance for children not improving, consider pediatric infectious disease consultation.
- CXR may be abnormal for up to 10 weeks after successful treatment. Consider follow-up CXR only if indicated for severe disease, clinical progression, or suspected complications (e.g., effusion, empyema).
- For children with recurrent bacterial pneumonia, consider an underlying anatomic or immunologic disorder (e.g., abnormal antibody production, cystic fibrosis, tracheoesophageal fistula, pulmonary sequestration).

COMPLICATIONS

- Pleural effusion
- Empyema
- Lung abscess
- Pneumatoceles
- Pneumothorax
- Bacteremia/sepsis

- J15.3 Pneumonia due to streptococcus, group B
- J15.5 Pneumonia due to *Escherichia coli*

FAQ

- Q: What are the indications for admission and inpatient treatment of pneumonia in children?
- A: Failure of outpatient therapy, moderate to severe pneumonia as defined by respiratory distress and hypoxemia, infants younger than 3–6 months of age, children and infants with pneumonia caused by a pathogen with increased virulence (e.g., community-associated MRSA)
- Q: What is the appropriate duration of therapy for bacterial pneumonia?
- A: Empiric treatment courses of 10 days have been studied the most, although shorter courses may be effective in uncomplicated disease. Pneumonias caused by some pathogens (e.g., CA-MRSA) may require longer duration.
- Q: What is the most common causative organism of pulmonary abscess, and what is the appropriate treatment?
- A: *S. aureus* is the most common causative organism. Treatment includes IV vancomycin, IV or PO clindamycin, or PO linezolid. If MSSA is confirmed cefazolin, nafcillin, or cefuroxime may be used.
- Q: Which children are most likely to have systemic complications from community-acquired pneumonia? Local complications?
- A: An analysis of inpatient data from pediatric hospitals from 1997 to 2006 suggests that children <1 year of age are more likely to have systemic complications (e.g., sepsis, acute respiratory failure), whereas

patients aged 1–5 years are more likely to have local complications (e.g., empyema, abscess).

- Q: What are risk factors for invasive pneumococcal disease?
- A: Conditions associated with invasive pneumococcal disease include congenital immune deficiency (e.g., B- or T-lymphocyte deficiencies) asplenia/functional hyposplenism, complement deficiency, diseases associated with immunosuppressive therapy or radiation therapy (including malignancies), and solid organ transplantation and chronic cardiac disease.

PNEUMOTHORAX

Richard M. Kravitz

BASICS

DESCRIPTION

Abnormal collection of free air or gas in the pleural space

EPIDEMIOLOGY

Depends on the underlying lung disease

Incidence

- Spontaneous pneumothorax
 - Male > female (1.4 to 10.1:1)
 - Peak incidence: 10–30 years
- Pneumothorax with cystic fibrosis (CF)
 - For overall CF population: 3.5–8%
 - CF patients >18 years: 16–20%
 - Risk factors for pneumothorax:
 - More severe disease
 - Decreased pulmonary function (i.e., forced expiratory volume in 1 second [FEV₁] <30–50%)
 - Colonization with *Pseudomonas aeruginosa*, *Burkholderia cepacia*, or *Aspergillus*

RISK FACTORS

- Asthma
- CF
- Pneumonia
- Collagen vascular diseases

PATHOPHYSIOLOGY

- Air can enter the pleural space via the following:
 - Chest wall (i.e., penetrating trauma)
 - Intrapulmonary (i.e., ruptured alveoli)
- Usually, collapse of the lung on the affected side seals the leak.

- If a ball valve mechanism ensues, however, air can accumulate in the thoracic cavity, causing the development of a tension pneumothorax (a medical emergency).

ETIOLOGY

- Spontaneous (secondary to rupture of apical blebs)
- Mechanical trauma
 - Penetrating injury (i.e., knife or bullet wound)
 - Blunt trauma (i.e., auto accident)
- Barotrauma
 - Mechanical ventilation
 - Cough (if severe enough)
 - Vaginal birth
- Iatrogenic
 - Central venous catheter placement
 - Bronchoscopy (especially with biopsy)
- Infection: most common organisms
 - Staphylococcus aureus
 - Streptococcus pneumoniae
 - Mycobacterium tuberculosis
 - Bordetella pertussis
 - Pneumocystis jiroveci
- Airway occlusion
 - Mucus plugging (asthma)
 - Foreign body
 - Meconium aspiration
- Bleb formation (i.e., idiopathic, secondary to CF)
- Malignancy
- Catamenial

DIAGNOSIS

HISTORY

- May be asymptomatic (pneumothorax discovered on chest film obtained for other reasons)

- Cough
- Shortness of breath
- Dyspnea
- Pleuritic chest pain that is usually sudden in onset and localized to apices (referred pain to shoulders)
- Respiratory distress
- Underlying medical problems which increases risk for pneumothorax
- Activity prior to developing symptoms that might have caused the pneumothorax:
 - Heavy lifting
 - Increased coughing

PHYSICAL EXAM

- May be normal
- Decreased breath sounds on the affected side
- Decreased vocal fremitus
- Hyperresonance to percussion on the affected side
- Tachypnea
- Tachycardia
- Shortness of breath
- Respiratory distress
- Shifting of the cardiac point of maximal impulse away from the affected side
- Shifting of the trachea away from the affected side
- Subcutaneous emphysema
- Cyanosis
- Scratch sign (heard through the stethoscope): A loud scratching sound is heard when a finger is gently stroked over the area of the pneumothorax.

DIAGNOSTIC TESTS & INTERPRETATION

- EKG
 - Diminished amplitude of the QRS voltage
 - Rightward shift of the QRS axis (if left-sided pneumothorax)

Lab

- Arterial blood gas

- PO₂ can frequently be decreased.
- PCO₂
 - Elevated with respiratory compromise
 - Decreased from hyperventilation
- Pulse oximetry
 - Useful for assessing oxygenation

Imaging

- Chest radiograph
 - Radiolucency of the affected lung
 - Lack of lung markings in the periphery of the affected lung
 - Collapsed lung on the affected side
 - Possible pneumomediastinum with subcutaneous emphysema
- Chest CT
 - Useful for finding small pneumothoraces
 - Can help distinguish a pneumothorax from a bleb or cyst
 - Helpful for locating small apical blebs associated with spontaneous pneumothoraces

Diagnostic Procedures/Other

- Pitfalls:
 - Not considering the diagnosis in otherwise healthy patients
 - Confusing the symptoms with those of an underlying lung disease
 - Inserting a needle into a cyst or bleb (can cause a tension pneumothorax with rapid respiratory compromise)

DIFFERENTIAL DIAGNOSIS

- Pulmonary
 - Congenital lung malformations
 - Cysts (i.e., bronchogenic cysts)
 - Cystic adenomatoid malformation
 - Congenital lobar emphysema
 - Acquired emphysema
 - Hyperinflation of the lung
 - Postinfectious pneumatocele
 - Bullae formation
- Miscellaneous

- Diaphragmatic hernia
- Infections (i.e., pulmonary abscess)
- Muscle strain
- Pleurisy (i.e., pleuritis)
- Rib fracture

TREATMENT

GENERAL MEASURES

- Stabilization of the patient
- Evacuation of the pleural air
 - Should be done urgently if a tension pneumothorax is suspected
 - In small asymptomatic pneumothoraces, observation of the patient is indicated.
- Treat the underlying condition predisposing for the pneumothorax:
 - Antibiotics for any underlying infection
 - Bronchodilators and anti-inflammatory agents for asthma attacks
- Oxygen
 - Used to keep $\text{SaO}_2 \geq 95\%$
 - Breathing 100% oxygen
 - ▢ Can speed the intrapleural air's reabsorption into the bloodstream, hastening lung reexpansion
 - ▢ Useful for treating smaller pneumothoraces, especially in neonates

SURGERY/OTHER PROCEDURES

- Needle thoracentesis: useful for evacuation of the pleural air in simple, uncomplicated spontaneous pneumothorax
- Chest tube drainage
 - Used for evacuation of the pleural air in recurrent, persistent, or complicated pneumothoraces and cases with significant underlying lung disease
 - Chest tube should be left in (usually 2–4 days) until
 - ▢ Most air is reabsorbed
 - ▢ No reaccumulation of air is seen on sealing of the chest tube

- Surgical removal of pulmonary blebs
 - Blebs have a high rate of rupturing with resultant pneumothorax.
 - In patients with established pneumothoraces, the blebs should be removed or oversewn to prevent reoccurrence of the pneumothorax (blebs have a high rate of reoccurrence if not repaired).
 - Thoracotomy versus video-assisted thoracoscopic surgery (VATS)
- Pleurodesis
 - Used to attach the lung to the intrathoracic chest wall to prevent reoccurrence of a pneumothorax
 - Useful in cases of recurrent pneumothorax or if the pneumothorax is unresponsive to chest tube drainage (i.e., CF, malignancy)
 - Mechanism of action: The surface of the lung becomes inflamed and adheres to the chest wall via the formation of scar tissue.
 - 2 commonly used methods:
 - Surgical pleurodesis:
 - Mechanical abrasion of part of the lung or pleurectomy
 - Advantages: very effective; low reoccurrence rate; site specific (limits affected area)
 - Disadvantages: requires surgery and general anesthesia; contraindicated if patient is unstable
 - Chemical pleurodesis
 - Chemicals are used to cause inflammation.
 - Chemicals commonly used: talc, tetracycline, minocycline, doxycycline, quinacrine
 - Advantages: requires no surgery or general anesthesia
 - Disadvantages: less effective than surgery; generalized inflammation (rather than site-specific; makes future thoracic surgery more difficult; painful)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Symptomatic relief within seconds of the air being evacuated

Patient Monitoring

Sign to watch for: inability to remove the chest tube without reaccumulation of air (suggestive of a bronchopulmonary fistula; requires surgical exploration if no improvement in 7–10 days)

PROGNOSIS

- Depends on the underlying cause of the pneumothorax
- If simple, spontaneous pneumothorax, recovery is excellent
- CF: Development of pneumothorax associated with increased morbidity and mortality (median survival after 1st pneumothorax is 4 years).

COMPLICATIONS

- Pain
- Hypoxia
- Respiratory distress
- Tension pneumothorax
 - Hypoxia
 - Hypercarbia with acidosis
 - Respiratory failure
- Pneumomediastinum with subcutaneous emphysema
- Bronchopulmonary fistula

CODES

ICD10

- J93.9 Pneumothorax, unspecified
- J93.11 Primary spontaneous pneumothorax
- S27.0XXA Traumatic pneumothorax, initial encounter

FAQ

- Q: Can a pneumothorax reoccur?
- A: Reoccurrence depends on the underlying cause of the pneumothorax. Spontaneous pneumothorax reoccurrence rates:
 - Observation alone: 20–50%
 - If thoracentesis performed: 25–50%
 - If chest tube drainage performed: 32–38%
 - Overall reoccurrence rate: 16–52%
- Chemical pleurodesis reoccurrence rates:
 - Tetracycline: 25%
 - Talc: 8–10%
- Surgical pleurodesis reoccurrence rates:
 - VATS: 13%
 - Thoracotomy: 3%
 - Thoracotomy with pleurectomy: 0–4%
- CF reoccurrence rates:
 - If no drainage attempted: 68%

- Thoracentesis alone: 90%
- Chest tube drainage alone: 72%
- Chemical pleurodesis:
 - Tetracycline: 42–86%
 - Quinacrine: 12.5%
 - Talc: 8%
- Surgical pleurodesis: thoracotomy with pleurectomy: 0–4%

POLYARTERITIS NODOSA

David D. Sherry

BASICS

DESCRIPTION

An inflammatory process of small- and medium-sized muscular arteries resulting in dysfunction of affected organs

EPIDEMIOLOGY

Incidence

Extremely rare in childhood

Prevalence

Prevalence equal in boys and girls

PATHOPHYSIOLOGY

Necrotizing arteritis of small- and medium-sized arteries resulting in segmental fibrinoid necrosis

ETIOLOGY

- Idiopathic
- Postinfectious (streptococcal, hepatitis B)

DIAGNOSIS

HISTORY

- Persistent constitutional symptoms
- Bilateral calf pain
- Abdominal pain
- Weight loss
- Unexplained fever
- Headache
- Arthralgia/myalgia
- Rashes
- Seizures

- Weakness

PHYSICAL EXAM

- Check skin for the following:
 - Livedo reticularis
 - Splinter hemorrhages
 - Erythema nodosum
 - Necrotic digits
- Assess BP and pulses.
- Neurologic exam for findings consistent with neuropathy (mononeuritis multiplex)
- Ophthalmologic exam for cotton wool spots
- Check testes for tenderness or swelling.
- Check muscles for tenderness, especially calves.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- ESR
 - Usually extremely elevated; leukocytosis and thrombocytosis are seen.
- Urine analysis
 - Proteinuria and hematuria can be present.
- Creatinine and BUN levels
 - May be elevated
- Antinuclear antibodies and rheumatoid factor
 - Usually negative
- Muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase, and aldolase levels)
 - Muscle involvement is common, especially in those with calf pain.
- Antineutrophil cytoplasmic antibodies (ANCA)
 - Detectable in some; usually perinuclear (p), rarely cytoplasmic (c) staining patterns; ANCA is more commonly associated with other vasculitides:
 - pANCA pattern usually caused by anti-myeloperoxidase (MPO) antibodies; also seen in microscopic polyangiitis

- cANCA pattern usually caused by anti-proteinase 3 (PR3) antibodies; also seen in granulomatous with polyangiitis (Wegener granulomatosis)

ALERT

The detection of ANCA, previously thought to be highly specific for vasculitis, now appears to be less so. Hence, it remains important to confirm the diagnosis of polyarteritis nodosa with biopsy or angiography.

- Hepatitis B serologies
 - Hepatitis B has been associated in some series of patients with polyarteritis nodosa.
- Streptococcal titers
 - Polyarteritis nodosa may develop after streptococcal infections.

Imaging

- MRI of tender muscles
 - Short T₁ inversion recovery (STIR) images may show edema, so a directed biopsy can be done to avoid false-negative muscle biopsy.
- MRA, CT angiography, or angiography
 - Can demonstrate vessel wall stenoses and aneurysm

Diagnostic Procedures/Other

Biopsy of affected tissue/organ: usually skin, kidney, nerve, testicle

DIFFERENTIAL DIAGNOSIS

- Infection
 - Bacterial endocarditis
 - Brucellosis
 - Influenza B (calf pain)
- Tumors
 - Left atrial myxoma
 - Burkitt lymphoma
- Metabolic
 - Homocystinuria (thromboembolic events)
- Congenital
- Immunologic
 - Systemic necrotizing vasculitis

- Systemic lupus erythematosus
- Kawasaki disease
- Systemic juvenile idiopathic arthritis
- Granulomatosis with polyangiitis (Wegener granulomatosis)
- Takayasu arteritis
- Cryoglobulinemia
- Antiphospholipid antibody syndrome
- Thrombotic thrombocytopenic purpura
- Psychologic
 - Munchausen syndrome (factitious skin lesions)
- Miscellaneous
 - Degos disease (malignant atrophic papulosis)

TREATMENT

MEDICATION

- Corticosteroids are mainstay.
 - Usually start at dose of 1–2 mg/kg/24 h and adjust based on response.
 - May initially give methylprednisolone 30 mg/kg up to 1 g/24 h IV once daily for 3 days
- Immunosuppressives such as methotrexate, azathioprine, and cyclophosphamide may be necessary.
- Hypertension should be managed aggressively.

ADDITIONAL TREATMENT

General Measures

- Medication
- Diet
- Caution
 - Do not initiate therapy before efforts to establish the diagnosis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Initiation of steroid therapy may bring response in 1–2 weeks; however, management of specific organs affected during acute stage is essential.
- May require long-term therapy

Patient Monitoring

- Watch for the following:
 - Rising creatinine and BUN levels
 - Abdominal pain
 - Uncontrolled hypertension
- Home testing
 - May wish to have patients monitor BP periodically if renal involvement suspected

DIET

- If renal system involved, diet low in sodium and potassium
- Possible conflicts with medications

PROGNOSIS

- May be extremely poor over the long term
- Risk is high for renal failure, hypertension, stroke, myocardial infarction, bowel infarction, and death.
- Owing to low incidence/prevalence, precise data are not available.
- Cutaneous polyarteritis nodosa is relatively benign.

COMPLICATIONS

- Hypertension
- Renal failure
- Digital necrosis
- Intestinal infarction
- Stroke

CODES

ICD10

M30.0 Polyarteritis nodosa

FAQ

- Q: When should I consider polyarteritis nodosa in the differential?
- A: There are 5 major clues to polyarteritis nodosa: (1) prolonged constitutional symptoms without a diagnosis, (2) multisystem disease, (3) an unusual patient for the presenting symptom (myocardial infarction in a teen), (4) a rash that looks vasculitic, and (5) bilateral calf pain in a sick child.
- Q: What is the difference between polyarteritis nodosa and systemic necrotizing vasculitis?
- A: Polyarteritis nodosa has a strict definition. Many children who clearly have vasculitis of the small- and medium-sized arteries do not fit precisely into the description of polyarteritis nodosa. In most ways, the search for organ involvement and therapy is the same.
- Q: Who should manage the patient with polyarteritis nodosa?
- A: Usually, one discipline provides comprehensive management plan (either the pediatrician or rheumatologist). Subspecialist(s) of the affected organ systems provide management guidelines for specific organ issues.

POLYCYSTIC KIDNEY DISEASE

Kelly A. Benedict • Paul Brakeman

BASICS

DESCRIPTION

- Polycystic kidney disease (PKD) is a heritable disorder with diffuse cystic involvement of both kidneys without other dysplastic elements. The term PKD is generally used to describe 2 genetically distinct syndromes:
 - Autosomal dominant polycystic kidney disease (ADPKD)
 - Saccular, epithelial-lined, fluid-filled cysts of various sizes are derived from all segments of the nephron.
 - Cysts progressively enlarge and become disconnected from the tubule of origin.
 - Usually not clinically apparent until the 3rd or 4th decade of life
 - ~2–5% of patients have early-onset disease.
 - Autosomal recessive polycystic kidney disease (ARPKD)
 - Fusiform dilations arise from the collecting ducts and maintain contact with the nephron of origin.
 - Associated hepatic abnormalities are obligatory such as biliary dysgenesis and periportal fibrosis (congenital hepatic fibrosis), with portal hypertension.
 - Affects both the kidneys and the liver in approximately inverse proportions

EPIDEMIOLOGY

- ADPKD
 - One of the most common human genetic disorders; the most common renal inherited disease
 - A major cause of end-stage renal disease (ESRD) in adults
 - Frequency: 1 in 400–1,000
- ARPKD
 - Incidence of 1 in 20,000–40,000 live births
 - Exact incidence unknown owing to perinatal deaths in severe cases

RISK FACTORS

Genetics

- ARPKD
 - Mutations in the polycystic kidney hepatic disease 1 gene (PKHD1, chromosome 6)
- ADPKD
 - Type I ADPKD accounts for 85–90% of cases of ADPKD and is caused by mutations in the PKD1 gene (chromosome 16).
 - Large genomic deletions may encompass PKD1 and TSC2 genes, resulting in early-onset ADPKD with tuberous sclerosis.
 - Type II ADPKD is caused by mutations in the PKD2 gene (chromosome 4) and accounts for 10–15% of the cases.
- Other
 - Presymptomatic genetic screening for ADPKD is not recommended.
 - Normotensive women with ADPKD usually have uncomplicated pregnancies.
 - Higher risk for maternal/fetal complications if there is preexisting hypertension

PATHOPHYSIOLOGY

- ADPKD is produced by decreased functional polycystins:
 - Polycystin-1 is a membrane mechanoreceptor-like protein that forms multiprotein complexes at focal adhesions, cell–cell junctions, and cilia. It is involved in cell polarity, proliferation, cell–matrix interactions, and secretion.
 - Polycystin-2 is a divalent cation channel involved in calcium signaling and intracellular calcium homeostasis and is likely critical for cytoskeletal organization, cell adhesion, migration, and proliferation.
- ARPKD is produced by loss of functional fibrocystin/polyductin:
 - Fibrocystin/polyductin is an integral membrane receptor with extracellular protein-interaction sites that transduce intracellular signals to the nucleus.
 - Proteins affected in cystic kidney disease localize to cilia on epithelial cells.
 - Cilia are critical for cell architecture, proliferation, apoptosis, and

polarity.

ETIOLOGY

- ADPKD is generally an adult-onset, systemic disorder with cystic and noncystic manifestations. Cysts occur in the kidneys and other epithelial organs (e.g., seminal vesicles, pancreas, and liver):
 - Polycystic liver disease is the most common extrarenal manifestation.
 - Intracranial aneurysms occur in ~8%.
 - Mitral valve prolapse is the most common valvular abnormality (demonstrated in up to 25% of affected individuals).
 - Colonic diverticula in 80% with ESRD
- ARPKD is a renal and hepatic developmental disorder. The hallmark of ARPKD liver disease is congenital hepatic fibrosis and dilation of intrahepatic bile ducts (Caroli disease).
 - Severely affected infants may have the oligohydramnios sequence at birth, and associated pulmonary hypoplasia and respiratory complications convey a high mortality risk.

DIAGNOSIS

HISTORY

- ADPKD
 - Detailed family history is essential.
 - Most common presenting complaint in adults is pain.
 - Hypertension, gross hematuria, nephrolithiasis, and UTIs are common.
- ARPKD
 - Oligohydramnios sequence
 - Postnatal respiratory insufficiency
 - Renal insufficiency
 - Hypertension (may be severe)
 - Hepatobiliary manifestations (cholestasis, cholangitis, liver failure, portal hypertension, hypersplenism) evolve in older patients.
- Signs and symptoms

- ADPKD
 - Older children are often asymptomatic but may present with hypertension, abdominal pain, abdominal mass, gross hematuria after trauma, proteinuria, UTI/cyst infection, renal calculi, or decreased renal function.
- ARPKD
 - Presentation variable
 - Severely affected infants have “Potter” oligohydramnios sequence.
 - Pulmonary hypoplasia/respiratory insufficiency is a major cause of neonatal mortality.
 - Renal insufficiency with neonatal survival
 - Hepatobiliary complications later in course (portal hypertension, hematemesis, hepatosplenomegaly hypersplenism with pallor, petechiae)

PHYSICAL EXAM

- Clinical spectrum variable, particularly in ARPKD
- Hypertension
- Abdominal pain; tenderness at flank or costovertebral angle
- Flank mass or palpable kidneys
- Hepatosplenomegaly, varices, jaundice/icterus, abdominal ascites in ARPKD

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Metabolic panel to include BUN, creatinine, electrolytes
- Calcium, phosphorus
- Liver function tests
- CBC
- Urinalysis
- Note: Hyponatremia is often present in the neonatal period in ARPKD.

Imaging

- Ultrasonography is the preferred screening method and should include liver and Doppler to evaluate for portal hypertension in ARPKD.
- ARPKD

- Kidneys enlarged with increased echogenicity and loss of corticomedullary differentiation
- The liver may be normal in infants and young children. Over time, it becomes enlarged and hyperechoic. Dilated intrahepatic biliary ducts may be seen.
- Prenatal ultrasound after 24–30 weeks' gestation may show hyperechoic enlarged kidneys, oligohydramnios, and absence of bladder filling.
- Ultrasound diagnostic criteria for ADPKD
 - <40 years should have at least 2 cysts in 1 of the kidneys and 1 cyst in the other kidney or 3 cysts in a single kidney.
 - ≥ 40 and ≤ 59 years of age should have at least 2 cysts in each kidney.
 - >60 years should have at least 4 cysts in each kidney.
- CT scan with contrast
 - Has limited use in young children owing to exposure to ionizing radiation.
 - It is mostly used in adults with ADPKD because it can distinguish between solid and liquid renal masses.
- MRI with gadolinium
 - Heavy-weighted T2 MRI is the most sensitive method currently available.
 - Can be used in both conditions
 - Particularly useful to evaluate liver involvement in ARPKD
 - Avoid gadolinium in patients with advanced chronic kidney disease.

DIFFERENTIAL DIAGNOSIS

- Multicystic dysplastic kidney (MCDK)
- Glomerular cystic kidney disease (GCKD)
- Acquired cystic disease may occur in patients with ESRD.
- Genetic syndromes with cystic renal dysplasia, including, but not limited to the following:
 - Meckel syndrome
 - Jeune syndrome
 - Ivemark syndrome
 - Zellweger syndrome

- Bardet-Biedl syndrome
- Tuberous sclerosis

TREATMENT

MEDICATION

- Hypertension is common in PKD. Patients respond well to diuretics, ACE inhibitors, or calcium channel blockers. ACE inhibitors or angiotensin-receptor blockers are 1st line.
- In patients with PKD and nephrolithiasis, thiazide diuretics may be used for hypercalciuria, and potassium citrate supplements if hypocitraturia is found.
- Pyelonephritis in patients with PKD may lead to infected cysts. The treatment should include antibiotics that penetrate into the cysts (quinolones, trimethoprim) if cephalosporins and aminoglycosides fail to eradicate the infection.

ADDITIONAL TREATMENT

General Measures

- No currently approved targeted treatments to cure or slow progression
- Medical management is supportive.
- Pain is the most common symptom in ADPKD and can be difficult to treat.

ADDITIONAL THERAPIES

Activity: Patients with PKD should not participate in high-contact athletics in which the abdomen may be traumatized repeatedly. Strenuous static exercise should be avoided in hypertensive patients.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

A pediatric nephrologist should be involved in the care of children with PKD.

DIET

In both conditions, dietary changes depend on the degree of renal failure. Sodium restriction is indicated in cases of hypertension and/or edema. Caffeine should be avoided in cases of ADPKD.

PATIENT EDUCATION

- Emotional support and education of patients with PKD and their families can be obtained through the Polycystic Kidney Foundation (<http://www.PKDCure.org>) and the PKD Alliance (<http://www.arpkdchf.org>).
- Genetic counseling is indicated in these disorders and genetic testing may help families understand future risks.

PROGNOSIS

- ADPKD
 - The probability of being alive and not having ESRD is about 77% at age 50 years, 57% at age 58 years, and 52% at age 73 years. Median onset of ESRD is 53 years (PKD1) versus 69 years (PKD2).
 - Cystic expansion occurs at a consistent rate per individual, although it is heterogeneous in the population.
 - Larger kidneys are associated with more rapid disease progression.
 - PKD1 mutation is more severe because more cysts develop earlier, not because they grow faster.
- ARPKD
 - Neonatal onset is fatal in up to 50% of infants because of pulmonary hypoplasia with associated respiratory failure.
 - Patients who survive the neonatal period have up to an 80% 10-year survival.

- Q61.19 Other polycystic kidney, infantile type
- Q61.2 Polycystic kidney, adult type

FAQ

- Q: What can be done to slow the progression of renal insufficiency in ADPKD?
- A: Well-controlled BP and rapid treatment of UTIs may decrease the progression of renal failure.
- Q: Should asymptomatic older siblings of an infant with ARPKD be evaluated?
- A: Yes. An older child may have congenital hepatic fibrosis with minimal renal involvement.
- Q: Should one screen ADPKD-affected family members for the presence of cerebral vessel aneurysms if other family members have berry aneurysms?
- A: Although routine screening is not recommended, intrafamilial clustering of aneurysms has been reported and it may be advisable to screen children with MRI or cranial CT in a family with aneurysms.

POLYCYSTIC OVARY SYNDROME

Selma Feldman Witchel

BASICS

DESCRIPTION

- Polycystic ovary syndrome (PCOS) is a heterogeneous familial disorder characterized by hyperandrogenism, chronic anovulation, and infertility. Hirsutism, polycystic ovaries, obesity, insulin resistance, and hyperinsulinemia may be present but are not required for diagnosis.
- The 1990 NIH consensus meeting criteria for the diagnosis of PCOS were chronic anovulation, hyperandrogenism, and exclusion of other disorders. The 2006 Rotterdam criteria expanded the diagnostic features to include polycystic ovary morphology on US. The Androgen Excess-PCOS Society criteria emphasized the importance of hyperandrogenism.
- Using adult criteria to diagnose PCOS may be inappropriate for adolescent girls because irregular menses and multifollicular ovaries are common during adolescence.

EPIDEMIOLOGY

- Very common endocrine disorder affecting approximately 6–8% of reproductive-aged women
- Onset often during the peripubertal years
- May be preceded by premature adrenarche

Genetics

- Multifactorial polygenic familial disorder
- More prevalent in 1st-degree relatives of affected women
- A few genes associated with PCOS have been identified and replicated in women of European and Chinese ancestry. These genes include fibrillin-3 (FBN-3), DENN/MADD domain containing 1A (DENND1A), FSH receptor (FSHR), and LH receptor (LHCGR) variants.

PATHOPHYSIOLOGY

- PCOS is associated with follicular growth arrest. Most follicles arrest at the small antral stage prior to selection of a dominant follicle, giving rise to the typical pattern of multiple small follicles forming a ring in the ovary. Failure to select a dominant follicle leads to chronic anovulation.
- Characterized by a paradox regarding insulin sensitivity. Muscle, liver, and adipose tissue manifest insulin resistance, whereas the adrenal, ovary, and perhaps, the hypothalamus retain insulin sensitivity. The insulin resistance leads to increased insulin secretion by pancreatic beta cells to maintain euglycemia. The elevated insulin concentrations amplify LH- and IGF-1–stimulated theca cell androgen production and decrease SHBG production leading to increased free testosterone concentrations. Obesity exacerbates insulin resistance, intensifies PCOS symptomatology, and increases the risk for development of type 2 diabetes (T2D).
- Prenatal and childhood factors appear to influence the development of insulin resistance consistent with the hypotheses regarding early developmental origins of PCOS. Infants born small for gestational age (SGA) who experience fetal growth restriction followed by significant postnatal catch-up growth show increased insulin resistance prior to the onset of puberty.
- PCOS symptoms tend to improve with age as demonstrated in a 20-year follow-up of young women with PCOS. These women demonstrated decreased androgen concentrations and decreased ovarian volumes without any significant change in BMI or insulin sensitivity.

ETIOLOGY

- The precise etiology or initiating events remain to be elucidated. Likely, there are several potential mechanisms that initiate the perpetual cycle involving neuroendocrine abnormalities, excessive ovarian (and adrenal) androgen secretion, and metabolic dysfunction.
- LH hypersecretion is commonly observed in women with PCOS. For some, this might represent an intrinsic neuroendocrine abnormality. However, in most instances hyperandrogenism is responsible for LH

hypersecretion. Amelioration of the LH hypersecretion by flutamide, an androgen receptor blocker, supports the relationship of hyperandrogenism and LH hypersecretion. One potential mechanism identified in adolescent girls is decreased hypothalamic sensitivity to progesterone.

- Although the molecular mechanisms responsible for insulin resistance and hyperinsulinemia in PCOS remain to be better characterized, post insulin receptor signal transduction is impaired. The compensatory hyperinsulinemia promotes ovarian (adrenal) androgen secretion. Adipose tissue dysfunction may provoke insulin resistance, but aberrant adipocyte function may also represent a consequence of hyperinsulinemia. Improved insulin sensitivity brought about by weight loss or metformin improves the symptomatology associated with PCOS.

COMMONLY ASSOCIATED CONDITIONS

- Obesity
- Insulin resistance
- Impaired glucose tolerance
- T2D
- Endometriosis
- Metabolic syndrome
- Dyslipidemia
- Hypertension
- Increased risk for cardiovascular disease
- Nonalcoholic fatty acid liver disease
- Sleep apnea
- Depression and impaired quality of life

DIAGNOSIS

SIGNS AND SYMPTOMS

- Irregular menses
- Infertility
- Hyperandrogenism

- Hirsutism
- Polycystic ovaries on US
- Exclusion of other disorders such as nonclassical congenital adrenal hyperplasia
- Obesity and insulin resistance may occur but are not required for diagnosis.

HISTORY

- Age at onset and sequence of pubertal development
- Menstrual history
- Infertility and reproductive history
- Signs and symptoms of androgen excess, for example, hirsutism, acne, male pattern baldness
- Family history of PCOS, hyperandrogenism, and fertility

PHYSICAL EXAM

- Increased terminal hair growth in androgen-dependent areas (hirsutism)
- Acne
- Obesity
- Acanthosis nigricans

DIAGNOSTIC TESTS & INTERPRETATION

- Hormone determinations:
 - Testosterone and free testosterone
 - Sex hormone-binding globulin
 - 17-hydroxyprogesterone
 - Androstenedione
 - DHEAS
 - LH and FSH
 - Prolactin
 - Thyroid function studies (T₄, TSH)
 - HgbA1c
 - Antimüllerian hormone (AMH)
- Stimulation and tolerance tests:
 - Oral glucose tolerance test to assess for impaired glucose tolerance, impaired fasting glucose tolerance, or diabetes
 - Consider referral to endocrinologist for ACTH stimulation test to

exclude the diagnosis of 21-hydroxylase deficiency and other disorders of steroidogenesis.

- Euglycemic and hyperinsulinemic clamp studies can be performed to assess insulin sensitivity. These tests are generally reserved for research purposes.
- Imaging studies:
 - Ovarian US to assess ovarian volume and follicle number. For the postpubertal girl, revised criteria suggest that a total ovary threshold count of 26 follicles provided the optimal compromise between sensitivity and specificity to distinguish polycystic from normal ovaries.
 - Pelvic MRI: ovarian volume and the number of ovarian follicles

DIFFERENTIAL DIAGNOSIS

- Nonclassic congenital adrenal hyperplasia
- Cushing syndrome
- Androgen-secreting tumors
- Hyperprolactinemia
- Thyroid dysfunction
- Exogenous androgen use

TREATMENT

GENERAL MEASURES

- Treatment should to be individualized to best address the needs of each patient. Common goals include reduced symptoms of hyperandrogenism, regular menses and ovulation, fertility, and decreased risk for comorbidities.
- Lifestyle. Lifestyle intervention to promote weight loss and regular exercise is extremely beneficial.
 - Pharmacologic
 - Oral contraceptives
 - Metformin
 - Spironolactone
 - Antiandrogens

- Statins
- Monthly progestins

SURGERY/OTHER PROCEDURES

Ovarian wedge resection was used in the past. This treatment is no longer advocated.

ONGOING CARE

COMPLICATIONS

- One systemic review of 35 studies concluded that women with PCOS have a 2.5-fold increased prevalence of impaired glucose tolerance, 2.5-fold increased prevalence of metabolic syndrome, and 4-fold increased prevalence of T2D.
- Women with the most extreme degrees of androgen excess and insulin resistance demonstrate increased risks for impaired oocyte development and may experience high rate of miscarriages.
- During pregnancy, risk of developing gestational diabetes, pregnancy-induced hypertension, and pre-eclampsia are increased.
- Possible cancer risk
- Quality of life concerns and issues

CODES

ICD10

- E28.2 Polycystic ovarian syndrome
- L68.0 Hirsutism

FAQ

- Q: Can I still get pregnant if I have this syndrome?
- A: Those patients who desire to become pregnant can be treated with ovulation-inducing agents and benefit from treatment by reproductive endocrine specialists.
- Q: I've noticed increased facial hair recently. Is there anything I can do about this?
- A: Yes. Oral contraceptives and spironolactone may be helpful. Cosmetic methods may be necessary to remove coarse hair growth.
- Q: Will my daughter inherit this disorder?
- A: Daughters and sisters of affected women have a higher chance of developing PCOS than daughters and sisters of unaffected women.

POLYCYTHEMIA

Benjamin J. Huang • Tannie Huang

BASICS

DESCRIPTION

Polycythemia (sometimes referred to as erythrocytosis) is defined as an absolute increase in red blood cell (RBC) mass, most commonly suspected in the context of an elevated hemoglobin, hematocrit, or RBC count. Use of age- and gender-based norms are critical, as they fluctuate throughout childhood. Polycythemia can be categorized as follows:

- Primary polycythemia: defect within erythroid progenitors, resulting in overproduction of RBCs. Serum erythropoietin (EPO) levels are usually low.
- Secondary polycythemia: stimulation of erythrocyte production by an increased level of EPO, which is either elevated appropriately in response to hypoxia or elevated inappropriately due to an EPO-producing tumor or exogenous administration
- Relative polycythemia: elevated hemoglobin, hematocrit, or RBC count without a true increase in RBC mass, often caused by decreased plasma volume

EPIDEMIOLOGY

Primary polycythemias are very rare in children:

- Myeloproliferative neoplasms, including polycythemia vera (PV): Vast majority of cases occur in older adults, but cases of childhood PV have been described.
- Primary familial and congenital polycythemia (PFCP): very rare but presents early during infancy or childhood

The incidence and prevalence of secondary polycythemias depend on the respective underlying conditions.

RISK FACTORS

Genetics

- PFCP: autosomal dominant

- Chuvash polycythemia: autosomal recessive
- 2,3-diphosphoglycerate (DPG) mutase deficiency: autosomal recessive

GENERAL PREVENTION

There are no preventive measures for conditions of primary polycythemia. Treatment of underlying conditions, such as correction of congenital heart disease, will prevent the development of secondary polycythemia.

PATHOPHYSIOLOGY

- Primary polycythemias
 - PV: myeloproliferative neoplasm arising from a clonal population of abnormal hematopoietic progenitor cells with EPO-independent proliferation. EPO levels are usually low. The mutation JAK2 V617F is found in the vast majority of cases.
- PFCP: Erythroid progenitors are hypersensitive to EPO. Some families have a mutation in the EPO receptor (EPO-R).
- Secondary polycythemias
 - High altitude: compensation for low atmospheric oxygen pressure
 - Chronic pulmonary disease or hypoventilation: compensation for inadequate oxygenation
 - Cyanotic heart disease and arteriovenous malformations: right-to-left cardiac or extracardiac shunting, resulting in desaturation of arterial blood
 - High oxygen-affinity hemoglobinopathies: mutation in either alpha or beta globin chains leading to increased oxygen affinity and decreased oxygen delivery to tissues
 - 2,3-DPG mutase deficiency: rare defect that leads to deficiency of 2,3-DPG. Because 2,3-DPG promotes the release of oxygen from hemoglobin, deficiency leads to decreased oxygen delivery to tissues.
 - Methemoglobinemia: elevated levels of Fe^{3+} hemoglobin, which has an increased affinity for oxygen compared to Fe^{2+} hemoglobin
 - Carboxyhemoglobinemia: Carbon monoxide binds to hemoglobin preferentially compared to oxygen.
 - Hypoxia-sensing pathway defects: Mutations in the genes von Hippel Lindau (VHL) are common in certain ethnic groups

(Chuvash polycythemia). Hypoxia-inducible factor 2 (HIF2) and proline hydroxylase (PHD2) have also been described.

- EPO-producing tumors: renal cell carcinoma, hepatocellular carcinoma, hemangioblastoma, pheochromocytoma, and uterine fibroids

DIAGNOSIS

HISTORY

- Age of onset
 - Neonates who are born to mothers with preeclampsia or diabetes, are small for gestational age, undergo delayed cord clamping, or have certain chromosomal abnormalities (e.g., Down syndrome) are at increased risk for polycythemia during the neonatal period.
- Gender
- Weight: Obesity is associated with obstructive sleep apnea.
- Dehydration
 - Diuretic use or abuse
 - Severe diarrhea
- Hyperviscosity
 - Headache, dizziness, syncope, transient blindness, history of thrombosis
- Symptoms concerning for congenital heart disease or chronic pulmonary disease:
 - Cyanosis
 - Decreased exercise tolerance
 - Shortness of breath
 - Dyspnea on exertion
- Pruritus
 - Seen with polycythemia vera
- Sleep history
 - Snoring, nocturnal apnea, mouth breathing, excessive daytime sleepiness, behavioral problems concerning for obstructive sleep apnea
- Living situation

- High altitude
- Older house with fuel-burning heaters
- Cigarette exposure
- Social history
 - Smoking (tobacco or marijuana)
 - Drug use including steroids, EPO, diuretics
- Family history
 - High hematocrit, hyperviscosity, or need for phlebotomy
 - Family members with similar symptoms may also indicate concurrent exposure to carbon monoxide

PHYSICAL EXAM

Signs and symptoms:

- Cyanosis
- Plethora
- Clubbing
- Cardiac murmurs or bruits
- Dehydration
- Splenomegaly

ALERT

- Fingertick hematocrit: Squeezing the finger to collect a specimen may give a falsely elevated hematocrit.
- Capillary hematocrit: often higher than venous hematocrit
- Dehydration during blood draw may result in relative polycythemia due to decreased plasma volume.
- PaO₂ is only interpretable with an arterial blood gas.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Many patients may be asymptomatic with polycythemia noted on routine screening.
- Initial workup should include the following:
 - CBC with differential: Polycythemia may be associated with abnormalities in other lineages. Leukocytosis and thrombocytosis may be noted in myelodysplastic disorders.

- Arterial blood gas with co-oximetry: PaO_2 may be low in cardiopulmonary diseases. Co-oximetry allows for evaluation of carboxyhemoglobin and methemoglobin levels. Half-life of carboxyhemoglobin is 4 hours, so testing should be timed to accurately reflect exposures.
- BUN, serum creatinine, and urinalysis to evaluate renal function
- Serum EPO: may be helpful in distinguishing primary from secondary polycythemia but significant overlap in EPO levels between the two categories
- Further investigation
 - Hemoglobin dissociation curve P50: the partial pressure of oxygen at which hemoglobin is 50% saturated (must be performed on fresh whole blood samples)
 - Hemoglobin electrophoresis: Normal results do not rule out the presence of high oxygen-affinity hemoglobin, as many can comigrate with normal hemoglobins.
 - Molecular genetic analysis of globin genes
 - 2,3-DPG level
 - Testosterone level
 - Genetic testing for JAK2 V617F mutation
 - RBC mass measurement using isotope dilution methods
 - Erythroid progenitor studies for erythroid burst-forming units (BFU-E) that grow independent of EPO

Imaging

- Chest radiograph: initial evaluation for chronic pulmonary disease
- Abdominal ultrasound: evaluation for abdominal tumors

Diagnostic Procedures/Other

- EKG and echocardiogram: for clinical findings concerning for congenital heart disease
- Polysomnography sleep study: for clinical findings consistent with sleep apnea
- If myeloproliferative neoplasm is suspected, bone marrow aspirate and biopsy with cytogenetics should be performed. Analysis of erythroid progenitors through colony-forming assays.

DIFFERENTIAL DIAGNOSIS

- Primary polycythemia
 - Polycythemia vera
 - Primary familial and congenital polycythemia
- Secondary polycythemia
 - High altitudes
 - Chronic pulmonary disease
 - Hypoventilation: obstructive sleep apnea, neuromuscular disorders, severe obesity (Pickwickian syndrome), or congenital central hypoventilation syndrome
 - Right-to-left cardiac shunts
 - Arteriovenous malformations
 - High oxygen-affinity hemoglobinopathies
 - 2,3-DPG mutase deficiency
 - Methemoglobinemia
 - Carbon monoxide poisoning
 - EPO-producing tumors: renal cell carcinoma, hepatocellular carcinoma, hemangioblastoma, pheochromocytoma, uterine fibroids
 - Status-post renal transplant
 - Exogenous testosterone or EPO: competitive athletes
 - Cobalt poisoning: Homemade beer may contain cobalt.
- Neonatal polycythemia
 - Preeclampsia or gestational hypertension
 - Small for gestational age
 - Gestational diabetes
 - Delayed cord clamping
 - Placental transfusion
 - Twin-to-twin transfusion
- Relative polycythemia
 - Cigarette smoking
 - Dehydration

TREATMENT

MEDICATION

Primary polycythemia should be managed by a hematologist. Certain medications, such as hydroxyurea and interferon alpha, may be considered.

ADDITIONAL TREATMENT

General Measures

- Most asymptomatic patients with secondary polycythemia require no additional therapy other than management of their underlying condition.
- Due to the long-term leukemic potential of many chemotherapy agents, many pediatric patients with primary polycythemia are managed with phlebotomy only. Low-dose aspirin may be considered to reduce thrombosis risk.
- In neonatal polycythemia, partial exchange transfusion should be considered based on symptoms and degree of polycythemia.

ISSUES FOR REFERRAL

Unexplained cyanosis, symptoms concerning for hyperviscosity, or persistent elevation in hematocrit that is not related to dehydration or neonatal etiologies

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Periodic laboratory follow-up depending on the etiology of polycythemia.

Monitor for the following:

- Headache, dizziness, or syncope
- Decreased exercise tolerance, shortness of breath, or dyspnea on exertion
- Stroke or thrombosis

PROGNOSIS

Depends on underlying condition:

- Polycythemia vera: guarded as may progress to acute leukemia
- High oxygen-affinity hemoglobinopathies: good
- Other secondary polycythemias: depend on underlying condition (e.g.,

poor prognosis for Eisenmenger syndrome due to progressive pulmonary hypertension and cor pulmonale)

COMPLICATIONS

From hyperviscosity:

- Decreased exercise tolerance, dyspnea on exertion, transient visual disturbances, and mental status changes
- Stroke or other thrombosis

CODES

ICD10

- D45 Polycythemia vera
- D75.1 Secondary polycythemia
- P61.1 Polycythemia neonatorum

FAQ

- Q: What are common causes of polycythemia in the pediatric population?
- A: Secondary polycythemias. In particular, neonates and patients with cyanotic heart disease commonly present with polycythemia.
- Q: What are common causes of relative polycythemia?
- A: Dehydration and heavy cigarette smoking have been associated with decreased plasma volume and relative polycythemia.
- Q: When should a child with polycythemia be referred to a pediatric hematologist?
- A: The child should be referred to a pediatric hematologist if there are symptoms concerning for hyperviscosity or if the elevation in hematocrit is persistent and not clearly due to dehydration or neonatal etiologies.

POLYPS, INTESTINAL

Steven Liu

BASICS

DESCRIPTION

- Intestinal polyps are abnormal tissue growths protruding from the intestinal mucosa into the lumen.
- Most commonly solitary lesions (juvenile polyps) but may also be multiple in number
- May be associated with various polyposis syndromes
- Classified by gross appearance
 - Pedunculated: mushroom-like and attached to mucosa with a narrow stalk
 - Sessile: elevated, flat lesions broadly attached to mucosa
- Types of polyps:
 - Hamartomas
 - Adenomatous
- Polyposis syndromes
 - Juvenile polyposis syndrome (>3–5 juvenile polyps)
 - Juvenile polyposis of infancy
 - Juvenile polyposis coli (colonic involvement only)
 - Generalized juvenile polyposis
 - Peutz-Jeghers syndrome
 - Familial adenomatous polyposis (FAP)
 - Other polyposis syndromes

EPIDEMIOLOGY

- Juvenile polyps are the most common childhood polyps:
 - Account for >90% of polyps seen in children
 - 1–2% of asymptomatic children are estimated to have juvenile polyps.
 - Typically present between 2 and 5 years of age
 - Twice as common in boys than girls
 - >5 juvenile polyps should raise a suspicion for juvenile polyposis

syndrome.

- Average age at onset of adenomatous polyps in FAP is 16 years.

Prevalence

- Juvenile polyposis syndrome: 1 in 100,000 to 1 in 160,000
- Peutz-Jeghers syndrome: 1 in 25,000 to 1 in 300,000
- FAP: 1 in 5,000 to 1 in 17,000

RISK FACTORS

Family history of polyposis syndrome

Genetics

Different genes and inheritance patterns with various polyposis syndromes:

- Juvenile polyposis syndrome
 - Autosomal dominant with variable penetrance
 - Mutations in SMAD4 and BMPR1A genes, involved in transforming growth factor- β (TGF- β) signal transduction
- FAP
 - Autosomal dominant
 - Mutation in adenomatous polyposis coli (APC) tumor suppressor gene
- Peutz-Jeghers syndrome
 - Autosomal dominant
 - Mutations in STK11/LKB1 tumor suppressor gene are associated.
- Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome (BRRS)
 - Autosomal dominant
 - Associated with mutations in PTEN gene

PATHOPHYSIOLOGY

Mutations in tumor suppressor genes likely lead to dysregulation of cell proliferation and apoptosis in polyposis syndromes.

COMMONLY ASSOCIATED CONDITIONS

- Juvenile polyposis syndrome, Cowden syndrome, and BRRS all have juvenile polyps as part of their manifestations.
- Peutz-Jeghers syndrome is characterized by multiple GI pedunculated hamartomatous polyps.

- FAP and Turcot syndrome are characterized by multiple adenomatous polyps.

DIAGNOSIS

HISTORY

- Family history of polyps or polyposis syndromes is essential to obtain.
- Presence and amount of blood in stool
- Signs and symptoms:
 - Frequently asymptomatic
 - Painless rectal bleeding is typical presentation.
 - Iron deficiency anemia
 - Prolapsing rectal lesion
 - Abdominal pain or obstruction from intussusception
 - Diarrhea

PHYSICAL EXAM

- Digital rectal exam may identify rectal polyp.
- Pigmentation of skin and mucous membranes consistent with Peutz-Jeghers syndrome
- Mucocutaneous lesions such as facial trichilemmoma, oral fibromas, and acral keratosis are seen in Cowden syndrome.
- Mental retardation, macrocephaly, lipomatosis, hemangiomas, and genital pigmentation are seen in BRRS.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool test for occult blood may be positive.
- CBC can assess degree of anemia and also for baseline hemoglobin before polypectomy.
- PT/PTT should be considered before polypectomy due to risk of bleeding.
- Genetic testing can be considered if a polyposis syndrome is suspected.
- Use of urine and tissue matrix metalloproteinases (MMPs) as biomarkers for the presence of polyps is being researched.

Imaging

Radiologic studies are not the most effective methods of identifying polyps but can be used:

- Barium enema may identify colonic polyps.
- Upper GI with small bowel study may locate presence of small bowel polyps.
- Use of CT and MR colonography has been studied mainly in adults.

Diagnostic Procedures/Other

- Full colonoscopy with polypectomy is the preferred test to perform.
- Flexible sigmoidoscopy may miss polyps in proximal colon:
 - 32% of juvenile polyps are located proximal to splenic flexure.
 - 12% of patients with juvenile polyps only have polyps located proximal to splenic flexure.
- Video capsule endoscopy and balloon enteroscopy may be useful to identify small bowel polyps.

Pathologic Findings

- Polyp pathology cannot be determined by gross visualization, hence polyps must be removed for histologic exam.
- Juvenile polyps
 - Hamartomatous but occasionally capable of adenomatous changes
 - Potential of malignancy in a solitary juvenile polyp is extremely low but is increased in juvenile polyposis syndrome.
- Peutz-Jeghers syndrome
 - Hamartomatous
 - Microscopically have hyperplasia of the smooth muscle layer, extending in an arborizing, tree-like manner
 - Relatively low potential of GI malignancy but increased potential in other organs such as breast, pancreas, ovary, testicle, and uterus
- FAP
 - Adenomatous polyps
 - Lifetime risk for colorectal cancer is 100%.
 - Increased association with hepatoblastoma, periampullary carcinoma, and desmoid tumors

DIFFERENTIAL DIAGNOSIS

- Because juvenile polyps often present with rectal bleeding, the differential diagnosis for lower GI bleeding should be considered:
 - Anal fissure
 - Meckel diverticulum
 - Infectious enterocolitis
 - Inflammatory bowel disease
 - Intussusception
 - Vascular malformation
 - Hemorrhoids
 - Hemolytic uremic syndrome
 - Henoch-Schönlein purpura
 - Rectal trauma
 - Neoplasm

TREATMENT

MEDICATION

Administration of some NSAIDs (such as sulindac and celecoxib) may slow progression or reduce the number of adenomatous polyps.

ADDITIONAL TREATMENT

General Measures

Full colonoscopy with polypectomy is an essential diagnostic and therapeutic tool. Removal of GI polyps can help to control symptoms and reduce the risk of malignancy.

ISSUES FOR REFERRAL

Patients suspected of having a polyp or polyposis syndrome should be referred to a gastroenterologist for evaluation. Patients with polyposis syndromes should be referred to a tertiary care center for genetic counseling.

SURGERY/OTHER PROCEDURES

- When adenomatous polyps are identified in FAP, prophylactic colectomy should be considered.
- Colectomy should also be considered in other polyposis syndromes

with innumerable polyps or polyps showing premalignant changes.

- The main surgical options include a subtotal colectomy with ileorectal anastomosis (IRA) or a proctocolectomy with ileal pouch–anal anastomosis (IPAA).

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- For solitary juvenile polyps, follow up with stool guaiac check and CBC 6 months after polypectomy. Repeat colonoscopy is indicated with any abnormalities.
- For polyposis syndromes, screening recommendations differ depending on the syndrome:
 - Typically involve surveillance colonoscopies every 1–3 years depending on findings
 - Asymptomatic children with an APC mutation for FAP should have annual colonoscopies starting at 10–12 years of age.
 - Published guidelines for follow-up of patients with various polyposis syndromes are available.

CODES

ICD10

- K63.89 Other specified diseases of intestine
- D12.6 Benign neoplasm of colon, unspecified
- Q85.8 Other phakomatoses, not elsewhere classified

FAQ

- Q: What is the potential of developing cancer from a polyp?
- A: Risk of neoplasia depends on the type of polyp:
 - Patients with solitary juvenile polyps have essentially no increased risk of colorectal carcinoma.
 - Patients with juvenile polyposis syndrome have been reported to have up to a 65% chance of developing GI cancer, with the risk of malignancy commencing from age 20 years.
 - Patients with Peutz-Jeghers syndrome have been reported to have almost a 50% chance of developing cancer in the intestinal tract or other organ systems.
 - Patients with FAP have a 100% lifetime risk of developing colorectal cancer.
- Q: Is a flexible sigmoidoscopy sufficient for the detection of polyps?
- A: No. Approximately 37% of patients with juvenile polyps have polyps proximal to the splenic flexure, and 12% of patients have only proximal colon polyps. A flexible sigmoidoscopy would not identify these polyps, making it necessary to perform a full colonoscopy.
- Q: What is your management recommendation for a patient with painless rectal bleeding that stops on its own?
- A: It is widely believed that pedunculated polyps will autoamputate after outgrowing their blood supply, although there is no objective

evidence supporting this. If there is no family history of a polyposis syndrome, the patient can be followed with stool guaiac checks and a CBC in 6 months. If there is a family history, then referral to a gastroenterologist for full colonoscopy is indicated.

- Q: How many polyps can patients have?
- A: Patients with juvenile polyposis syndrome often have 50–200 polyps distributed throughout the colon. Patients with FAP may have a few to over a thousand polyps in the colon.
- Q: When does endoscopic surveillance typically begin for children with FAP?
- A: It is generally recommended that annual endoscopic surveillance begin between 10 and 12 years of age in patients with an APC mutation.

PORTAL HYPERTENSION

Rose C. Graham

BASICS

DESCRIPTION

- Definition: elevation of portal blood pressure greater than 10 mm Hg
 - May be pre-, intra-, or posthepatic in origin
 - A major cause of morbidity and mortality in children with chronic liver disease

PATHOPHYSIOLOGY

- An increase in portal resistance and increased portal blood flow are the main pathogenic factors initiating the process of portal hypertension:
 - Other factors contribute to increased portal blood flow and pressure including hyperdynamic circulation, expanded intravascular volume, systemic arteriolar vasodilatation, decreased splanchnic arteriolar tone, and humoral factors (i.e., nitric oxide).
- Decompression of the high venous pressure through portosystemic collaterals leads to all the major sequelae of portal hypertension:
 - Splenomegaly
 - Varices (esophageal, gastric)/GI bleeding
 - Hemorrhoids
 - Caput medusa (periumbilical varices)
 - Ascites
 - Hepatic encephalopathy
 - Hepatopulmonary syndrome

DIAGNOSIS

HISTORY

- History of umbilical catheterization
- History of hepatitis, abdominal trauma, clotting disorder, contraceptive pills, underlying medical problem such as cystic fibrosis, tyrosinemia,

Wilson disease

- Ingestion of excessive amounts of vitamin A
- Hematemesis or melena: Upper GI tract bleed from varices may be the 1st sign of long-standing silent liver disease or previously undiagnosed portal vein thrombosis.

PHYSICAL EXAM

- Splenomegaly
- Hepatomegaly may or may not be present.
- Ascites (distension, fluid wave)
- Hemorrhoids
- Prominent vascular pattern on the abdomen (caput medusa)
- Digital clubbing
- Telangiectasia
- Palmar erythema
- Growth failure

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC and smear: detect hypersplenism, GI tract blood loss, and chronic liver disease
- PT/INR and PTT: detect coagulation defects
- Hepatic function panel includes liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST]), albumin (measure of hepatic function), alkaline phosphatase, and γ -glutamyl transferase (GGT; may be elevated with cholestasis and bile duct injury).
- Additional laboratory testing to determine the cause of underlying liver disease, depending on clinical scenario (see chapter on “[Cirrhosis](#)” for more details)

Imaging

- Abdominal ultrasound with Doppler to evaluate
 - Liver size and echogenicity
 - Biliary anatomy
 - Spleen size
 - Renal cysts

- Presence of ascites
- Vessel diameter
- Direction of blood flow
- Presence of esophageal varices
- Esophagogastroduodenoscopy (EGD) to identify the presence of esophageal varices. EGD is also useful for determining if variceal rupture is the cause of GI tract bleeding.

Diagnostic Procedures/Other

- Liver biopsy: identify the underlying cause of the portal hypertension
- Hepatic venous wedge pressure gradient correlates and selective angiography are not used in pediatrics because of a lack of well-documented pediatric measurements and lack of a favorable risk–benefit ratio.

DIFFERENTIAL DIAGNOSIS

- Prehepatic causes:
 - Portal vein thrombosis with cavernous transformation (increased risk with umbilical vein catheterization, sepsis, dehydration, hypercoagulable state)
 - Splenic vein thrombosis
- Intrahepatic causes:
 - Hepatocellular disorders: viral hepatitis, α_1 -antitrypsin deficiency, chronic hepatitis, autoimmune hepatitis, Wilson disease, glycogen storage disease, tyrosinemia, schistosomiasis, peliosis hepatitis, vitamin A toxicity
 - Biliary tract disorders: extrahepatic biliary atresia, ductal plate malformation/congenital hepatic fibrosis, intrahepatic cholestasis syndromes, primary sclerosing cholangitis, choledochal cyst, cystic fibrosis
- Posthepatic causes:
 - Budd-Chiari syndrome: occlusion of suprahepatic inferior vena cava or hepatic veins by congenital web, tumor, or thrombus
 - Congestive heart failure
 - Veno-occlusive disease of hepatic venule

TREATMENT

MEDICATION

- β -Blockade: Nonselective β -blockers, such as propranolol, have been shown to be effective in preventing both initial and recurrent variceal bleeds in adults. Data are limited on use of β -blockers in children with portal hypertension to prevent primary or secondary variceal bleeds. Use in children for this indication is empiric and mainly based on adult data:
 - Mechanisms include lowering portal blood flow and thus portal pressure by both β_2 -blockade, which increases splanchnic tone, and β_1 -blockade, which decreases cardiac output.
 - Propranolol, specifically, may also decrease collateral circulation.
 - β -Blocker effect on decreasing cardiac output may blunt an adaptive cardiovascular response (elevated heart rate) in the event of a hemorrhage; these medications should not be used in patients with asthma or diabetes.
 - Owing to lack of sufficient prospective data, routine use of β -blockers in children for primary or secondary prevention of variceal bleeding cannot be recommended.
- Diuretic therapy (spironolactone +/- chlorothiazide) when ascites is present

ADDITIONAL TREATMENT

General Measures

Chronic management of varices:

- Surveillance endoscopy and primary prophylaxis in pediatric patients with portal hypertension who have not had a 1st variceal bleed are controversial; however, they may be recommended in select patients.
- Long-term care of patients with portal hypertension who have had a variceal bleed depends on the underlying cause of the portal hypertension and may include secondary prophylactic endoscopic band ligation or sclerotherapy, portosystemic shunts, and liver transplantation.

ADDITIONAL THERAPIES

- Endoscopic sclerotherapy: reduces rebleeding episodes and long-term mortality when initiated after 1st bleed; unclear whether effective primary prophylaxis; in general, supplanted by endoscopic band ligation, except for small children
- Endoscopic band ligation is preferred, as it carries fewer complications compared with sclerotherapy. Endoscopic band ligation is not feasible in small patients.

SURGERY/OTHER PROCEDURES

- Portosystemic shunts
 - May be helpful in the setting of prehepatic causes of portal hypertension to reduce portal pressure. The Rex shunt (mesenteric-left portal bypass) has been used successfully in the setting of cavernous transformation of the portal vein.
 - Does not improve long-term survival in patients with intrahepatic disease
 - Complications may include thrombosis and worsening of hepatic encephalopathy.
 - Transjugular intrahepatic portosystemic shunt (TIPS) procedure may be an effective bridge to liver transplantation in pediatric patients with progressive liver disease and recurrent variceal bleeds.
 - Data in pediatric patients are limited.
- Liver transplantation
 - The current approach at most institutions is liver transplantation for those patients with life-threatening bleeds not amenable to β -blockade or endoscopic therapies.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Acute management of variceal bleed
 - Vital signs: Remember that hemodynamic instability can be masked by β -blockers.
 - Fluid resuscitation: two large-bore IV catheters or intraosseous needles, give crystalloid initially, then RBC transfusion with goal hemoglobin of around 10 g/dL
 - Nasogastric tube placement: Lavage with room temperature saline

or sterile water until clear; leave tube in place for evaluation and removal of continued or recurrent bleeding.

- Correction of coagulopathy: Parenteral vitamin K, fresh frozen plasma, platelet transfusion if platelets $<50,000/\mu\text{L}$
- IV antibiotics: Acute variceal hemorrhage increases the risk of spontaneous bacterial peritonitis in the setting of ascites.
- IV proton pump inhibitor or histamine receptor antagonist to decrease risk of bleeding from ulcers or erosions
- Pharmacotherapy to control active bleeding
 - Octreotide (somatostatin analog) decreases splanchnic blood flow via its inhibition of intestinal vasoactive peptide secretion. In turn, portal blood pressure is decreased. Somatostatin can be used but has a shorter half-life compared with octreotide.
 - Vasopressin decreases splanchnic blood flow via its vasoconstriction effects, but its use is limited owing to systemic vasoconstriction and a poor side effect profile. Nitroglycerin, a venodilator, has been used in conjunction to decrease side effects. This combination is not preferred.
- Lactulose to prevent hepatic encephalopathy in patients with cirrhosis
- Endoscopy (after stabilization) to determine source of hemorrhage (variceal rupture or other, such as gastric ulcer) and perform therapeutic procedures such as sclerotherapy or band ligation for varices or electrocautery or clip placement for ulcer
- Direct tamponade: Sengstaken-Blakemore tube for severe uncontrollable hemorrhage, but high rate of complications
- Interventional radiology: variceal embolization, TIPS
- Surgical intervention: portosystemic shunt, esophageal devascularization, and/or transection; in general, last resort

ALERT

- The site of bleeding needs to be identified and managed appropriately: Not all GI bleeding in a patient with portal hypertension is an upper GI tract source (i.e., hemorrhoids); nasogastric lavage will help to determine if the problem is from the upper tract.
- Be careful not to overestimate the hemoglobin because equilibration

may not have taken place at the time of presentation with an acute bleed.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients are followed closely for hepatic decompensation.
- Growth failure, recurrent life-threatening bleeds not controllable with prophylactic intervention, refractory ascites, and poor quality of life are indications for liver transplantation.

DIET

Sodium restriction when ascites is present

PROGNOSIS

- The disease course and prognosis depend on the underlying cause.
- Acute variceal bleeding is associated with a 6-week mortality of up to 30% in adults. The mortality rate in children is much lower.
- Variceal bleeding associated with prehepatic causes of portal hypertension such as portal vein thrombosis typically becomes less problematic as the child ages; these patients will most likely not require a shunt and may be managed with endoscopic therapy.
- Patients with congenital hepatic fibrosis also do very well because the underlying disease is not progressive and bleeding may be easily managed with endoscopic therapy.
- Progressive liver disease has a worse prognosis and often requires liver transplantation.

COMPLICATIONS

- Hemorrhage from varices may present as hematemesis, hematochezia, or melena.
- Hypersplenism
- Malabsorption due to congestion of the intestinal mucosa
- Abnormal sodium retention
- Ascites: Presence of ascites increases risk of spontaneous bacterial peritonitis.

- Hepatorenal syndrome
- Hepatopulmonary syndrome (intrapulmonary right-to-left shunting) leads to hypoxemia, shortness of breath, exercise intolerance, and digital clubbing.
- Pulmonary hypertension can be a life-threatening complication of portal hypertension.

CODES

ICD10

- K76.6 Portal hypertension
- K72.90 Hepatic failure, unspecified without coma
- K76.81 Hepatopulmonary syndrome

FAQ

- Q: What is my child's long-term prognosis?
- A: Disease prognosis of portal hypertension depends on the underlying cause. Variceal bleeding associated with prehepatic causes of portal hypertension such as portal vein thrombosis typically becomes less problematic as the child ages and may be managed with endoscopic therapy.

- Q: Are there any medications I should avoid?
- A: Avoid aspirin and NSAID-containing products such as ibuprofen.

POSTERIOR URETHRAL VALVES

Andrew A. Stec

BASICS

DESCRIPTION

A posterior urethral valve (PUV) is an embryologic remnant of tissue in the urethra that causes obstruction of the lower urinary tract during fetal development; this obstruction results in short-and long-term structural abnormalities and physiologic dysfunction in the genitourinary system (kidney, ureter, bladder, and urethra).

EPIDEMIOLOGY

- Most common cause of lower urinary tract obstruction in males
- The incidence is estimated to be between 1:3,000 and 1:8,000 live male births.
- Approximately 24–45% of children born with PUV will exhibit renal insufficiency during childhood.
- PUV accounts for up to 17% of the cases of children with end-stage renal failure.

RISK FACTORS

Genetics

- Majority of cases are isolated and occur sporadically.
- Rarely, cases have been reported in siblings.

PATHOPHYSIOLOGY

- Multiple theories exist as to the embryologic origin of PUV.
- Male urethral development is usually complete by 14 weeks' gestation; PUV formation is presumed to occur prior to this point.
- Possible embryologic origin of PUVs include (1) presence of an obstructing membrane in the posterior urethra, (2) overgrowth or abnormal folding during normal urethral development, (3) abnormal integration of the Wolffian ducts into urethral development, or (4) abnormal persistence of the urogenital membrane.

- PUVs exist in a spectrum of severity, likely related to the timing and degree of obstruction during development.
- The valve is a leaflet or membrane of thin connective tissue that extends from the anterior urethral lip to the verumontanum posteriorly, obstructing the normal flow of urine through the urethra. This results in an elongated urethra and upstream dilation in the urinary system.
- PUVs are commonly associated with intrinsic renal dysplasia. Studies have demonstrated that dysplastic renal parenchyma at time of birth is permanent.
- Commonly associated pathophysiologic findings in children with PUV include (1) hydroureteronephrosis, (2) dilated bladder with trabeculations and/or diverticulum, and (3) vesicoureteral reflux.
- PUVs may result in early or late bladder dysfunction with decreased compliance and increased voiding pressure that affect both the storage and expulsion of urine as well as expose the upper tract of the urinary system to increased pressure, which leads to worsening renal function over time.

COMMONLY ASSOCIATED CONDITIONS

- Genitourinary: hydroureteronephrosis, vesicoureteral reflux, bladder wall thickening and diverticulum, obstructive urinary symptoms, urinary ascites in cases of bladder rupture, perirenal urinoma in cases of renal collecting system rupture
- Varying degrees of renal insufficiency may also be present in patients from birth through adulthood.
- PUV has been associated with other congenital anomalies of the genitourinary tract: prune belly syndrome, imperforate anus, and congenital heart disease.

DIAGNOSIS

HISTORY

- PUVs generally present in four ways:
 - Fetal diagnoses by ultrasound (US)
 - Neonates with respiratory distress, abdominal distension, metabolic

abnormalities

- Infants with febrile UTI/sepsis/poor urinary stream
- Delayed presentation in children with UTI or voiding difficulties
- Fetal presentation (diagnosis on ultrasound)
 - Dilated, thick-walled bladder
 - Bilateral and in some cases unilateral hydroureteronephrosis
 - “Keyhole sign”: dilated posterior urethra at the base of the bladder
 - Decreased amniotic fluid/oligohydramnios
- Neonatal presentation
 - Tachypnea/respiratory distress
 - Poor feeding/failure to thrive/abdominal distension
 - Lethargy/acidosis and azotemia
 - Cardiovascular compromise and arrhythmia/hyperkalemia
 - Delayed or infrequent voiding
- Infant/toddler presentation
 - Failure to thrive
 - Abdominal distension
 - Fever of unknown origin
 - Febrile UTI
 - Urosepsis
- Delayed presentation
 - UTI
 - Abnormal or weak urinary stream
 - Urinary complaints such as hesitancy, incomplete emptying, dysuria, straining
 - Urinary incontinence, sometimes with palpable bladder
 - Polyuria and urinary frequency secondary to renal concentrating defect

PHYSICAL EXAM

A palpable bladder is the most common physical exam finding. In infants, abdominal distension may be present from severe bladder distension and hydroureteronephrosis or urinary ascites. Hyperpigmented perigenital skin may also be noted from severe incontinence and urine irritation of the skin.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urinalysis: UTI, proteinuria, low specific gravity
- Metabolic panel: elevated creatinine, azotemia, acidosis, hyperkalemia, hyponatremia, renal tubular acidosis (RTA) (type IV)
- CBC: elevated WBC in face of UTI; anemia in renal insufficiency

Imaging

- Renal and bladder US: dilation of posterior urethra (keyhole sign), distended/thick-walled bladder with possible diverticuli, hydronephrosis, echogenic or dysplastic renal parenchyma
- Voiding cystourethrogram (VCUG): diagnostic study. Shows dilated posterior urethra with abnormal runoff of urine in the posterior urethra, capacious bladder with possible trabeculations or diverticulum, vesicoureteral reflux
- KUB: ground-glass appearance in cases of bladder rupture and urinary ascites

Diagnostic Procedures/Other

Operative cystoscopy: visual evaluation of urethra, and bladder provides definitive diagnosis

DIFFERENTIAL DIAGNOSIS

- Prune belly syndrome
- Vesicoureteral reflux
- Urethral stricture disease (congenital and acquired)
- Anterior urethral valves
- Urethral atresia
- Primary ureterovesical junction (UVJ) obstruction (megaureter)
- Severe voiding dysfunction
- Polyuria
- Megacystis–megaureter syndrome
- UTI

**TREATMENT****GENERAL MEASURES**

Supportive

- Insertion of a urethral catheter or feeding tube in the neonate to bypass obstruction
- Confirm placement of catheter in the bladder by ultrasound, as small catheters may coil in the posterior urethra and drain some urine, giving the false impression of being located within the bladder.
- Correction of electrolyte abnormalities with careful observation for postobstructive diuresis
- Monitoring of fluid status
- Antibiotics for any evidence of a UTI; treat UTI as complex
- Consultation with a pediatric urologist

SURGERY/OTHER PROCEDURES

- Resection of the valve (ablation) is the definitive treatment of the primary lesion; typically performed cystoscopically (through the urethra).
- In utero drainage of the fetal bladder is performed at some centers. Typically performed on patients with good urine parameters to mitigate pulmonary dysfunction from oligohydramnios. No significant improvement found in long-term renal outcome compared to valve ablation after delivery.
- If the infant is premature or the urethra is too small for the cystoscope, a vesicostomy may be required.
- Supravesical diversion (of the kidney or ureter) is sometimes performed in select patients who fail to improve after bladder decompression; associated with poorer long-term bladder function.
- Following valve ablation, the posterior urethra should have decreasing dilation on VCUG. Improvement in hydroureteronephrosis and vesicoureteral reflux (if it resolves spontaneously) will occur more slowly.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Lifelong follow-up is required, as renal insufficiency and bladder dysfunction can occur at any time during infancy, childhood, puberty,

or adulthood.

- Pediatric urology follow-up is required for future reconstructive procedures and monitoring of bladder function, reflux, and hydronephrosis.
- Pediatric nephrology follow-up is recommended for long-term monitoring and mitigation of renal dysfunction.
- Delayed urethral obstruction is possible due to urethral stricture or incomplete initial valve resection.
- Patients with persistent incontinence, those who develop incontinence, or those with incomplete bladder emptying may require urodynamic evaluation to evaluate the bladder function/physiology and tailor therapy.

Patient Monitoring

- Careful follow-up through adulthood should be performed.
- Visits should include the following:
 - Imaging (US) to evaluate renal, ureteral, and bladder anatomy
 - Assessment of bladder function (incontinence, UTI, incomplete emptying)
 - Blood pressure monitoring
 - Serial creatinine
 - Urinalyses to assess for proteinuria
 - Assessment of overall linear growth

PROGNOSIS

- Oligohydramnios during pregnancy is a predictor of worse long-term renal outcomes. The earlier it occurs during pregnancy, typically more severe issues are noted.
- Pulmonary hypoplasia (with concomitant renal dysfunction) accounts for the highest mortality in infants.
- Overall, the prognosis for severe PUV has improved over the past few decades, owing to earlier recognition and improved management of pulmonary hypoplasia and fluid and metabolic derangements.
- The rate of improvement in renal function after the valvular obstruction is relieved is more indicative of prognosis than initial creatinine at presentation.

- A creatinine level of <0.8 mg/dL around 1 year of age has the best long-term renal prognosis in patients treated in infancy.
- A nadir creatinine level <1.0 mg/dL may still be associated with eventual renal failure as the child ages; monitoring is warranted in all cases.
- Patient may progress to renal failure and require renal transplantation at any point during childhood or adulthood. An abnormal creatinine at 2 years of age carries higher likelihood of end-stage renal progression during adolescence or puberty.
- Children who develop proteinuria have bilateral renal dysplasia and/or bladder dysfunction and are more likely to eventually develop renal insufficiency and hypertension.

COMPLICATIONS

- Intrauterine oligohydramnios in severe cases may result in Potter syndrome and pulmonary hypoplasia.
- Renal dysplasia and parenchymal damage may lead to progressive renal failure, including associated issues, such as anemia, acidosis, fluid and electrolyte abnormalities, and failure to thrive.
- UTIs and vesicoureteral reflux are commonly associated with PUV.
- Urinary incontinence may result from overactive bladder (uninhibited contractions), incomplete emptying (bladder noncompliance), and polyuria.

CODES

ICD10

- Q64.2 Congenital posterior urethral valves
- Q64.39 Other atresia and stenosis of urethra and bladder neck
- N28.89 Other specified disorders of kidney and ureter

FAQ

- Q: What can be done for children with long-term bladder dysfunction and incontinence?
- A: Patients should be on a comprehensive bowel and bladder regimen due to increased incidence of voiding dysfunction. Additionally, more advance bladder management including intermittent catheterization and pharmacotherapy may be required.
- Q: Are patients with PUVs good candidates for renal transplantation?
- A: PUV patients have a 5-year transplanted kidney survival rate of around 50%, likely resulting from poor bladder function. Therefore, aggressive bladder management and long-term follow-up are prudent in these patients.
- Q: What is “valve-bladder syndrome”?
- A: A valve-bladder is a bladder that is noncompliant and stores urine at high pressure, increasing the incidence of renal damage. It is thought to occur in approximately 20% of PUV patients.

- Q: What is VURD syndrome in PUV patients?
- A: Vesicoureteral reflux and unilateral renal dysplasia (VURD) occurs in 13% of PUV patients. A single renal unit has renal dysplasia and severe reflux, thereby allowing the high bladder pressures in PUV to be transmitted to a single kidney, sparing the contralateral (nonrefluxing) kidney from damage.

PREBIOTICS

Gigi Veereman • Andi L. Shane

BASICS

DESCRIPTION

- Prebiotics are nondigestible carbohydrates that promote growth of favorable intestinal microbiota (probiotic microorganisms) by selective fermentation. Prebiotics may occur naturally or may be manufactured. Naturally occurring prebiotics include human milk oligosaccharides; many are substrates for bifidobacteria. Manufactured prebiotics that mimic this effect are therefore called “bifidogenic.”
- The following manufactured nondigestible carbohydrates were shown to be bifidogenic when added to standard infant formula:
 - Galacto-oligosaccharides (GOS) and long-chain fructo-oligosaccharides (lc-FOS from plants or sucrose); also called fructans
 - Some prebiotics are found in foods including chicory, cereals, agave, and milk, although may not be present in levels that would result in fermentation and a change in host microbiota. Additional processing or synthesis is required in these to achieve prebiotic activity.
 - Candidate prebiotics include lactulose, polysaccharides, oligosaccharides, and polyols.

PATHOPHYSIOLOGY

- Prebiotics such as FOS and GOS are selectively fermented resulting in a change in the composition or activity of the microbiota. Fermentation in colon → increased bacteria → increased water binding → increased stool weight → softer stools → increased stool frequency. Butyrate may increase peristalsis, decrease intestinal transit time and reduce bloating, flatulence, and constipation.
- Prebiotics may impact the immune system directly.
- In vitro studies
 - Proposed mechanisms of indirect prebiotic action include gas and

short-chain fatty acid production, pH changes, and promotion of fecal bacterial growth. Direct effects include binding of the prebiotic to microbe receptors.

- Animal studies
 - Prebiotics exert their effects by enhancing intestinal barrier function. They also promote the growth of ileal lactobacilli through the production of lactic acid and decreasing intestinal pH.
 - Prebiotics increase calcium, magnesium, and iron absorption; growth; and bone mass in rats and pigs.
- Clinical studies
 - Prebiotics exert their effects in the colon. They must retain the ability to be active through intestinal transit and changes in gastrointestinal pH. Most prebiotics interact with bifidobacteria and lactobacilli without altering other bacteria.
 - Stool bulk and intestinal transit time are frequently measured clinical markers of prebiotic effect.
 - Immune function including cytokine levels and antibody function are biomarkers that are measured to assess prebiotic effect.
 - FOS and long-chain inulin (50/50) increased bone mineral density and content in adolescents.
- Clinical studies on effectivity
 - Variability in subjects including age, nutrition, and health status must be considered when interpreting results.
 - Reduced symptoms, decreased infections, and enhanced immune responses are health outcomes measured in clinical studies with prebiotics.
 - Human feeding trials to assess change in microbiota optimally monitor response to prebiotic intake.
- Challenges to applying clinical studies in clinical practice
 - The body of evidence on some clinical effects is highly variable.
 - Prebiotic effects are specific to a particular product or combination of products.
 - Prebiotic effects are modulated by resident flora and by direct effects on the immune system
 - Effects depend on base line, on host: Pooling results is difficult.

TREATMENT

DOSING

- Optimal prebiotic intake ranges from 2 to 20 g per day, depending on desired effect and prebiotic ingredient.
- Prebiotic ingredients may be added to or be contained in cereals, breads, yogurts, sauces, and drinks.
- Regular intake of prebiotic or prebiotic-containing foods is necessary for sustained effect.
- Prebiotic formulations
 - GOS
 - Not widely studied as single prebiotic
 - Major compound of prebiotic combination products
 - No known safety concerns
 - sc-FOS
 - Not widely studied as single prebiotic
 - Some safety concerns and questionable benefits
 - Sc-FOS:lc-FOS
 - Not widely studied combination
 - No safety concerns
 - GOS:lc-FOS (9:1)
 - Best studied prebiotic mixture
 - Initial safety concerns shown not to be relevant.
 - Long history of safe use; benefits questioned
 - GOS:sc-FOS (9:1)
 - Not widely studied as a prebiotic mixture
 - No safety concerns
 - GOS:polydextrose (PDX) (1:1)
 - Several studies with this prebiotic mixture
 - Initial safety concerns addressed.
 - Good history of safe use
- Safety, growth, and tolerance
 - Adding prebiotics to infant formula may create an osmotic effect resulting in softer stools.
 - A theoretical risk for dehydration has not been observed with usual

dosing.

- Increased intake of prebiotics may result in bloating and diarrhea that resolves with decreased consumption.

CLINICAL APPLICATIONS

- Inflammatory bowel disease (IBD)
 - Consumption of the prebiotic fructan may reduce inflammatory markers in persons with IBD.
- Irritable bowel syndrome (IBS)
 - Low-dose consumption of prebiotics may reduce symptoms of IBS.
- Stool consistency
 - Consumption of infant formulas supplemented with bifidogenic prebiotics including GOS, fructans, and oligosaccharides may result in a microbiota and stooling pattern similar to that of infants who consume human milk.
- Other effects
 - Daily prebiotic intake, especially of fructans, may reduce appetite, increase gut peptide levels, and improve glucose tolerance.
 - Changes in the microbiota were noted.

FAQ

- Q: What is the difference between prebiotics and probiotics?
- A: Probiotics are external microorganisms that are consumed to result in a health benefit. Prebiotics have actions that complement those of probiotics but are separate from those of probiotics. A prebiotic is fermented, stimulating the growth and activity of microorganisms, resulting in a health benefit.
- Q: What are synbiotics?
- A: Synbiotics are combinations of the beneficial effects of prebiotics and probiotics. The probiotic organism may play a role in the fermentation of the prebiotic. The probiotic may in turn create a more favorable environment for the proliferation of the probiotic.
- Q: Where can I buy prebiotics?
- A: Naturally occurring prebiotics occur in foods such as chicory, cereals, agave, and milk. However, prebiotic intake may be optimized by consuming foods with labels that indicate that the food contains FOS, inulin (a type of FOS), GOS, or TOS (transgalacto-oligosaccharides).

PRECOCIOUS PUBERTY

Jennifer C. Kelley • Andrew C. Calabria

BASICS

DESCRIPTION

- In most populations, the mean age of onset of puberty is 10.5 years in girls and 11.5 years in boys.
- The first sign of puberty in girls is most commonly breast development (thelarche), followed by pubic hair development (pubarche), and then menarche, which generally occurs 2–3 years after thelarche; in boys, the first sign is usually testicular enlargement, followed by pubarche and penile growth.
- Precocious puberty has traditionally been defined as physical signs of sexual development before age 8 years in girls and age 9 in boys (2.5–3 standard deviations below the mean age of onset of puberty).
- Recent guidelines propose lowering the age considered to be normal for sexual development in girls to as young as age 6 years in black girls and age 7 years in white girls. These new guidelines have not been universally adopted.
- When evaluating precocious puberty, the entire clinical picture, including rate of pubertal progression and the presence of any neurologic symptoms, must be considered.

EPIDEMIOLOGY

- Occurs in ~1 in 5,000 children
- Precocious puberty is up to 10 times more common in girls than boys.
- Racial differences observed in girls: African-American girls may enter puberty 1 year sooner on average than Caucasian girls. Racial difference not present in males.
- Increased incidence in internationally adopted children and in children born premature or small for gestational age
 - In girls: 80–90% of central precocious puberty are idiopathic.
 - In boys: Precocious puberty is more likely to be associated with underlying pathology.

- ~50% of affected boys have idiopathic central precocious puberty.

Genetics

- Genetic causes include the following:
 - Familial male precocious puberty (testotoxicosis): sex-limited, autosomal dominant inheritance of luteinizing hormone (LH) receptor activating mutation
 - McCune-Albright syndrome: sporadic, postzygotic, somatic mutation in the stimulatory subunit of G-protein receptor; precocious puberty more common in girls

PATHOPHYSIOLOGY

- Central precocious puberty can be associated with CNS disorders.
- Peripheral precocious puberty
 - Arises from peripheral sex hormone sources, including gonadal and adrenal disorders, abdominal or pelvic tumors, or exogenous sex steroids
 - Can progress to central precocious puberty due to maturation of the hypothalamic–pituitary axis by sex steroids

ETIOLOGY

- Central precocious puberty (gonadotropin-releasing hormone [GnRH] dependent)
 - Associated with gonadotropin (LH and/or follicle-stimulating hormone [FSH]) levels that are elevated beyond the normal prepubertal range. Results from activation of hypothalamic–pituitary–gonadal axis.
 - Physical changes are typically those of normal puberty for a child of that sex.
- Peripheral sex hormone effects (peripheral precocious puberty or GnRH-independent; less common)
 - Gonadotropin-independent elevation of sex steroids arising (i) directly from gonads and/or adrenals, (ii) through stimulation of gonads by GnRH-independent mechanism, or (iii) from an exogenous source
 - Physical changes reflect predominant excess hormones (estrogenic or androgenic) and are often markedly discordant from normal

pubertal development.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Careful chronology: physical changes, growth spurt, onset of menses
- Neurologic, visual, or behavioral changes suggest a CNS lesion.

HISTORY

- Family history of early puberty (e.g., menarche before age 10 years) or hyperandrogenic disorders (e.g., congenital adrenal hyperplasia)
- Presence of exogenous sex steroid medications or creams in the home

PHYSICAL EXAM

- Plot accurate height (using wall-mounted stadiometer), weight, and growth velocity. Growth acceleration within the past year may be strong evidence for puberty.
- Careful inventory of early estrogenic and androgenic effects
- Estrogenic effects
 - Girls: careful staging of breasts and color of vaginal mucosa
 - Boys: gynecomastia in prepubertal child (gynecomastia is common and normal part of puberty in pubescent male.)
- Androgenic effects
 - Girls: careful staging of pubic hair, clitoromegaly
 - Boys: careful staging of testicular volume (with Prader gonadometer or by measuring testicular length), penile size, and pubic hair
- Examine skin for acne and café au lait spots.
- Perform comprehensive neurologic evaluation to assess for possible CNS pathology.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Labs should be selected based on inventory of estrogenic and/or androgenic effects and drawn in early morning.
- Estrogenic effects
 - Girls: FSH and LH (ultrasensitive, pediatric,

- immunochemiluminometric [ICMA] or electrochemiluminescent [ECL]) (LH is most accurate) and estradiol
- Boys: ultrasensitive LH and FSH, estradiol, human chorionic gonadotropin (hCG) level
 - Androgenic effects
 - Total testosterone by assay designed to measure low concentrations, adrenal steroids including 17-hydroxyprogesterone (17-OHP) to evaluate for late-onset congenital adrenal hyperplasia and dehydroepiandrosterone sulfate (DHEA-S) to exclude or confirm adrenarche, and ultrasensitive LH to evaluate for central puberty
 - Other tests
 - Prolactin: may be elevated with CNS tumors
 - Thyroid-stimulating hormone (TSH) and free thyroxine (T₄)
 - Avoid lower yield tests, such as total estrogens, nonultrasensitive LH, free testosterone levels (more helpful in adolescent girls with testosterone levels above 30 ng/dL), and other adrenal steroids such as 17-hydroxypregnenolone and DHEA.
 - Provocative stimulation tests should be done when the aforementioned tests are abnormal or equivocal:
 - GnRH test (typically leuprolide stimulation) for central precocious puberty; prepubertal GnRH response is predominantly FSH, whereas pubertal response is predominantly LH.
 - Adrenocorticotrophic hormone (ACTH) stimulation test for adrenal abnormalities. Exogenous corticosteroid therapy will interfere with ACTH test but does not interfere with GnRH test of pituitary–gonadal axis.

Imaging

- Bone age x-ray of left hand and wrist: if advanced, further studies, guided by history and physical examination, warranted. If not advanced, or if only early breast or pubic hair development (but not both), premature thelarche or premature adrenarche, respectively, most likely diagnoses.
- MRI of head: In the absence of specific clues to CNS disease, the probability of an intracranial abnormality depends primarily on age of onset of puberty, rate of progression, and the sex of the child. MRI is

almost always done in boys because they are less likely than girls to have idiopathic precocious puberty.

- Ultrasound of gonads/adrenals: as indicated by examination and studies. Evaluates for tumors in both sexes; in girls, ultrasound can also evaluate ovarian/uterine maturity.

ALERT

- Obese children often have advanced bone ages.
- Palpation of breast tissue (buds) can be difficult due to adiposity.

DIFFERENTIAL DIAGNOSIS

- Causes of central precocious puberty:
 - Often idiopathic (girls >> boys)
 - Any cause of peripheral precocious puberty
 - CNS tumors
 - Hypothalamic hamartoma: most common CNS mass causing precocious puberty; benign (nonprogressive) congenital malformation of GnRH-secreting neurons
 - Hypothalamic–chiasmatic glioma: often associated with neurofibromatosis
 - Astrocytoma
 - Ependymoma
 - Post-CNS trauma or damage
 - Surgery
 - Radiation: may occur after 18-Gy exposure
 - Hydrocephalus/other CNS malformations
 - Infections: brain abscess, meningitis, encephalitis, granuloma. Lesions may result in stimulation or lack of inhibition of GnRH-secreting area of the hypothalamus, resulting in early pituitary activation.
- Mimickers of central precocious puberty:
 - hCG-secreting tumors (pineal gland or liver): Ectopic hCG activates testicular LH receptors.
 - Severe, acquired hypothyroidism: Elevated TSH may cross-stimulate gonadal FSH and/or LH receptors.
- Causes of peripheral sex hormone effects:

- Tumors (gonadal and adrenal)
- Environmental: exogenous estrogens (creams and oral forms) and/or exogenous androgens (anabolic steroids or testosterone formulations)
- Congenital adrenal hyperplasia: Poorly controlled congenital adrenal hyperplasia can activate the hypothalamic–pituitary–gonadal axis in either gender.
- McCune-Albright syndrome: triad of precocious puberty, café au lait spots, and polyostotic fibrous dysplasia
- Familial male precocious puberty (testotoxicosis)
- Refeeding after severe malnutrition during early development (such as adopted children who had kwashiorkor)
- Incomplete pubertal development
 - Premature thelarche
 - Premature adrenarche
 - Premature menarche

TREATMENT

MEDICATION

- Central precocious puberty: GnRH agonists are the treatment of choice. Adjunctive therapy with growth hormone may be needed to optimize final adult height.
- Calcium supplementation may assist bone mass accretion during GnRH agonist therapy.
- Peripheral sex hormone effects: aromatase inhibitors and antiandrogens (spironolactone or ketoconazole), glucocorticoids for congenital adrenal hyperplasia

ONGOING CARE

- When to expect improvement:
 - Depends on cause. For example, sexual changes of McCune-Albright syndrome are due to autonomously functioning ovarian

cysts, which regress variably over time.

- Treatment of central precocious puberty with a GnRH agonist usually results in cessation of menses within 2 months, slowing or nonprogression of pubertal changes over 4–6 months, and decreased rate of bone age acceleration within 12 months.
- Typically, GnRH agonists such as leuprolide (Lupron) are administered in a depot form every 28 days. Some children require shortening of the interval, often prompted by incomplete pubertal suppression. A longer acting formulation of leuprolide is sometimes used as an every 3-month injection. A 12-month duration implantable formulation (histrelin) is also available.
- The length of treatment is highly individualized but typically continues until the age of normal pubertal onset.

PROGNOSIS

- With treatment, improvement in predicted height may be achieved. Earlier treatment results in improved final height, but most children do not reach target height predicted by mid-parental height measurements.
- Treatment may decrease psychosocial distress.
- Long-term effects of central precocious puberty and GnRH agonists on fertility have not been fully elucidated.

COMPLICATIONS

- Short stature
- Psychosocial stresses of early puberty

- Oostdijk W, Rikken B, Schreuder S, et al. Final height in central precocious puberty after long term treatment with a slow release GnRH agonist. *Arch Dis Child.* 1996;75(4):292–297.

CODES

ICD10

- E30.1 Precocious puberty
- E22.8 Other hyperfunction of pituitary gland
- E30.8 Other disorders of puberty

FAQ

- Q: If my child is treated with a GnRH agonist, will he or she go through puberty when we stop the medication?
- A: Yes. Children on GnRH agonist treatment proceed through normal puberty when the medication is stopped. Effects on fertility have not been fully studied long-term.
- Q: If my child already has some pubertal changes, can they be reversed?
- A: If GnRH agonists are used, menses will cease and breast tissue and pubic hair will often partially or completely regress.

PREMATURE ADRENARCHE

Jennifer C. Kelley • Andrew C. Calabria

BASICS

DESCRIPTION

- Appearance of pubic hair younger than age 8 years in girls and age 9 years in boys
- Recent data suggest that the age of normal sexual development onset in girls is younger than previously recognized, but lowering of the traditionally accepted limits remains subject to debate.
- Axillary hair, acne, and apocrine sweat gland secretion are not always present with premature adrenarche.
- No other signs of sexual development are exhibited. Presence of breast development in girls or testicular enlargement in boys suggests precocious puberty and not premature adrenarche.
- Occurs independently of hypothalamic–pituitary–gonadal axis activation

Genetics

Often sporadic. Familial patterns suggesting recessive and dominant inheritance have been described.

PATHOPHYSIOLOGY

- Concentrations of adrenal steroids such as dehydroepiandrosterone (DHEA) and dehydroepiandrosterone-sulfate (DHEA-S) increase earlier than typically seen in normal puberty.
- Adrenal zona reticularis normally begins to increase androgen secretion at age 7–8 years.

DIAGNOSIS

HISTORY

- Careful attention to presence of any other signs of sexual precocity as well as rate of progression

- Family history of pubertal development, infertility, irregular menses, hirsutism, polycystic ovarian syndrome, and premature male-pattern balding
- Birth weight that is small for gestational age (SGA) may predispose children to development of premature adrenarche.
- Obesity has been associated with an increased incidence of premature adrenarche.
- Girls with premature adrenarche are at increased risk for the development of polycystic ovarian syndrome.

PHYSICAL EXAM

- Linear growth velocity may be increased.
- The presence of pigmented, curly hairs in the pubic area is consistent with androgenic effect from adrenal steroids.
- In girls, clitoromegaly suggests congenital adrenal hyperplasia or androgen-secreting tumors.
- The finding of acanthosis nigricans suggests that insulin resistance and the risk of developing ovarian hyperandrogenism (polycystic ovarian syndrome) are present.

ALERT

Be careful to differentiate between true pubic hair (curly and short) and dark lanugo hair (straight, long, fine). An extra light source may be helpful.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- If predominantly androgenic effects are present, the most useful initial tests are as follows:
 - Total testosterone by pediatric assay
 - Adrenal steroids including 17-hydroxyprogesterone (17-OHP) to evaluate for late-onset congenital adrenal hyperplasia and DHEA-S to exclude or confirm adrenarche
 - Pediatric luteinizing hormone (LH), also listed as immunochemiluminometric (ICMA), electrochemiluminescent (ECL), or ultrasensitive, to evaluate for central puberty
- Adrenal steroids are often elevated for chronologic age but normal for

pubertal stage (usually Tanner 2 or 3). However, testosterone and 17-OHP should be in prepubertal range.

- Additional hormone measurements are often lower yield. These include hormones to evaluate for estrogenic effects (e.g., estradiol) when these effects (e.g., thelarche) are not present, adult LH or testosterone assays, and free testosterone levels (more helpful in adolescent girls with testosterone levels above 30 ng/dL and with concerns for hyperandrogenism/polycystic ovarian syndrome [PCOS]). Other adrenal steroids, such as 17-hydroxypregnenolone and DHEA, are typically less useful as 1st-line tests.
- Gonadotropin-releasing hormone (leuprolide) stimulation test: not routinely recommended but would have a normal prepubertal response
- Children with systemic signs of virilization (such as a significantly advanced bone age) or elevated adrenal steroids (17-OHP) should have adrenocorticotrophic hormone (ACTH) stimulation testing to exclude congenital adrenal hyperplasia and other hyperandrogenic syndromes.

Imaging

- Bone age may be advanced by 1–2 years but correlates with height age.
- Abdominal ultrasound, CT scan, or MRI should be considered if signs of significant virilization are present or if rapid progression has occurred; look for intracranial or intra-abdominal masses, especially if androgens are markedly elevated.

DIFFERENTIAL DIAGNOSIS

- For infants with isolated pubic hair: idiopathic pubic hair of infancy
- Congenital: late-onset (nonclassic) congenital adrenal hyperplasia
- Tumors: Androgen-secreting tumors can arise in the gonads or adrenal glands.
- Miscellaneous:
 - Central precocious puberty
 - Familial male precocious puberty (testotoxicosis)
 - Exogenous male hormone exposure

TREATMENT

GENERAL MEASURES

- No treatment
- Reassure parents and children that this is a benign process.
- Reassess every 6 months to look for signs of virilization and pubertal progression.

ONGOING CARE

- Regression does not occur.
- Watch for other signs of puberty, such as breast development, testicular enlargement (≥ 4 mL), or growth acceleration, that suggest onset of true precocious puberty.
- Increasing virilization suggests nonclassic congenital adrenal hyperplasia or early polycystic ovarian syndrome.
- Acanthosis nigricans or signs of insulin resistance have been reported in girls with a history of premature adrenarche.
- Monitor for glucose intolerance or early type 2 diabetes. Fasting glucose and insulin levels or oral glucose tolerance test may be checked if suspicion is high (e.g., obesity, acanthosis nigricans, polyuria, polydipsia).

PROGNOSIS

- Undergo puberty appropriately with normal fertility
- Development of ovarian or adrenal hyperandrogenism during adolescence (also known as “polycystic ovarian syndrome”) is more common in some girls with a history of premature adrenarche. Insulin resistance, a common finding in ovarian hyperandrogenism, has been reported in some children and adolescents with a history of premature adrenarche.
- Final adult height is not affected.

COMPLICATIONS

- Can be the first sign of true precocious puberty (i.e., development of breast tissue and advancement of bone age) and thus warrants careful observation
- Boys with premature adrenarche and precocious puberty are more

likely than girls to have an underlying CNS disorder.

CODES

ICD10

E27.0 Other adrenocortical overactivity

FAQ

- Q: Is there a dietary cause of excess adrenal hormones?
- A: No.
- Q: Does premature adrenarche mean puberty will be early?
- A: The onset of puberty in these children is within the normal range and should follow the familial pattern.
- Q: Can anything be done to reverse the changes?
- A: This is a benign process that does not require treatment. Antiandrogen drugs are available but are not recommended. Girls are at increased risk for the development of polycystic ovarian syndrome, but most children do not have long-term sequelae of premature adrenarche.

PREMATURE THELARCHE

Patricia Vuguin

BASICS

DESCRIPTION

- Breast development in girls <8 years of age without evidence of sexual hair development, vaginal mucosa estrogenization, linear growth acceleration, rapid bone maturation, adult body odor, or behavioral changes
- Exaggerated thelarche, a variant of isolated breast development, occurs without axillary or pubic hair, but with some acceleration of growth and bone maturation, and increased uterine size.
- Data suggests that African American girls may develop pubertal changes as early as 6 years of age and Caucasian girls as early as 7 years of age. However, caution should be used when evaluating children because signs of puberty at these younger ages may not be considered normal and may be due to pathologic conditions.

EPIDEMIOLOGY

- 60–85% of cases are noted between 6 months and 2 years of age.
- There is no one identifiable group of girls who develops early thelarche.
- Note: Breast enlargement in a male infant or young (prepubertal) boy should be concerning.

PATHOPHYSIOLOGY

- Transient increases in follicle-stimulating hormone levels causing follicular ovarian development
- Low levels of estrogen secretion by normal follicular cysts
- Increased sensitivity of breast tissue to low levels of estrogen
- Delay in inhibition of the “minipuberty” of infancy
- Exposure to exogenous estrogen (e.g., cosmetic and hair products, infant formulas containing soy, and xenoestrogens)

DIAGNOSIS

HISTORY

- Careful assessment of onset and progression of breast tissue
- Careful assessment of growth (growth velocity changes in height percentiles)
- Family history of early puberty and or early menses
- Exogenous exposure to estrogens (foods, creams, etc)

PHYSICAL EXAM

- Palpate carefully to distinguish fat from true breast tissue.
- Areolar hyperpigmentation and/or enlargement is usually not present.
- Galactorrhea is not present.
- Look carefully for other signs of puberty:
 - Menstrual blood
 - Dull, gray-pink, or rugose vaginal mucosa (vs. prepubertal appearance: shiny, bright red, and smooth)
 - Pubic or axillary hair or any other sign of androgen excess
- Inspect skin for birthmarks suggestive of McCune–Albright syndrome (café au lait spots in a coast of Maine pattern).
- Evaluate height and assess growth velocity.
- Evaluate for signs of hypothyroidism: goiter, short stature.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No test is specific.
- Serum follicle-stimulating hormone, inhibin B, and estradiol may be slightly higher than age-matched controls but are not consistently elevated.
- In isolated premature thelarche, serum ultrasensitive luteinizing hormone level is prepubertal.

Imaging

- Bone age is not significantly or is very mildly advanced (<1 year ahead of chronologic age).
 - Bone age estimates the extent of estrogenic stimulation because

- estrogen promotes bone maturation.
- Advanced bone age implies significant estrogen effect, suggesting the need for evaluation of true precocious puberty.
- Exception: Prepubertal obese girls often have advanced skeletal maturation.
- Pelvic ultrasonography
 - May demonstrate presence and regression of small ovarian cysts (1–15 mm) and a prepubertal-size uterus

DIFFERENTIAL DIAGNOSIS

- Tumors: benign lipomas
- Congenital
 - Neonatal breast hyperplasia in newborn boys or girls that appears shortly after birth and is caused by gestational hormones
 - This form of breast development is normal and usually regresses.
- Severe acquired hypothyroidism
 - High levels of thyroid-stimulating hormone may cross-stimulate gonadal follicle-stimulating hormone and/or luteinizing hormone receptors.
- Gonadotropin-independent estrogen production
 - McCune–Albright syndrome: triad of precocious puberty, café au lait spots, and polyostotic fibrous dysplasia due to gain of function mutations of G proteins
 - Ovarian or adrenal tumors
- True precocious puberty

ALERT

- Must distinguish fat from breast tissue in obese girls
- Caution should be used when evaluating 6–7-year-old girls because signs of puberty at these younger ages may not be considered normal.
- It is a concern if a male infant outside of the newborn period or a young prepubertal boy shows breast enlargement.
- Removal of a breast bud will result in failure of that breast to develop during adolescence.

TREATMENT

GENERAL MEASURES

- Observation
- Reassurance for benign processes

ONGOING CARE

- Regression often occurs by 2 years but may occur up to 6 years after onset.
- No specific characteristics that can assist with prediction of which girls with premature thelarche will go on to have precocious puberty.
- Evidence of pubertal progression should prompt additional evaluation by an endocrinologist:
 - Rapid increase in size of breast tissue
 - Growth acceleration
 - Development of other secondary sexual characteristics
 - Vaginal bleeding

PROGNOSIS

- No known effects on growth, timing of menarche, fertility, or increase risk of breast cancer.
- Onset after age 2 years may be associated with increased risk of progression to precocious puberty.

COMPLICATIONS

May be the first sign of true precocious puberty or may be associated with other pathologies (e.g., tumors, hypothyroidism, and McCune-Albright syndrome)

PATIENT EDUCATION

- Many newborn male and female infants have breast buds as a result of exposure to maternal estrogen in utero; this resolves quickly.
- Asymmetric breast development is quite common in the early stages of pubertal development.
- Malignant tumors of the breast during childhood are extremely rare.
- Any removal of breast tissue prior to or during puberty must be

avoided.

CODES

ICD10

E30.8 Other disorders of puberty

FAQ

- Q: Does premature thelarche predispose the child to later abnormalities in pubertal development?
- A: If onset occurs after age 2 years, the girl may be more likely to enter puberty earlier. However, most girls with premature thelarche will have normal pubertal development and fertility.

PREMENSTRUAL SYNDROME

Ann B. Bruner

BASICS

DESCRIPTION

- Premenstrual syndrome (PMS), also called luteal phase disorder, is characterized by psychological and physical symptoms that occur cyclically and consistently during the second half of the menstrual cycle, which negatively impact usual activities of daily living and remit after the onset of menstruation.
- PMS is diagnosed through prospective symptom charting with symptoms present beginning at approximately day 13 of the cycle and resolving within 4 days of menses for 2 consecutive cycles.
 - At least 1 of the following symptoms must occur within 5 days of menses onset: breast tenderness, bloating/weight gain, headache, swelling of hands/feet, aches/pains, mood symptoms (depression, anger, irritability, anxiety, social withdrawal), poor concentration, sleep disturbance, or change in appetite.
- Premenstrual dysphoric disorder (PMDD) is the extreme variant of PMS; defined in DSM-5 as severe psychological symptoms causing significant dysfunctions in activity, which are not an exacerbation of symptoms of a chronic condition; have occurred in most cycles in the previous year; and are confirmed through prospective daily ratings of at least 2 symptomatic cycles
- Criteria for PMDD: at least 5 symptoms among the following, present in the final week before menses, and improving within a few days of onset of menses, with at least 1 of the symptoms being among the first 4:
 - Depressed mood: feeling sad, hopeless, or self-deprecating
 - Anxiety or tension: feeling tense, anxious, or “on edge”
 - Affective lability: fluctuating emotions interspersed with frequent tearfulness
 - Irritability or anger: increased interpersonal conflicts

- Decreased interest in usual activities, which may be associated with withdrawal from social relationships
- Difficulty concentrating
- Feeling fatigued, lethargic, or lacking in energy
- Marked changes in appetite, which may be associated with binge eating or craving certain foods
- Hypersomnia or insomnia
- A subjective feeling of being overwhelmed or out of control
- Physical symptoms such as breast tenderness/swelling, headaches, bloating or weight gain, arthralgias, or myalgias

EPIDEMIOLOGY

Prevalence

- Up to 75% of women experience some PMS symptoms at some time.
- Clinically significant PMS occurs in 3–8% of women.
- 2% of women have symptoms that interfere with their usual activities (PMDD).
- 14–88% of adolescent girls have moderate to severe PMS; one study demonstrated a 5.8% prevalence of PMDD in young women ages 14–24 years.

RISK FACTORS

- Age
 - More severe symptoms of PMDD may be seen in younger women.
- Culture
 - PMS/PMDD appear to be more prevalent in Western cultures, possibly due to differences in socialization and symptom expectations.
- Stress
 - PMS and PMDD may be associated with high levels of day-to-day stress and/or a history of stressful events, including sexual abuse.

Genetics

Genetic factors may play a role in the development of PMS/PMDD: Twin studies show a 93% concordance rate in monozygotic twins, with only a 44% rate in dizygotic twins.

PATHOPHYSIOLOGY

- Occurrence of symptoms is related to ovarian function/ovulation:
 - PMS does not occur before menarche, during pregnancy, or after menopause.
 - PMS can occur after hysterectomy but not after bilateral oophorectomy.
 - Symptoms not observed during anovulatory cycles
- Research suggests altered cyclic interactions between sex hormones (particularly progesterone produced by corpus luteum), prostaglandins, and neurotransmitters including serotonin, γ -aminobutyric acid (GABA), and endogenous opioids.
- Women with PMS do not have abnormal serum concentrations of estrogen or progesterone or hormonal imbalance; women with PMS seem to have abnormal responses to normal variations in sex hormones.

ETIOLOGY

Etiology unknown but presumed to be multifactorial

DIAGNOSIS

HISTORY

- Many women report that their PMS symptoms are not taken seriously.
- Complete medical history, including use of medications or illicit substances, cigarettes, dietary evaluation
- Gynecologic history: age at onset of pubertal development, menstrual pattern, sexual activity, contraceptive use, dysmenorrhea
- Psychiatric history: mental health disorders, medications
- Family history: mental health and substance use/abuse
- Psychosocial history: living situation, school/vocational activities and goals, hobbies, peers
- Complete review of systems including both physical symptoms (fatigue, breast tenderness/swelling, bloating, edema, weight gain, headache, arthralgias, myalgias, pelvic discomfort, changes in bowel habit, reduced coordination) and emotional/psychological symptoms

(depression, mood lability, irritability, tension, anxiety, tearfulness, restlessness, reduced concentration, fatigue, altered libido, altered appetite/eating habits, altered sleep)

- Chronologic review to determine if symptoms are recurrent with most menstrual cycles, isolated to luteal phase of cycle, and remit with onset of menses

PHYSICAL EXAM

- There are no specific physical findings of PMS.
- Enlarged thyroid gland: may suggest hypothyroidism and need to evaluate for thyroid disease
- Virilization (hirsutism, clitoromegaly): may suggest hyperandrogenism and need to evaluate for adrenal disease, including Cushing syndrome, or other hormonal disorders such as polycystic ovarian syndrome
- Pallor: may suggest anemia
- Orthostatic hypotension: may suggest neurally mediated hypotension

DIAGNOSTIC TESTS & INTERPRETATION

Premenstrual Assessment Form (PAF), Prospective Record of the Impact and Severity of Menstruation (PRISM), or Calendar of Premenstrual Experiences (COPE): Prospective symptom calendars can help establish diagnosis and provide information about symptom patterns (recurrence and relation to menses). Differences in symptom severity between the follicular and luteal phases (before and after ovulation) may be most diagnostic.

Lab

- CBC: Rule out anemia.
- Thyroid-stimulating hormone (TSH) assay: Rule out thyroid disease.

DIFFERENTIAL DIAGNOSIS

- Psychiatric
 - Mood disorder, including major depression, dysthymia, bipolar disorder, postpartum depression, anxiety disorder
 - Substance abuse
 - Physical, sexual, or emotional abuse
 - Somatization disorder

- Eating disorder
- Endocrinologic
 - Thyroid disease
 - Cushing disease
 - Diabetes mellitus
- Gynecologic
 - Dysmenorrhea (primary or secondary)
 - Pregnancy
 - Endometriosis
 - Hormonal contraceptive use
 - Perimenopause
- Immunologic/hematologic
 - Anemia
 - Fibromyalgia
 - Systemic lupus erythematosus (SLE)
 - Chronic fatigue syndrome
- Neurologic
 - Migraine headache
 - Neurally mediated hypotension

TREATMENT

GENERAL MEASURES

- Treatment goals include reducing both symptom frequency and severity and the impact of symptoms on patients' activities.
- Patient education, counseling, and reassurance may be all that is needed for women with milder symptoms.
- Many pharmacologic and nonpharmacologic modalities have not been formally evaluated.

Diet

- Research supports reducing caffeine and alcohol intake and suggests that reductions in salt and refined sugars may also be beneficial.
- Meta-analyses of research to date have shown that some supplements are beneficial in reducing symptom frequency and severity, including

calcium carbonate (1,200 mg/day), pyridoxine/vitamin B₆ (50 mg/day), and possibly magnesium (400 mg/day).

- Many herbal therapies are in use, including evening primrose oil, chaste berry, black cohosh, ginkgo, and St. John's wort. However, there is no strong evidence to support their use in PMS.

Activity

- Increasing physical activity, ensuring adequate and regular sleep, and maintaining a healthy diet are important first steps.
- Mind/body therapies are frequently used including individual psychotherapy, relaxation techniques, guided imagery, yoga, massage, biofeedback, and group therapy; to date, there is no strong evidence to support their use in PMS.

MEDICATION

First Line

- Many menstrually associated symptoms can be managed with nonsteroidal anti-inflammatory drugs (NSAIDs).
- NSAIDs (e.g., naproxen sodium 275–550 mg b.i.d.) relieve the majority of physical symptoms: premenstrual/menstrual cramping, headaches, and myalgias/arthralgias.
- Side effects include gastrointestinal upset and renal dysfunction.

Second Line

SSRIs are first line for PMDD and severe PMS, especially those with predominantly psychological symptoms. SSRIs have been shown to improve mood, decrease irritability, ameliorate physical symptoms such as bloating and breast tenderness, and improve psychosocial function.

Continuous and intermittent (during luteal phase) dosing can be used, and symptom amelioration can occur during the first cycle of treatment.

Intermittent use includes administration during the last 14 days of the menstrual cycle or treatment begun at expected date of symptom onset:

- Fluoxetine (20–60 mg/24 h), sertraline (50–150 mg/24 h), paroxetine (10–30 mg/24 h), and citalopram (5–20 mg/24 h) are some of the most commonly used SSRIs for PMS/PMDD; side effects include gastrointestinal upset, insomnia, tremor/agitation, fatigue, dry mouth, and sexual dysfunction. SSRIs recently received a U.S. FDA black box

warning concerning an increased risk of suicidality among depressed children and adolescents; the warning was for the treatment of depression, not PMS/PMDD.

- Hormonal contraceptives (i.e., low-dose oral contraceptive pills, contraceptive patch) suppress ovulation; formulations with drospirenone may be more effective against hormonally mediated symptoms such as breast swelling/tenderness and bloating.
- Spironolactone (50 mg b.i.d.) is effective for breast tenderness and bloating; potassium levels must be monitored, and spironolactone is contraindicated in patients with abnormal renal function.
- Calcium carbonate 500–600 mg b.i.d. has been shown to decrease PMS symptoms.

ONGOING CARE

- Frequent follow-up and the use of a prospective menstrual/symptom calendar are important.
- After the diagnosis of PMS is established, and after recommending appropriate lifestyle changes (and possibly NSAIDs), the patient should be reevaluated after 3 months. If there has not been substantial improvement, secondary pharmacologic therapies (SSRIs) may need to be considered. When SSRIs are prescribed as 1st-line therapy for patients with more severe PMS or PMDD, response to SSRIs and any adverse reactions should be assessed at follow-up and dosage adjusted as needed.

ISSUES FOR REFERRAL

A gynecologist/reproductive endocrinologist can assist in the management of severe PMS/PMDD: Other pharmacologic agents that are used include gonadotropin-releasing hormone (GnRH) analogues, danazol, estrogen implants, and androgens.

COMPLICATIONS

Psychological morbidity includes difficulty with interpersonal relationships (family and friends) and school absence/failure.

CODES

ICD10

N94.3 Premenstrual tension syndrome

FAQ

- Q: Can adolescent girls have PMS and PMDD?
- A: The incidence of PMS and PMDD in adolescents is not well established. Although $\leq 50\%$ of cycles are anovulatory during the first

1–2 years after menarche, younger patients experience many PMS symptoms, and menstrual problems are some of the most common reasons for school absence. Most experts believe that PMS/PMDD will not develop until a regular ovulatory pattern is established, ~2–3 years after menarche.

- Q: Is family history important?
- A: Genetic factors may play a role in the development of PMS/PMDD; twin studies show a 93% concordance rate in monozygotic twins, with only a 44% rate in dizygotic twins.
- Q: Are there any common comorbidities?
- A: The symptoms of PMS/PMDD are also seen with depression, anxiety, and other mood disorders. Psychiatric symptomatology can fluctuate, and symptoms may change in relation to the menstrual cycle. Careful and thorough history taking and prospective symptom diaries can help differentiate PMS/PMDD from another mental health disorder.

PRIMARY ADRENAL INSUFFICIENCY

Jennifer M. Barker

BASICS

DESCRIPTION

Deficiency in the secretion of cortisol and/or aldosterone by the adrenal glands

EPIDEMIOLOGY

- Age
 - Adrenal insufficiency associated with congenital adrenal hyperplasia (CAH) presents in the newborn period.
 - Adrenal hypoplasia congenita presents in infancy or early childhood.
 - Adrenocorticotrophic hormone (ACTH) unresponsiveness presents in late infancy or the toddler period.
 - Adrenoleukodystrophy typically presents late in the 1st decade of life with neurologic symptoms. Signs and symptoms of adrenal insufficiency in persons with adrenoleukodystrophy may first present at any age.
 - Addison disease is rare in children and usually presents between the ages of 20 and 50 years. In the pediatric population, it is most often seen in late childhood and adolescence.
- Sex
 - CAH and ACTH unresponsiveness affect both sexes equally.
 - Adrenal hypoplasia congenita, an X-linked disorder, predominantly affects boys
 - Adrenoleukodystrophy, an X-linked disorder, predominantly affects boys.
 - Addison disease is more common in girls.

RISK FACTORS

Genetics

- CAH: autosomal recessive inheritance associated with a gene defect in

1 of multiple adrenal steroidogenic enzymes, most commonly CYP21A2 for the 21-hydroxylase gene

- Adrenal hypoplasia congenita: X-linked mutation in DAX1 gene
- ACTH unresponsiveness: autosomal recessive ACTH receptor defect
- Adrenoleukodystrophy
 - X-linked recessive disorder of very-long-chain fatty acid metabolism due to ABCD1 gene mutation
 - An autosomal recessive form of the disease exists, with presentation during infancy.
- Addison disease
 - Autoimmune adrenal insufficiency may be isolated or part of autoimmune polyglandular syndrome (APS) type 1 or 2. Mutations in the AIRE1 gene have been identified as the cause of APS type 1. An association exists between idiopathic Addison disease and human leukocyte antigen (HLA)-B8 and DR3.

PATHOPHYSIOLOGY

- CAH: a group of enzymatic disorders of steroid metabolism, of which 21-hydroxylase deficiency is the most common (Appendix, [Table 13](#))
- Adrenal hypoplasia congenita: a defect in adrenal organogenesis
- ACTH unresponsiveness
 - Inherited defect in the ACTH receptor, resulting in isolated glucocorticoid deficiency with hypoglycemia in infancy and hyperpigmentation
- Adrenoleukodystrophy
 - Inherited disorders of impaired peroxisomal degradation of very-long-chain fatty acids, resulting in adrenal insufficiency and progressive neurologic deterioration
- Addison disease
 - Primary hypoadrenalism due to bilateral destruction of the adrenal cortices; this can be due to autoimmune destruction (isolated or associated with APS), tuberculosis, hemorrhage, fungal infection, neoplastic infiltration, or AIDS.
- Waterhouse-Friderichsen syndrome: bilateral adrenal gland hemorrhage classically associated with fulminant meningococcemia but also reported with *Staphylococcus aureus* and *Streptococcus*

pneumoniae

COMMONLY ASSOCIATED CONDITIONS

- Deficiencies of other hormones, including aldosterone and adrenal sex steroids
- Adrenal hypoplasia congenita is associated with hypogonadotropic hypogonadism.
- APSs are associated with other autoimmune disorders:
 - APS type 1: mucocutaneous candidiasis, hypoparathyroidism
 - APS type 2: autoimmune thyroid disease, type 1 diabetes
 - Both types can also present in conjunction with multiple other autoimmune disorders (e.g., primary ovarian or testicular insufficiency, celiac disease, pernicious anemia, vitiligo, autoimmune hepatitis).

DIAGNOSIS

HISTORY

Symptoms of primary adrenal insufficiency are nonspecific and similar to those found in many disease processes. Symptoms may be present for years prior to diagnosis. The electrolyte picture of adrenal insufficiency can be seen in renal disorders, obstructive uropathy, and isolated aldosterone deficiency:

- Weakness and fatigue
- Anorexia, weight loss
- Headache
- Nausea, vomiting, diarrhea, abdominal pain
- Orthostatic symptoms
- Muscle or joint pains
- Emotional lability
- Salt craving
- Hyperpigmentation
- Decreased axillary or pubic hair in females due to lack of adrenal androgens
- Amenorrhea in females

- Unexplained hypoglycemia, decreasing insulin requirements and decreasing HgbA1c in patients with type 1 diabetes

PHYSICAL EXAM

- Hyperpigmentation, especially on lip borders, buccal mucosa, nipples, and over skin creases (associated with elevated ACTH)
- Weight loss
- Hypotension or orthostatic hypotension
- Evaluate for other signs of autoimmune disease (e.g., thyromegaly, vitiligo).
- Pubertal staging
- Signs of virilization in females

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Specific
 - Newborn screening (NBS) for 21-hydroxylase deficiency identifies infants with CAH prior to presentation with adrenal crisis. Abnormal NBS results require follow-up with serum 17-hydroxyprogesterone, plasma renin activity, and/or electrolytes depending on clinical scenario.
 - Random elevated ACTH with low cortisol may be sufficient to diagnose primary adrenal insufficiency.
 - Cosyntropin (Cortrosyn) stimulation test: Administer cosyntropin (synthetic ACTH) 250 mcg IV and measure cortisol at baseline, 30 and 60 minutes.
 - A normal response is a final cortisol >18 mcg/dL. An insufficient cortisol response is diagnostic of adrenal insufficiency.
 - A baseline ACTH >200 pg/mL with inadequate cortisol is seen in primary adrenal insufficiency.
 - Serum adrenal antibodies may be positive in autoimmune Addison disease.
 - Very-long-chain fatty acids are elevated in adrenoleukodystrophy.
 - Low gonadotropin and sex steroid levels suggesting hypogonadotropic hypogonadism may be seen with adrenal hypoplasia congenita.

- Adrenal steroid precursors will be elevated in CAH.
- Nonspecific
 - Electrolytes
 - Hyponatremia: result of the mineralocorticoid defect and glucocorticoid deficiency; combination of sodium loss from kidneys, and the inability to excrete a water load
 - Hyperkalemia and acidosis: chronic mineralocorticoid deficiency with the inability to excrete potassium and acid
 - Hypercalcemia: most likely a result of increased calcium absorption due to the lack of glucocorticoid effect on the gut
 - Hypoglycemia: Glucocorticoids have permissive effects on gluconeogenesis.
 - Renin levels are elevated when a mineralocorticoid deficiency is present.

DIFFERENTIAL DIAGNOSIS

- CAH
- Adrenal hypoplasia congenita
- ACTH unresponsiveness
- Adrenoleukodystrophy
- Autoimmune adrenal cortical destruction
- Infectious adrenal cortical destruction
 - Tuberculous
 - Fungal
 - HIV
- Adrenal hemorrhage
- Neoplastic adrenal infiltration

ALERT

- Differential above only covers primary forms of adrenal insufficiency; secondary/tertiary forms may also need to be considered (ACTH/CRH deficiency). For these children, evaluation for other pituitary hormone disorders often warranted (see [Panhypopituitarism](#)).
- Replacing thyroid hormone in a child with untreated adrenal insufficiency can precipitate adrenal crisis.

TREATMENT

MEDICATION

- Acute adrenal crisis
 - Hydrocortisone (HC): stress dosage of hydrocortisone: 100 mg/m² IV/IM followed by 100 mg/m²/24 h of hydrocortisone divided q4–6h. Decrease to a physiologic replacement dosage when acute illness has resolved.
 - Mineralocorticoid replacement: Florinef 0.1 mg daily when able to take PO
- Chronic adrenal insufficiency
 - Hydrocortisone 10–12 mg/m²/24 h PO divided as t.i.d. Increase the dose to 30–50 mg/m²/24 h for stress of fever, illness, or vomiting. Lower doses may sometimes be used, particularly for forms of adrenal insufficiency other than CAH.
 - For major stress (surgery, significant illness), give hydrocortisone 50–100 mg/m² IV/IM followed by 50–100 mg/m²/24 h IV divided q4–6h. IM hydrocortisone is recommended for emergency home use. In some cases, equivalent doses of prednisone or dexamethasone may be used.
 - Florinef 0.1 mg PO daily
 - May require sodium supplementation (especially infants)

INPATIENT CONSIDERATIONS

Initial Stabilization

- Acute adrenal crisis
 - An intercurrent illness or surgical procedure may provoke an episode of hypotension, tachycardia, and shock.
 - Electrolytes reveal decreased serum sodium, elevated potassium, metabolic acidosis, and a decreased or normal glucose.
 - Serum should be drawn and saved to aid in diagnosis, but emergent treatment should not be delayed for a diagnostic ACTH stimulation test.
- Treatment
 - 5% dextrose in normal saline solution (D5NS) for volume repletion

- and treatment of salt wasting and hypoglycemia
- HC or other glucocorticoid
- Mineralocorticoid replacement

IV Fluids

D5NS for volume repletion and treatment of salt wasting

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Acute adrenal crisis usually improves rapidly with the administration of fluids and glucocorticoids. Once the acute phase of illness has resolved, steroids can be resumed at physiologic replacement doses.

Patient Monitoring

- Clinical status
- Reduction in hyperpigmentation
- Electrolytes, ACTH, and renin levels
- Screen for polyautoimmune disorders.
- Growth
- Very-long-chain fatty acid levels and neurologic function in adrenoleukodystrophy
- Pubertal development

PATIENT EDUCATION

- Stress dosing
- Importance of seeking medical attention for significant illness, persistent vomiting, or the inability to take fluids by mouth
- MedicAlert bracelet

PROGNOSIS

- Long-term prognosis of isolated adrenal insufficiency is good, provided adequate hydrocortisone is administered, particularly in times of illness.
- Risk for early mortality related to inappropriately treated adrenal crisis
- Adrenoleukodystrophy carries a poor prognosis.

COMPLICATIONS

- If not diagnosed and/or treated properly, a significant physical stress such as surgery or illness may result in a life-threatening adrenal crisis.
- CAH can cause virilization/ambiguous genitalia in female infants with the disease and can cause salt-wasting crises in infants of both sexes.
- Pubertal delay or hypogonadotropic hypogonadism is seen with adrenal hypoplasia congenita due to DAX1 mutations.
- Unrecognized ACTH unresponsiveness is associated with recurrent hypoglycemia, seizures, mental retardation, and death.
- Adrenoleukodystrophy results in severe neurologic impairment and death.
- Autoimmune adrenal insufficiency is commonly associated with additional autoimmune disease that can complicate treatment

CODES

ICD10

- E27.1 Primary adrenocortical insufficiency
- Q89.1 Congenital malformations of adrenal gland
- E71.529 X-linked adrenoleukodystrophy, unspecified type

FAQ

- Q: What are the indications for stress dosing and how rapidly can the stress hydrocortisone dose be tapered?
- A: Patients will require stress dosing of hydrocortisone for surgical procedures, fever ($>37.7^{\circ}\text{C}$ [100°F]), vomiting, diarrhea, and particularly vigorous exercise. The stress dose is typically given for 24 hours, after which the usual dose is resumed. Should it be necessary to administer the stress dosage for a more prolonged period, the dosage can usually be tapered rapidly to physiologic dosage, once the patient's clinical condition has improved.

PRION DISEASES (TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES)

Jason Y. Kim

BASICS

DESCRIPTION

- Transmissible spongiform encephalopathies (TSEs) or prion diseases are a family of progressive neurodegenerative diseases of humans and animals that cause irreversible cumulative brain damage and are uniformly fatal.
 - Prions
 - The infectious agents that cause TSE
 - The term prion was coined to denote “a small proteinaceous infectious particle resistant to inactivation by most procedures that modify nucleic acids.”
 - Prion proteins (PRP)
 - Normal cellular glycoproteins (PRP^C) encoded by the PRNP gene
 - Are found on neurons and white blood cells
- The infectious particles that cause TSEs are protease-resistant conformers of PRP^C (PRP^{RES} or PRP^{SC} for protease-resistant or scrapie-causing PRPs, respectively).
- Human TSEs include Creutzfeldt-Jakob disease (CJD), the more recently identified variant CJD (vCJD), kuru, Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia syndrome.
- Six TSEs in animals have been described: bovine spongiform encephalopathy (BSE, also known as mad cow disease), scrapie in sheep and goats, feline spongiform encephalopathy, transmissible mink encephalopathy, exotic ungulate encephalopathy, and chronic wasting disease of cervids.

EPIDEMIOLOGY

- CJD
 - CJD is the most prevalent form of TSE in humans and occurs as

either a sporadic or a familial disease.

- ~85% of cases are sporadic because there is no family history and no known source of transmission. Sporadic CJD occurs throughout the world at a rate 1/1,000,000 people.
- Familial CJD (fCJD) cases are associated with a gene mutation in PRNP and account for ~10–15% of cases. fCJD shows an autosomal dominant inheritance, with >50 mutations in PRNP identified.
- ~1% of CJD cases are iatrogenic, resulting from accidental transmission of the causative agent via contaminated surgical equipment, as a result of cornea or dura mater transplants, or administration of human-derived pituitary growth hormones.
- No evidence confirms person-to-person transmission among family members via direct contact, droplet, or airborne spread.
- Disease is characterized by progressive dementia, myoclonus, visual or cerebellar disturbance, pyramidal/extrapyramidal dysfunction, and/or akinetic mutism.
- Classic sporadic CJD most often occurs between the ages of 50 and 70 years and affects both sexes equally; whites have about a 2-fold higher rate than blacks.
- Death usually occurs within 1 year of onset of symptoms.
- vCJD
 - New form of CJD, first reported in 1994; has unique clinical features
 - In contrast to CJD, affects younger patients including adolescents (average age, 29 years) and has a longer duration of illness with median of 14 months as opposed to 4.5 months with CJD
 - Strong epidemiologic evidence links vCJD to BSE:
 - BSE is a TSE that affects cattle; it was first reported in the United Kingdom. The most likely route of exposure is through bovine-based foods derived from BSE-infected cattle.
 - Highest incidence of vCJD is seen in the United Kingdom, the country with the largest potential exposure to BSE.
 - 3 cases of vCJD have been confirmed in the United States, although each were likely to have been contracted outside the United States.

- Clinical features, found early in the illness, include the following:
 - Prominent psychiatric symptoms (e.g., depression, schizophrenia-like psychosis) and ataxia
 - Other neurologic signs (e.g., paresthesia/dysesthesia, chorea, dystonia, myoclonus, and akinetic mutism) develop as the disease progresses.
- Recently, clinical criteria for the diagnosis of vCJD were validated in the United Kingdom by autopsy-/biopsy-proven cases compared to noncases.
- Fatal familial insomnia (FFI)
 - An autosomal dominant disorder, caused by mutation at codon 178 of PRNP, also identified in fCJD. If there are homozygous alleles at codon 129 encoding methionine in conjunction with the codon 178 mutation, FFI ensues. If codon 129 encodes valine in conjunction with the codon 178 mutation, then fCJD develops.
 - Clinical features include insomnia, dysautonomia, ataxia, myoclonus, and late dementia.
 - Pathology reveals minimal vacuolization and no plaques.
- Gerstmann-Sträussler-Scheinker syndrome
 - A disorder with autosomal dominant inheritance
 - Clinical features include ataxia and dementia.
 - Pathology reveals amyloid plaques.

PATHOPHYSIOLOGY

- TSE arises when exogenous or endogenous PRP^{RES} cause PRP^C to misfold into the abnormal protease-resistant form associated with TSE.
- Progressive accumulation of PRP^{RES} in the CNS disrupts function, leading to vacuolization and cell death. There is no host-adaptive immune response beyond microglial cell activation involved in the pathologic process.
- Neuropathologic findings include neuronal loss, atrophy, vacuolization or spongiform change, reactive astrogliosis, and cell death.
- PRP^{RES} also accumulate in the reticular endothelial system, mucosa-associated lymphoid tissues, and areas of chronic inflammation throughout the body.

ETIOLOGY

- Prions are infectious proteins lacking nucleic acids that are believed to cause TSE.
- Infection arises when normal protease-sensitive host proteins, involved in neuronal function, undergo spontaneous misfolding to yield the abnormal protease-resistant form associated with infectivity.
- Newly formed host PRP^{RES} recruit neighboring cellular PRP^C and convert it to the infectious conformer. The exact molecular and cellular mechanisms surrounding propagation of PRP^{RES} remains unknown.
- Although the presence of PRP^C is necessary for the migration of PRP^{RES} to the RES, the mechanism for migration to the CNS remains unknown.
- Prions reproduce by recruiting neighboring normal cellular PRP and stimulating its conversion to the infectious form.
- Whether PRP^{RES} reproduce without any genetic material, thus bypassing the central dogma is still hotly debated.
- Not all scientists believe the prion hypothesis, and some have argued that the causative agent is virus-like and possesses nucleic acids although none has ever been isolated from TSE pathologic specimens.

DIAGNOSIS

HISTORY

- Evidence of a familial form of TSE
- Potential iatrogenic exposures such as administration of human-derived pituitary growth hormones, implantation of dura mater or corneal grafts from humans, epilepsy surgery, or other CNS surgery involving stereotactic electrodes
- Duration of symptoms >6 months
- Afebrile illness
- In vCJD, progressive neuropsychiatric symptoms including:
 - Depression, anxiety, apathy, withdrawal, or delusions
 - Painful sensory symptoms including pain and/or dysesthesia
 - Ataxia
 - Myoclonus, chorea, or dystonia

- Dementia

PHYSICAL EXAM

- Afebrile
- Abnormal mental status exam with defects in memory, personality, and other higher cortical functions, or psychosis
- Neurologic signs include unsteady gait and the presence of involuntary movements.
- Late findings include mutism and complete immobility.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Most laboratory tests are of little value in the diagnosis of TSE. Exam of CSF fluid may reveal a mild elevation of protein, but otherwise the cerebrospinal fluid is normal.
- EEG
 - In CJD, generalized slowing is seen early in the disease with progression to periodic burst of biphasic or triphasic sharp-wave complexes.
 - In vCJD, the EEG does not show the waveforms characteristic of sporadic CJD.
 - Although EEG abnormalities are seen in most patients, these findings are not specific.

Imaging

- MRI
 - In patients with vCJD, abnormally high T2 signal in the bilateral pulvinar regions of the thalamus may be seen.
 - In CJD, hyperintense signals in the basal ganglia are often seen.
 - In later stages of CJD and vCJD, imaging studies such as MRI or CT scan reveal generalized atrophy with large ventricles.

Diagnostic Procedures/Other

- Diagnosis of TSE in humans can be confirmed only following pathologic exam of the brain.
- Microscopic exam of patients with all types of human TSEs reveals spongiform change accompanied by neuronal loss and gliosis.

- Amyloid plaques or immunohistochemical demonstration of abnormal PRP in the brain may also be seen.
- “Florid” plaques (amyloid plaques encircled by holes or vacuoles resulting in a daisy-like appearance) are consistently present in patients with vCJD.
- Tonsil biopsy revealing accumulation of PRP^{RES} may be helpful in confirming suspected cases of vCJD.

DIFFERENTIAL DIAGNOSIS

- Neurodegenerative disorders—mostly seen in older adults with the exception of Alpers disease
 - Alzheimer disease
 - Parkinson disease
 - Frontotemporal dementia
 - Pick disease
 - Alpers disease (progressive cerebral hemiatrophy)
 - Amyotrophic lateral sclerosis
 - Huntington disease
 - Spinocerebellar ataxia
- Psychiatric disorders—especially when considering vCJD as a diagnosis
 - Depression
 - Schizophrenia
 - Drug-induced psychosis
- Encephalitis, infectious
- Sydenham chorea
- Subacute sclerosing panencephalitis
- Progressive multifocal leukoencephalopathy
- Toxic encephalopathy
- Inborn errors of metabolism
- Hashimoto thyroiditis
- CNS vasculitis
- CNS tumors

TREATMENT

GENERAL MEASURES

- No treatment is effective in slowing or stopping the progression of disease. Appropriate supportive care should be provided. Prognosis for patients with human TSEs is uniformly poor.
- Several compounds and methods have undergone testing in cell-free, tissue, and animal models of TSE. Some decrease the rate of PRP^{RES} accumulation and allow animals to reach their expected lifespan. None reverses the damage seen in the CNS after plaques have formed.
- Infection control
 - Standard universal precautions are indicated for infection control.
 - Strict isolation is not necessary.
 - Caution should be used in obtaining cerebrospinal fluid and handling tissues obtained at autopsy.
 - Equipment contaminated by high-risk tissue should be soaked in ≥ 1 N sodium hydroxide solution for at least 1 hour and then autoclaved at 134°C for at least 1 hour.

- A81.00 Creutzfeldt-Jakob disease, unspecified
- A81.81 Kuru

FAQ

- Q: Is transmission of TSEs from human blood possible?
- A: There have been 3 verified cases of vCJD attributed to transfusion of blood products in the United Kingdom. There have been no cases of transfusion-related vCJD in the United States.
- Q: Is our food supply safe?
- A: No cases of BSE have been recognized in North America. The incidence in the United Kingdom has been low and is not increasing rapidly. Measures have been taken by the World Health Organization and the U.S. Food and Drug Administration (FDA) to reduce the risk of TSE, including a ban on the use of ruminant tissues in animal feed and surveillance systems to detect TSE in animals and to prevent any part or product of an animal with suspected TSE to enter the human or animal food chain. The FDA has banned biologic agents of bovine origin produced in countries at risk of BSE. There have been 3 cases of vCJD in U.S. citizens, but each case was likely contracted outside the United States (United Kingdom and Saudi Arabia).

PROBIOTICS

Andi L. Shane • Dan Merenstein

BASICS

DESCRIPTION

- Probiotics are defined by the World Health Organization as “live microorganisms, which when administered in adequate amounts, confer a health benefit to the host.”
- The presence of “live cultures” does not make a product a probiotic. The microorganism has to be present in adequate amounts to provide specified health benefit, which can vary, depending on the microorganism. The optimal dosing varies with probiotic product, indication, and host.
- Specific probiotic strains are generally regarded as safe. The Center for Food Safety and Applied Nutrition (CFSAN) provides guidelines for the manufacture of probiotic products, but clinicians must carefully evaluate the probiotic agent selected.
- Levels of evidence to support use of a probiotic depend on the formulation and indication (food, supplement, or drug) and the consumer (clinician, patient, healthy individual, and regulatory authority).
- Several formulations of probiotic products are available both in single-strain and multistrain preparations:
 - Probiotic organisms may be consumed as fermented dairy products or as supplements in the form of a capsule, tablet, liquid, or powder formulation.
- Commonly used probiotic supplements contain single organisms, including the following strains:
 - *Bifidobacterium bifidum* strain YIT 4002
 - *Lactobacillus rhamnosus* ATCC 53103
 - *Lactobacillus delbrueckii* subsp. *bulgaricus*
 - *Streptococcus salivarius* subsp. *thermophilus*
- Yeast, including *Saccharomyces boulardii*, is an alternative to bacterial

probiotic formulations.

- Multistrain probiotics incorporate a combination of organisms in varying quantities.

PATHOPHYSIOLOGY

- Probiotics are hypothesized to exert their primary effects on the gut by reestablishing the intestinal microbiota balance, competing for receptor sites in the intestinal lumen, and competing with pathogens for nutrients.
- The proposed immunomodulatory functions of probiotics include enhancing host immune defenses via strengthening tight junctions between intestinal enterocytes, increasing immunoglobulin A production, stimulating cytokine production, and producing substances (e.g., arginine, glutamine, and short-chain fatty acids) thought to secondarily act as protective nutrients.

DIAGNOSIS

- The selection of a single-strain versus a multistrain probiotic product, or a bacterial probiotic versus a yeast probiotic, should be based on the underlying indication, host factors, and whether the probiotic is administered for treatment or prophylaxis.
- The following selected probiotics have been shown to be efficacious for the treatment and/or prevention of the following gastrointestinal conditions:
- Efficacy with one probiotic strain or species does not imply that other strains will be equally efficacious. Host factors, dosing, and indication must be considered in formulating recommendations.

Probiotic	Indication
<i>L. rhamnosus</i> GG	Infectious diarrhea, especially of viral etiology
<i>S. boulardi</i>	Antibiotic-associated diarrhea
Combination therapy with lactobacilli, bifidobacteria,	<i>Clostridium difficile</i> –associated diarrhea

streptococci, *S. boulardii*

Lactobacillus reuteri DSM 17938 Colic

TREATMENT

DOSING GUIDELINES

- The unit of dosing for oral probiotic supplements is the colony-forming unit (CFU).
- Currently, there are no established dosing guidelines based on pharmacokinetic data for children.
- Studies have used oral doses of 1–10 billion CFUs per dose, with administration frequency ranging from 3 times daily to weekly.
- Practitioners have used 1/2 of the adult dose for children of average weight and 1/4 of the adult dose for infants.
- The optimal dosing regimen with respect to timing of antimicrobials and probiotic supplements is not known. Currently, available data suggest that temporal separation of probiotic and antimicrobial is not essential for efficacy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- The American Academy of Pediatrics (AAP) issued a clinical report summarizing the evidence for use of probiotics and supports their use on a case-by-case basis in children who may benefit from supplementation.
- Probiotics have been shown to be efficacious in randomized, double-blind, placebo-controlled studies for the following indications:
 - Decreasing the duration of infectious diarrheal episodes in hospitalized children, childcare attendees, and children with enteric viral infections in resource-poor areas
 - Reducing the mortality and morbidity of necrotizing enterocolitis (NEC), a devastating condition in neonates
 - Reducing antibiotic-associated diarrhea in children receiving oral

and intravenous antibiotics

- Treating and preventing pouchitis, inflammation of a surgically created distal small bowel reservoir, and irritable bowel syndrome in children and adults (multistrain probiotic)
- Reducing the risk of developing *C. difficile*–associated diarrhea and associated symptoms in children and adults when probiotics and antibiotics are coadministered.
- Probiotic applications currently being evaluated include the following:
 - Maintenance of remission in persons with ulcerative colitis
 - Treatment and prevention of atopic disease including rhinitis and asthma
 - Improving tolerance of *Helicobacter pylori* eradication therapy
 - Prevention of genitourinary infections, such as urinary tract infections and candidiasis
 - Prevention of dental caries
- Future investigations to evaluate the efficacy and safety of probiotics in large-scale, multicenter trials; to monitor the potency and composition of probiotic formulations; to develop in vitro and in vivo systems to understand the molecular mechanisms of action; and to understand the balance among infection, immunity, and probiotics are in progress.
- The selection of a probiotic for pediatric use requires an understanding of the indication, the optimal formulation (single strain vs. multistrain), delivery system, and the host.

Patient Monitoring

- Currently available probiotic formulations are viable microorganisms and therefore have the potential to cause invasive infections in hosts who may have compromised mucosal epithelia.
- Probiotics should be used with caution in children with major risk factors or multiple minor risk factors:
 - Major risk factors include immune compromise or prematurity.
 - Minor risk factors include the presence of a central venous catheter, impaired intestinal epithelial barrier, administration of a probiotic by jejunostomy, concomitant administration of a broad-spectrum antibiotic which may reduce the effectiveness of the probiotic organism, and the presence of cardiac valvular disease.

- An extremely low incidence of bacteremia has been observed with widespread use of probiotics in Finnish adults.
- To date, there have not been any adverse effects attributable to probiotic consumption in pregnant women consuming a probiotic supplement to prevent atopic dermatitis in their infants.
- HIV-infected adults taking a probiotic supplement to prevent diarrhea and improve tolerance of antiretroviral agents have not experienced adverse effects attributable to the probiotic supplement.

FAQ

- Q: What is the best way to consume probiotics?
- A: Probiotic organisms may be found in fermented foods and yogurt products. Some patients might benefit from probiotic supplements over consumption of probiotic-containing foods. Both supplements and foods may offer beneficial doses of probiotic organisms.
- Q: What is the difference between probiotics and prebiotics?
- A: Probiotic supplements contain live microorganisms, whereas

prebiotic supplements are substances that promote the growth of probiotic organisms. The most common prebiotic supplements are fructo-oligosaccharides and galacto-oligosaccharides, which are present in human milk and other naturally occurring food products.

- Q: What factors should a clinician consider when recommending use of a probiotic supplement?
- A: Dose, duration, how administered, the host, and the indication. Probiotic therapy should be considered similarly to an antibiotic regimen, tailoring the therapy and course to the individual.
- Q: What is the standard dose for a probiotic supplement?
- A: There are no uniform dosing recommendations for probiotics. The optimal dose depends on the indication, the host, and the species and strain of the probiotic being used. Many probiotic products include suggested dosing on their packages.

PROTEIN-ENERGY MALNUTRITION

Robert D. Karch

BASICS

DESCRIPTION

- The World Health Organization (WHO) defines malnutrition as “the cellular imbalance between the supply of nutrients and energy and the body’s demand for them to ensure growth, maintenance, and specific functions.”
- A comprehensive definition of pediatric malnutrition has recently been proposed, which incorporates the chronicity, etiology, and severity of malnutrition, as well as the pathogenic mechanism of nutrient imbalance, association with inflammatory state, and impact on functional outcomes such as growth, development, neurocognition, lean body mass, muscle strength, and immune function.
- This novel definition of pediatric malnutrition considers the etiology of energy, protein, and/or micronutrient imbalance as either “illness-related malnutrition” (secondary to disease/injury) or “non–illness-related malnutrition” (secondary to environmental/behavioral factors). Malnutrition may also be classified as either acute (shorter than 3 months in duration) or chronic (longer than 3 months in duration).
- The term “protein-energy malnutrition” (PEM) describes a general state of undernutrition and deficiency of multiple nutrients and energy.
- There are three clinical presentations of severe PEM: kwashiorkor, marasmus, and marasmic kwashiorkor.
 - Kwashiorkor results from relative protein deficiency in the setting of adequate energy intake and is characterized by hypoproteinemia, pitting edema, varying degrees of wasting and/or stunting, dermatosis, and fatty infiltration of the liver.
 - Marasmus results from both energy and protein deficiency and is characterized by wasting, fatigue, and apathy.
 - Marasmic kwashiorkor is caused by acute or chronic protein deficiency and chronic energy deficit and is characterized by edema,

- wasting, stunting, and mild hepatomegaly.
- The distinction between kwashiorkor and marasmus is frequently blurred, and many children present with features of both conditions.
 - Severe PEM covers a broad clinical spectrum ranging from frank kwashiorkor to severe marasmus when the body's protein and energy requirements are not adequately met.
 - Cicely Williams introduced the name “kwashiorkor” in 1935 in a classic description of her observations of the Ga tribe on the Gold Coast of Africa (currently Ghana).
 - “Kwashiorkor” in the Ga language is translated as “the disease of the deposed child (deposed from the breast) when the next baby is born.”

RISK FACTORS

- In developed nations, symptoms of kwashiorkor have been described in chronic malabsorptive conditions such as cystic fibrosis.
- In the United States, a few cases of kwashiorkor unrelated to chronic illness have been described.
- Consumption of a protein-deficient milk alternative, sugar water, or fruit juice can be due to poor caregiver knowledge about nutrition, a perceived milk or formula intolerance or adherence to food fads.
- Consumption of a low-protein health food milk alternative, such as rice milk, secondary to a history of chronic eczema and perceived milk intolerance, has occurred in the United States.

EPIDEMIOLOGY

- Malnutrition underlies 55% of childhood mortality worldwide.
- Kwashiorkor may occur at any age but is seen most frequently in children 1–3 years of age.
- Kwashiorkor is seldom seen in the 1st year of life. It is usually seen in the 2nd year or beyond, when a toddler is fully weaned or only partially breastfed and may have a low intake of dietary protein.

PATHOPHYSIOLOGY

- Temperature regulation is impaired, leading to hypothermia in a cold environment and hyperthermia in a hot environment.
- Increase in total-body sodium and decrease in total-body potassium
- Hypophosphatemia is associated with malnutrition and can result in

high mortality, especially upon refeeding.

- Protein synthesis is reduced, particularly albumin, transferrin, and apolipoprotein B. Decreased ability to transport fat leads to fatty infiltration of the liver.
- Gluconeogenesis is reduced, which increases risk of hypoglycemia during infection.
- Reduced cardiac output leads to low blood pressure, compromised tissue perfusion, and a reduction in renal blood flow and glomerular filtration rate.
- Diminished inspiratory and expiratory pressures and vital capacity
- Reduction of gastric and pancreatic secretions
- Reduced intestinal motility
- Intestinal mucosa atrophy resulting in malabsorption of carbohydrates, fats, fat- and water-soluble vitamins
- Low circulating insulin levels
- Growth hormone secretion is increased, whereas somatomedin activity is reduced.
 - Glucagon, epinephrine, and cortisol levels are increased.
 - Serum T₃ and T₄ levels are reduced.
- Immune system
 - T-cell immune function is diminished in malnutrition, thereby increasing susceptibility to infection.
 - Serum immunoglobulins are typically normal or increased, although the humoral immune system may be less protective.
 - Delayed wound healing may be seen owing to nutritional deficiencies.

ETIOLOGY

- There are two principal theories regarding the etiology of kwashiorkor: the classical theory of protein deficiency and the newer theory of free radical damage.
- Both theories emphasize different aspects of the environment: in the classical theory, nutrients, and in the free radical theory, oxidative stresses.
- The classical theory of protein deficiency was supported by Williams' original description of kwashiorkor developing in children who were

weaned onto starchy gruels after being deposed from the breast and being cured by milk.

- The free radical theory of kwashiorkor proposes that kwashiorkor results from an imbalance between the production of toxic free radicals and their safe disposal. Inadequate diet leads to a state of impaired antioxidant defense.
- The free radical theory attempts to explain the entire spectrum of clinical findings in kwashiorkor by implicating a wide range of nutritional deficiencies, as well as environmental oxidative stressors (noxae):
 - Important noxae include infections and exogenous toxins such as aflatoxin and its metabolites.
 - Aflatoxin, from the fungus *Aspergillus flavus*, has been found in greater concentrations in the serum and urine of children with kwashiorkor than in controls.
 - There is a hierarchy of causes of PEM operating at different levels and interacting with one another; from food scarcity, infection, malabsorption, and neglect, to poverty and social disadvantage, to drought, war, or civil disturbance.
- The multiplicity of causes of PEM necessitates a multidisciplinary approach to its treatment and prevention.

DIAGNOSIS

HISTORY

- Dietary history:
 - Diet before current illness episode
 - Adequacy of protein and total calories
 - Food and fluids taken in past few days
 - Assess whether parents and children adhere to special diets or whether health food milk alternatives, such as rice milk, are given.
- Determine duration and frequency of emesis or diarrhea.
- Loose stools with evidence of malabsorption are common. Stools may be watery and/or tinged with blood.
- Any death of siblings

- Cultural beliefs and practices regarding infant and childhood feeding
- Growth records: Decreased growth velocity commensurate with poor protein intake.

PHYSICAL EXAM

- Weight and length/height
 - Growth failure always occurs to some extent.
 - Wasting is also typical, although it may be masked by the presence of edema.
- Midarm muscle circumference (MAMC) can be used as an indicator of lean body mass and is a useful screening tool in mass settings.
- Triceps skinfold thickness (TSF) can be used to monitor changes in body fat and provides a useful estimate of energy stores.
- Hypothermia or hyperthermia
- General appearance
 - Affected child is usually apathetic and irritable.
 - Child is usually unsmiling and prefers to remain in one position.
- There is some degree of edema in all cases of kwashiorkor:
 - Peripheral edema usually begins in the feet and ascends up the legs.
 - Pitting of the skin above the ankle is diagnostic.
 - The hands and face may become edematous.
 - Facial edema gives the characteristic “moon facies.”
 - Hair lacks luster, and color may change to brown or reddish-brown.
 - Hair is easily pluckable.
 - Bands of discolored hair, representing periods of malnutrition, are termed the “flag sign.”
 - Dermatitis often develops in areas of friction or pressure.
 - Hypo- or hyperpigmented patches may appear, which subsequently desquamate in scales or sheets, exposing atrophic ulcers resembling burns.
- Additional clinical signs of PEM:
 - Signs of B-vitamin deficiency, such as perioral lesions
 - Signs of vitamin A deficiency, such as xerosis and/or xerophthalmia
 - Pale, cold, and cyanotic extremities: decreased vascular volume secondary to decreased protein concentration
 - Abdomen is frequently protuberant secondary to poor peristalsis,

- leading to distended stomach and intestinal loops.
- Respiratory: Look for signs of pneumonia or heart failure.
- Enlargement of liver and jaundice may also be seen.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum protein
- Prealbumin and serum transferrin may be useful in determining severity of kwashiorkor.
- Retinal binding protein may be reduced.
- Hemoglobin and hematocrit are usually low.
- Ratio of nonessential to essential amino acids in plasma is elevated in kwashiorkor and usually normal in marasmus.
- Increased serum elevation of free fatty acids
- Low serum and urine carnitine levels
- Stool exam to rule out infectious cause of chronic diarrhea
- Chest radiograph and PPD to rule out TB

DIFFERENTIAL DIAGNOSIS

- Nephrotic syndrome
- Hookworm anemia
 - May cause edema alone; commonly seen in association with kwashiorkor
 - It is not associated with the kwashiorkor-related dermatologic findings.
- Chronic dysentery
- Protein-losing enteropathy (PLE)
- Pellagra
 - Dermatitis of pellagra and kwashiorkor are similar; however, the dermatosis of pellagra is often seen in sun-exposed areas, not in areas such as the groin, as commonly seen in kwashiorkor.
 - Kwashiorkor dermatosis is often described as “flaky paint” dermatosis.

TREATMENT

- WHO guidelines:
 - Prevent and treat the following:
 - Hypoglycemia
 - Hypothermia
 - Dehydration
 - Electrolyte imbalances
 - Infection
 - Micronutrient deficiencies
 - Provide special feeds for the following:
 - Initial stabilization
 - Providing catch-up growth
 - Providing loving care and stimulation
 - Where guidelines have been fully implemented, mortality has been reduced by at least half.

ADDITIONAL TREATMENT

General Measures

- Whenever possible, a dehydrated child with malnutrition should be rehydrated orally or by nasogastric tube.
- IV infusion should be avoided except for when it is essential (e.g., severe dehydration and shock).
- Hypoglycemia is an important cause of death in the 1st 2 days of treatment.
- Suspected hypoglycemia should be treated with oral rehydration salts solution (ORS) or 10% glucose by mouth or nasogastric tube.
- Severely malnourished children have high levels of sodium and are deficient in potassium. Standard WHO ORS does not meet the special electrolyte requirements of the severely malnourished child.
- ReSoMal is a modified ORS that contains less sodium and more potassium than the standard WHO ORS and is the recommended ORS for severely malnourished children.

ALERT

Rapid and inappropriate refeeding of malnourished individuals may result in the refeeding syndrome, which is manifested as hypophosphatemia. Hypomagnesemia and hypokalemia may also be associated. Cardiac

dysfunction, edema, and neurologic changes, due to shifts in fluid and electrolytes following aggressive introduction of nutrients, are associated with the refeeding syndrome.

ONGOING CARE

PROGNOSIS

- Treatment corrects the acute signs of the disease, but catch-up growth in height may never be achieved.
- Mortality rate in kwashiorkor can be as high as 40%, but adequate treatment can reduce it to <10%.
- Some of the factors that indicate poor prognosis:
 - Age <6 months
 - Infections
 - Dehydration and electrolyte abnormalities
 - Persistent tachycardia, signs of heart failure
 - Total serum protein <3 g/100 mL
 - Elevated serum bilirubin
 - Severe anemia with hypoxia
 - Hypoglycemia and/or hypothermia

COMPLICATIONS

Several longitudinal studies have demonstrated associations between early childhood stunting and later cognitive function and academic attainment.

- E41 Nutritional marasmus

FAQ

- Q: What are the signs and symptoms of kwashiorkor, and how do these change over the course of the clinical spectrum of severe protein-energy malnutrition; from kwashiorkor to marasmus?
- A: Signs and symptoms of kwashiorkor:
 - Growth failure, wasting
 - Edema that is peripheral in onset and ascending
 - Hair changes including color change, “flag sign,” and easy pluckability; “flaky paint” dermatosis of skin
 - In addition to earlier signs and symptoms, child may also develop vitamin A and B deficiency, decreased peripheral circulation, and

decreased peristalsis with distended bowel loops.

Hepatomegaly/splenomegaly may also be observed. The child is at higher risk for developing other conditions such as pneumonia or congestive heart failure.

- Q: What are some common causes of severe undernutrition in the United States that may present as kwashiorkor?
- A: Chronic malabsorptive conditions (e.g., cystic fibrosis) and consumption of protein-deficient milk substitutes such as rice milk, fruit juices, etc.

PROTEINURIA

Stephanie Nguyen

BASICS

DESCRIPTION

- Protein may be found in the urine of healthy children.
- The term proteinuria is used to indicate urinary protein excretion beyond the upper limit of normal (100 mg/m²/day or 4 mg/m²/h in children and 150 mg/day in adults).
 - Nephrotic range proteinuria >1,000 mg/m²/day or 40 mg/m²/h
 - Nephrotic syndrome: nephrotic-range proteinuria with edema and hypoalbuminemia (<2.5 g/dL)
 - Microalbuminuria: elevated urinary excretion of albumin (30–300 mg/g albumin/creatinine ratio or 30–300 mg/day). Currently, it is only used to indicate kidney disease in those with diabetes mellitus.
- Classification
 - Persistent or fixed proteinuria
 - Urinary dipstick ≥1+ in the first morning urine specimen on ≥3 samples >1 week apart
 - Requires prompt referral to nephrology
 - Transient proteinuria
 - Proteinuria absent on subsequent urine examinations
 - It is not usually associated with clinically significant underlying renal disease.
 - Often associated with high fever, cold stress, dehydration, and exercise
 - Orthostatic or postural proteinuria
 - Elevated protein excretion when the patient is upright that normalizes when patient is supine
 - The most common cause of fixed or transient proteinuria in childhood and adolescence
 - Proteinuria rarely exceeds 1 g/m²/day.
 - Benign condition

PATHOPHYSIOLOGY

- Normally, ~50% urinary proteins are derived from tissue proteins and proteins from cells lining the urinary tract (i.e., Tamm-Horsfall protein).
- Proteinuria may be the result of glomerular proteinuria or tubular proteinuria.
- Glomerular proteinuria
 - An increased permeability of the glomeruli to the passage of plasma proteins
 - Normally may range from <1 to >30 mg/day
 - Large amounts of glomerular proteinuria may be found in the context of edema and hypoalbuminemia (nephrotic syndrome).
 - If there is hypertension, abnormal glomerular filtration rate, and hematuria, there may be nephritis as well.
- Tubular proteinuria
 - Decreased reabsorption of low-molecular-weight proteins by the proximal renal tubules
 - Rarely >1 g/day and is not associated with edema.
 - The major marker is urinary beta-2-microglobulin.
 - It may be associated with other defects of proximal tubular function (e.g., renal tubular acidosis [RTA], glucosuria, phosphaturia, aminoaciduria) and tubular interstitial processes.

DIAGNOSIS

The American Academy of Pediatrics (AAP) no longer recommends screening urinalysis for asymptomatic children due to high false-positive rate, low cost-effectiveness, and lack of treatable disease.

HISTORY

- **Question:** Changes in the aspect of the urine?
- Significance: Foamy or colored (red, tea-colored)
- **Question:** Recent illness?
- Significance: Pharyngitis and upper respiratory infections
- **Question:** Frequent episodes of fever?

- Significance: Lymphoma, malignancies, vasculitides
- **Question:** Medications or herbal/folk remedies?
- Significance: Toxins
- **Question:** Illicit drug use and risk factors for STD in adolescent and adults?
- Significance: HIV, syphilis, hepatitis
- **Question:** Urinary tract infection in the past?
- Significance: Reflux nephropathy
- **Question:** Family history of renal, rheumatologic diseases or hearing loss?
- **Question:** Fatigue, general malaise, reduced appetite?
- **Question:** Weight changes?
- **Question:** Facial swelling (in the morning) and lower limb swelling (in the afternoon)?
- **Question:** Symptoms related to rheumatologic conditions (skin rash, joint pain, joint stiffness)?
- **Question:** Cough, shortness of breath?

PHYSICAL EXAM

- General
 - Hypertension
 - Growth and development
- HEENT
 - Periorbital edema
 - Malar rash
- Chest
 - Pericardial or pleural effusions
- Abdomen
 - Ascites
 - Hepatosplenomegaly
 - Abdominal masses/organomegaly
- Genitalia
 - Scrotal edema
 - Ambiguous genitalia (Denys-Drash syndrome)
- Skin
 - Purpuric or petechial rash (leukemia, lymphomas)

- Pallor (malignancies, chronic renal failure, hemolytic uremic syndrome [HUS])
- Angiokeratomas (Fabry disease)
- Extremities
 - Pitting edema
 - Arthralgias/arthritis
- Dystrophic nails

DIAGNOSTIC TESTS & INTERPRETATION

- Dipstick testing
 - Always to be performed in a first morning urine sample
 - Instruct patient to urinate before bedtime and to collect urine as soon as he or she awakens and before ambulation.
 - A negative or trace result in a concentrated urine specimen (specific gravity >1.020) is normal.
 - 1+ protein may be normal in very concentrated samples (specific gravity >1.030).
- Spot urine protein and urine creatinine (urine protein/creatinine ratio):
 - Always to be performed in a first morning urine sample
 - Simplest method to quantitate proteinuria
 - Normal values
 - ▢ <0.2 mg/mg in children >2 years of age
 - ▢ <0.5 mg/mg in children 6–24 months old
- 24-hour collection of urine for protein
 - Indicated for quantification of proteinuria and to confirm the diagnosis
 - Normal range: <100 mg/m²/day or <4 mg/m²/h
- Serum albumin
 - To assess for hypoalbuminemia, nephrotic syndrome
- Serum BUN and creatinine levels
 - Impaired renal function suggests inflammation, infection, or obstruction.
- Serum electrolytes and phosphorous levels
 - To screen for RTA
- Evaluation for glomerulonephritis (GN)
 - Proteinuria with edema, hematuria, hypertension, and/or impaired

renal function

- Streptococcal serology (ASO titer, streptozyme): acute postinfectious GN
- Complement studies (C3,C4): hypocomplementemic GN—immune complex mediated (lupus nephritis, postinfectious GN, membranoproliferative GN)
- Antinuclear antibody (ANA) titer or anti–double-stranded DNA, hypocomplementemic or signs of systemic vasculitis: vasculitis (lupus)

ALERT

- Most patients with proteinuria will have orthostatic proteinuria that is identified by a first morning urine sample testing negative for protein while samples collected while upright test positive for protein.
- It is important to check the urine sediment for red cell casts; this indicates a glomerular involvement and requires additional studies for nephritis and chronic renal disease.

DIFFERENTIAL DIAGNOSIS

- Idiopathic nephrotic syndrome
 - Minimal change nephrotic syndrome
 - Mesangial proliferation
 - Focal segmental glomerulosclerosis
 - Membranous nephropathy
- Nephrotic syndrome due to genetic causes
 - Finnish-type congenital nephrotic syndrome
 - Familial focal segmental glomerulosclerosis
 - Diffuse mesangial sclerosis
 - Denys-Drash syndrome (nephropathy, Wilms tumor, and genital abnormalities)
- Chronic kidney disease
- Acquired glomerular disease
 - Idiopathic glomerulonephritis
 - Lupus-associated nephritis
 - IgA nephropathy
 - Systemic vasculitides

- Subacute bacterial endocarditis
- Diabetes mellitus
- Hypertension
- HUS
- Hyperfiltration secondary to nephron loss (with or without sclerosis)
- Genetic disorders
 - Nail-patella syndrome
 - Alport syndrome
 - Fabry disease
 - Glycogen storage disease
 - Cystic fibrosis
 - Hurler syndrome (mucopolysaccharide type-1)
 - α -1-antitrypsin
 - Mitochondrial disorders (usually tubular proteinuria)
 - Gaucher disease
 - Dent disease (X-linked nephrolithiasis)
 - Cystinosis
 - Wilson disease
- Oncologic/hematologic
 - Sickle cell disease
 - Renal vein thrombosis
 - Leukemia
 - Lymphoma
- Infectious
 - Poststreptococcal glomerulonephritis
 - HIV-associated nephropathy
 - Hepatitis B and C virus infection
 - Malaria
 - Syphilis (can present as congenital nephrotic syndrome)
 - Pyelonephritis
- Drugs/toxins
 - Bee sting
 - Food allergens
 - Antibiotic-induced interstitial nephritis
 - Penicillamine

- Gold salts
- NSAIDs
- Heavy metals (e.g., mercury, lead)
- Miscellaneous
 - Tubular interstitial nephritis
 - Acute tubular necrosis
 - Reflux nephropathy
 - Hypothyroidism
- Congestive heart failure

CODES

ICD10

- R80.9 Proteinuria, unspecified
- R80.2 Orthostatic proteinuria, unspecified
- R80.1 Persistent proteinuria, unspecified

FAQ

- Q: When to refer to nephrology?
- A: Patients with one of the following: fixed proteinuria, associated hypertension, associated hematuria, clinical evidence of nephritis, and patient with family history of renal diseases with proteinuria

- Q: When are imaging studies indicated?
- A: Patients with abnormal renal function, hematuria, or nephrolithiasis.
The best initial study is renal and bladder ultrasound.

PRUNE BELLY SYNDROME

Shamir Tuchman

BASICS

DESCRIPTION

- Rare congenital disorder characterized by the triad of
 - Deficiency of abdominal musculature
 - Bilateral cryptorchidism
 - Dilated, anomalous development of the bladder and upper urinary tract
- Presents with a broad spectrum of severity, from mild hydroureter with an enlarged bladder and normal renal function to severe renal dysplasia and pulmonary hypoplasia
- Also known as Eagle-Barrett syndrome

EPIDEMIOLOGY

- Incidence: 1/35,000–50,000 live births
- Most patients are detected during the neonatal period or prenatally during maternal ultrasound.
- Prune belly syndrome is much more common in males (>95%). Females with urethral atresia may be affected.

RISK FACTORS

Genetics

- The genetic basis of prune belly syndrome remains unclear.
- Most patients have normal karyotypes.
- Most cases are sporadic, although rare cases in sibs have been reported.
- Genetic analysis of rare inherited forms have revealed homozygous mutations in the muscarinic acetylcholine receptor gene (CHRM3) and heterozygous mutations in α -smooth muscle actin (ACTA2), with sporadic forms rarely having mutations in hepatocyte nuclear factor 1 β transcription factor (HNF1 β).

PATHOPHYSIOLOGY

The bladder in prune belly syndrome is large, irregularly shaped, and thick walled. Many patients have poor urinary flow and high residual volumes:

- Ureters are usually markedly dilated, tortuous, and elongated. Peristalsis is ineffective, and the distal ureters are most severely affected. Vesicoureteral reflux is present in over 75% of cases.
- Renal involvement is variable; the most severe dysplasia occurs in patients with extensive dilation of the urinary tract. Dysplastic changes are usually symmetric.
- Usually, the bladder neck is wide and the prostatic urethra is dilated and triangular.

ETIOLOGY

The cause of prune belly syndrome remains unclear. Two theories have been proposed:

- The triad of congenital defects may result from a primary mesodermal defect in development with congenital deficiency of smooth muscle in the bladder, ureter, and renal pelvis.
- Outflow obstruction of the bladder in utero may result in dilation of the bladder and upper urinary tract with subsequent renal injury. The expanded bladder may block the route of the descending testicles and may cause abdominal distention and abdominal wall muscle atrophy.

COMMONLY ASSOCIATED CONDITIONS

Many patients have associated anomalies:

- GI anomalies
 - Affect up to 25% of patients (e.g., imperforate anus, malrotation, gastroschisis, omphalocele, bowel atresia, and increased risk of volvulus)
- Musculoskeletal anomalies
 - talipes equinovarus, congenital hip dislocation, pectus excavatum, scoliosis, hemivertebrae
- Respiratory
 - Affect upward of 60% of patients (e.g., pulmonary hypoplasia, chronic respiratory tract infections due in part to impaired coughing, reactive airway disease, respiratory difficulty after general anesthesia)

- Genital anomalies in females
 - genital sinus, urethral atresia, vesicovaginal fistula, vaginal atresia, and bicornuate uterus
 - Ovaries in affected female patients are typically normal.
- Cardiac anomalies
 - Affect up to 25% of patients (e.g., patent ductus arteriosus [PDA], atrial septal defect [ASD], ventricular septal defect [VSD], tetralogy of Fallot [TOF])
- Other genetic conditions
 - Children with trisomy 21 (Down syndrome) have an 11-fold increased risk of prune belly syndrome compared with other children.

DIAGNOSIS

HISTORY

In patients with mild involvement of the abdominal wall that is not detected in the neonatal period, evaluation of UTIs may reveal the dilated urinary tract.

PHYSICAL EXAM

- Abdominal wall is characterized by multiple wrinkles and redundant skin.
- A large, distended bladder creates a suprapubic mass.
- Ureters and kidneys are readily palpable.
- Intestinal loops and peristalsis may be observed.
- Testes are undescended.
- Myopathy results in difficulty in sitting up from a supine position.
- Abnormal gait secondary to congenital hip dislocation and abdominal muscular hypoplasia
- Chronic constipation from abdominal muscular hypoplasia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum levels of creatinine and BUN may be elevated.
- Renal failure may result in anemia and elevated levels of potassium,

phosphorus, hydrogen ion, and uric acid; tubular dysfunction may result in decreased concentrations of sodium and bicarbonate.

Imaging

- Ultrasound will demonstrate dilatation and redundancy of the upper urinary tract.
- When considering a voiding cystourethrogram, assess possible risk of introducing infection into dilated, poorly draining urinary tract.
- Renal function and drainage of the dilated tract can be assessed by radioisotope renal scan or an excretory urogram.

Diagnostic Procedures/Other

Initial evaluation should include assessment of renal function.

DIFFERENTIAL DIAGNOSIS

- Distinctly abnormal findings of physical exam of the affected infant results in an early, accurate diagnosis in most cases.
- Pseudo–prune belly syndrome (e.g., prune belly syndrome uropathy, normal abdominal wall exam, and incomplete or absent cryptorchidism)

TREATMENT

SURGERY/OTHER PROCEDURES

- Many clinicians advocate minimal surgical intervention (e.g., conservative approach), based on lack of functional obstruction and that the dilated system has a low pressure owing to the deficient smooth musculature. If renal function deteriorates, urinary tract dilation progresses, the patient has evidence of mechanical obstruction such as urethral atresia, or the patient develops recurrent UTIs despite antibiotic prophylaxis, cutaneous vesicostomy is recommended to facilitate drainage.
- Other physicians advocate extensive early surgical remodeling. Possible procedures include, as indicated:
 - Internal urethrotomy, reduction cystoplasty
 - Excision of the redundant ureter with reimplantation of the remaining segment

- Cutaneous ureterostomy
- Pyelostomy
- Reconstruction of the abdominal wall has yielded good cosmetic results but only questionable improvements in physical function.
- Bilateral orchiopexy is indicated, ideally within the 1st year of life.
- Circumcision to prevent UTI has been advocated, but no large trials to document its effectiveness in prune belly syndrome have been published to date.

INPATIENT CONSIDERATIONS

Admission Criteria/Initial Stabilization

- Basic principles of supportive care and management of renal failure apply.
- Antibiotics in the neonatal period and antibiotic prophylactic of indefinite duration are indicated to prevent infection.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Regardless of how patients are managed, affected patients require long-term follow-up, with meticulous attention to renal function, pulmonary function, bladder drainage, and urine bacteriology.

PROGNOSIS

- Patients with the most severe renal dysplasia and pulmonary hypoplasia (e.g., sequelae of severe, early oligohydramnios) succumb as neonates.
- Associated with a mortality rate of up to 20% in the neonatal period
- ~25% of patients with prune belly syndrome who survive the neonatal period will progress to end-stage renal disease (ESRD).
- Those with a milder form do not require urinary tract surgery; renal function is usually stable and prognosis is excellent.
- For patients with moderate involvement, the degree of renal dysplasia and insufficiency determines outcome. In addition, upper urinary tract stasis, poor bladder emptying, vesicoureteral reflux, and bacteriuria are factors that may combine to worsen the long-term prognosis.

COMPLICATIONS

- Pulmonary hypoplasia
- Frequent UTIs secondary to upper urinary stasis, vesicoureteral reflux, and bacteriuria
- Sequelae of progressive renal insufficiency

CODES

ICD10

Q79.4 Prune belly syndrome

FAQ

- Q: Are patients with prune belly syndrome candidates for renal transplantation?
- A: Yes. However, special pretransplantation consideration should be given to patients with dilated tracts to optimize bladder function.
- Q: How does the urinary tract function in older children?
- A: A tendency for bladder tone and ureteral peristalsis to improve with age has been noted.
- Q: Are such patients infertile?
- A: Normal sexual activity has been described. However, there are no reports of fertility, and the patients usually have azoospermia.
- Q: What is the usual cause of morbidity in the newborn period?
- A: Respiratory failure.

PRURITUS

Anubhav Mathur • Ilona Frieden

BASICS

DESCRIPTION

Pruritus, or itch, is one of the most frequent dermatologic complaints. It is an unpleasant sensation characterized by the reflexive behavior to scratch and is a symptom associated with numerous inflammatory and infectious skin diseases. However, generalized and persistent pruritus without or with minimal skin changes may be a presenting feature of a variety of systemic diseases.

PATHOPHYSIOLOGY

- Itch-specific peripheral nerves are unmyelinated afferent C-fibers.
- Pruritus depends on the complex interplay of neuroinflammatory modulators among peripheral nerves, keratinocytes, and leukocytes as well as CNS processing.
- There are numerous mediators of pruritus, although histamine is the prototypical pharmacologic target for many patients.

ETIOLOGY

- Dermatologic: arising from skin disease
- Systemic: arising from noncutaneous organ systems including metabolic causes, drugs, and multifactorial disorders
- Neurogenic: arising from disorders of the central or peripheral nervous system
- Psychogenic: arising from primary psychiatric disorders
- Mixed: coexistence of more than one etiology of pruritus
- Idiopathic: pruritus of uncertain etiology

DIAGNOSIS

HISTORY

- Acute versus chronic (>6 weeks) pruritus

- Location: generalized, scattered spots, or localized
- Severity of symptoms
- Presence or absence of a preceding or concurrent rash
- Family members or close contacts with a similar complaint
- Environmental exposures: pets/other animals, poison oak or ivy, skin care products, soaps, shampoos, length and frequency of bathing/showering
- Medications (topical or systemic) or recreational drugs
- History of hematologic, hepatobiliary, renal, metabolic, neurologic, neoplastic, and psychiatric diseases
- Complete review of systems: particularly important for those without obvious skin findings

PHYSICAL EXAM

- Define and differentiate primary morphologies from secondary changes.
- Determine the location of the rash and areas of sparing.
- Evaluate for evidence of secondary cutaneous infections.

APPROACH TO THE PATIENT

- Most children with pruritus have a primary dermatologic disease.
- Common conditions include atopic dermatitis, allergic reactions to insect bites (so-called papular urticaria), fungal infection, scabies, hives, and dermatographism.
- To develop a differential diagnosis, it is helpful to subdivide patients into 1 of 4 groups as below:
 - Generalized pruritus with definite skin disease
 - Generalized pruritus without definite skin disease (minimal or nonspecific skin lesions)
 - Localized pruritus with definite skin disease
 - Localized pruritus without definite skin disease (minimal or nonspecific skin lesions)
- To identify common patterns of pruritus, consider the questions listed below:
- **Question 1:** Are the findings characteristic of atopic dermatitis, the most common skin disease in children?

- Does the patient have a history of severe cradle cap or chronic/intermittent rash involving the face, antecubital or popliteal fossae, ankles, or wrists?
- Atopic dermatitis is very common and typically has distinctive sites of predilection.
- **Question 2:** Are there specific or nonspecific (scratching/rubbing induced) skin lesions present?
 - If there are multiple morphologies, consider scabies.
 - If minimal or mostly secondary skin changes are present but pruritus is severe, consider either scabies or a systemic cause (see below).
- **Question 3:** Does the patient have clustered pink excoriated papules on the ankles, mid torso, or legs?
 - This finding may represent bugbite reactions, which are a common cause of pruritus in children.
 - These reactions disproportionately affect young children and may not be evident in their parents/guardians or even siblings.
- **Question 4:** Does the patient have acute onset of rash with tiny vesicles or linear streaks of erythema on the face, arms, or legs?
 - Poison oak/ivy is common and presents as an acute eczematous or vesiculobullous reaction.
- **Question 5:** Does the patient have well-defined erythematous and scaling rash involving the scalp, extensor elbows, knees, umbilicus, or gluteal cleft?
 - These findings suggest psoriasis. Although less common in children than atopic dermatitis, and usually less itchy, it has distinct sites of involvement with characteristic morphology.
 - Family history of psoriasis is common in patients who develop it in childhood.
- **Question 6:** Does the patient have a chronic pruritic scaly rash around the umbilicus?
 - Chronic allergic contact dermatitis from metals, especially to nickel, may present as an isolated itchy rash around the umbilicus due to a belt buckle or pant button.
 - For patients who wear earrings, ear lobes may be affected,

providing a diagnostic clue.

- Many patients with nickel dermatitis have fine papules scattered on the arms and legs (so-called id reaction) or may have preexisting atopic dermatitis.
- **Question 7:** Does the patient have any itchy rash involving the cheeks and nose with a rash on the dorsal forearms, sparing the volar arms?
 - This pattern may present photosensitivity and suggests possible polymorphous light eruption or actinic prurigo.
- For patients with a definite dermatologic cause for pruritus, treat the underlying cause.
- Consider nondermatologic causes (listed below) for patients with severe generalized pruritus and nonspecific skin lesions—exclude scabies/infestation, dermatographism, and atopic dermatitis.
- Localized pruritus with minimal or nonspecific skin lesions may suggest neuropathic itch, which is rare in children.

DIFFERENTIAL DIAGNOSIS

- Dermatologic Diseases
 - Inflammatory skin diseases
 - Dermatitis (atopic including nummular morphology, allergic contact, irritant contact, other)
 - Urticaria
 - Dermatographism
 - Psoriasis
 - Lichen planus
 - Mastocytosis
 - Dermatitis herpetiformis
 - Bullous pemphigoid
 - Epidermolysis bullosa pruriginosa
 - Polymorphous light eruption
 - Cutaneous infections and arthropod reactions
 - Scabies
 - Tinea/dermatophyte infection
 - Pediculosis
 - Flea bites
 - Mite reactions

- Bedbug bites
 - Papular urticaria
 - Other arthropod reactions
- Neoplastic
 - Cutaneous lymphomas
- Systemic Diseases
 - Endocrine
 - Thyroid and parathyroid disease
 - Diabetes mellitus
 - Infections
 - HIV
 - Hepatitis B and C
 - Systemic parasitic infections
 - Hematologic
 - Polycythemia vera/aquagenic pruritus
 - Iron deficiency anemia
 - Lymphomas
 - Leukemias
 - Hypereosinophilic syndrome
 - Myelodysplastic syndromes
 - Biliary diseases leading to cholestasis
 - Renal disease: uremic pruritus in chronic kidney disease
 - Malignancies
 - Solid tumors
 - Carcinoid syndrome
- Neurologic Diseases
 - CNS malignancies or infections
 - Multiple sclerosis
 - Peripheral nerve injuries from compression or irritation
 - Radiculopathy
 - Polyneuropathy
- Psychiatric Diseases
 - Psychogenic excoriations
 - Delusions of parasitosis
 - Somatoform disorders

DIAGNOSTIC TESTS & INTERPRETATION

- Diagnostic testing is rarely required or helpful, as most children with pruritus have a primary dermatologic cause that can be clinically diagnosed.
- In patients with generalized pruritus without an obvious primary skin disease, the following studies should be considered based on clinical suspicion of the underlying cause for pruritus.
- Labs
 - CBC with differential, TFTs, PTH, HgbA1c, AST, ALT, alkaline phosphatase, total bilirubin, BUN, creatinine, HIV 1, HIV 2, ELISA, HBsAg, hepatitis C serology, iron studies
- Imaging
 - Abdominal ultrasound, chest x-ray, CNS imaging with MRI
- Light microscopy (from skin scrapings)
 - KOH prep for dermatophyte infections and mineral oil examination for scabies. Note: must only be done with proper training
- Pathology
 - Skin biopsy specimens for hematoxylin and eosin (H&E) and direct immunofluorescence may be helpful in confirming the suspected dermatologic diagnosis.

TREATMENT

- Treatment is directed to the underlying cause.
- Supportive measures:
 - Gentle skin care measures, including the use of nonsoap cleansers and gentle emollients
 - Loose cotton clothing
 - Sedating antihistamines in select cases
 - Topical corticosteroids and/or topical calcineurin inhibitors in select cases
- Phototherapy
 - Certain inflammatory conditions including psoriasis and some cases of severe atopic dermatitis may benefit from narrow band ultra violet B (NBUVB) therapy.

- Patients with certain systemic causes of pruritus such hepatobiliary or renal pruritus may benefit from NBUVB.

ISSUES FOR REFERRAL

- Severe cases of inflammatory or cutaneous infectious diseases
- Identification of or suspicion for a noncutaneous cause for pruritus

CODES

ICD10

- L29.9 Pruritus, unspecified
- F45.8 Other somatoform disorders
- L23.9 Allergic contact dermatitis, unspecified cause

FAQ

- Q: Which antihistamines work the best to treat itch?
- A: Although evidence is conflicting, sedating antihistamines such as hydroxyzine tend to work better than nonsedating ones for itch.
- Q: How does scratching affect pruritus?
- A: Scratching disrupts the skin barrier. By irritation or secondary infection, inflammatory mediators in the skin (such as histamine) can worsen pruritus, leading an “itch-scratch-itch” cycle.
- Q: What is gentle skin care?

- A: Gentle skin care is the concept of keeping the skin moist with emollients including creams or ointments, thereby “repairing” the skin barrier. Application of an emollient, particularly after bathing, will help to keep the skin moist and reduce pruritus in patients with several inflammatory skin diseases.

PSITTACOSIS

Nicholas Tsarouhas

BASICS

DESCRIPTION

- An acute febrile disease characterized by pneumonitis and other systemic symptoms
- The name is derived from the Greek for parrot, psittakos; thus, psittacosis is often referred to as “parrot disease.”
- Also known as ornithosis

EPIDEMIOLOGY

- Birds are the major reservoir of the psittacosis pathogen.
- Nearly all domestic and wild birds may spread this infection.
- Psittacine birds (parakeets, parrots, and macaws) are a major source of disease in the United States, but pigeons and turkeys are also common culprits.
 - Infecting agent is present in bird nasal secretions, urine, feces, feathers, viscera, and carcasses.
 - Inhalation of aerosols of feces, urine, and secretions of infected birds is the most common route of infection.
 - Handling of plumage, bird bites, and mouth-to-beak contact are known to spread infection.
 - Birds may be healthy or sick.
- Most reported cases (70%) are the result of exposure to pet caged birds (especially parrots, parakeets).
- Most common mammalian source of infection is sheep.
- Occupational hazard of workers in poultry plants, pet shops, zoos, farms
- Rarely transmitted person to person

Incidence

- Only 100–200 total cases reported in United States each year
- Very rare disease in young children

RISK FACTORS

Close human contact with birds and, in some cases, sheep

GENERAL PREVENTION

- Epidemiologic investigation is indicated in all suspected cases.
- Birds suspected to be infected should be killed, transported, and analyzed by qualified experts.
- Potentially contaminated living areas where bird was kept should be disinfected and aired.
- Pathogen is susceptible to most household disinfectants (rubbing alcohol, Lysol, bleach).

PATHOPHYSIOLOGY

- Inhalation of aerosolized organisms into the respiratory tract
- Incubation period 5–14 days; may be longer
- Spreads via bloodstream to lungs, liver, and spleen
- Lymphocytic inflammatory alveolar response

ETIOLOGY

- Infection produced by *Chlamydophila psittaci*, an obligate intracellular parasitic bacterium
- Morphologically, antigenically, and genetically different from *Chlamydia* species

COMMONLY ASSOCIATED CONDITIONS

Pneumonitis (with a severe headache) is a common presentation.

DIAGNOSIS

HISTORY

- Mandatory to question parents about exposure of the patient to any type of bird—wild or domestic
- Signs and symptoms
 - Abrupt onset of symptoms
 - Fever, headache, cough, weakness, chills, muscle aches, and joint pain
 - Nonproductive cough

- Vomiting, confusion, and photophobia are less common findings.

PHYSICAL EXAM

- Ill-appearance, tachypnea, rales, and splenomegaly are common.
- A relative bradycardia is found in some cases.
- Less common findings
 - Rash
 - Meningismus
 - Pharyngeal injection
 - Cervical adenopathy
 - Hepatomegaly
 - Mental status changes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Routine laboratory studies are rarely helpful.
- Isolation of the organism is diagnostic.
- Complement fixation titers (see “[FAQ](#)”)
- Microimmunofluorescence studies and polymerase chain reaction assays are more specific than complement fixation studies.
- Complement fixation titers do not, however, distinguish between the chlamydial infections (*Chlamydia trachomatis*) and the various chlamydophilal infections (*Chlamydophila psittaci*, *Chlamydophila pneumoniae*, and *Chlamydophila pecorum*).

Imaging

- Chest x-rays are abnormal in 90% of hospitalized cases.
- Chest x-rays often demonstrate diffuse interstitial infiltrates but may also have unilateral lower lobe consolidation.

DIFFERENTIAL DIAGNOSIS

- Psittacosis should be considered in a patient with fever of unknown origin or atypical pneumonitis.
- Differential diagnosis includes the following:
 - *Mycoplasma pneumoniae*
 - *C. pneumoniae*
 - *Legionella* spp.

- Coxiella burnetii (i.e., Q fever)
- Tuberculosis
- Viral pneumonitis
- Fungal pneumonitis
- Pneumococcal pneumonia

TREATMENT

MEDICATION

First Line

- Tetracycline (40 mg/kg/24 h) or doxycycline (100 mg b.i.d.) in children ≥ 8 years of age
- Erythromycin (40 mg/kg/24 h) in children < 8 years of age
- Antibiotics should be continued for at least 10–14 days after defervescence.

Second Line

Azithromycin is an additional option.

ONGOING CARE

PROGNOSIS

- Although complete recovery is the rule (even without antibiotic use), fatality rates as high as 15–20% have been reported.
- Resolution of fever and most other systemic symptoms can be expected within 48 hours of antibiotic therapy.
- Untreated patients may have severe pulmonary symptoms for 1–3 weeks.

COMPLICATIONS

- Hepatitis
- Anemia
- Thrombophlebitis
- Pulmonary embolus
- Adult respiratory distress syndrome

- Arthritis
- Keratoconjunctivitis
- Endocarditis
- Myocarditis
- Pericarditis
- Encephalitis: agitation, delirium, confusion, stupor

CODES

ICD10

A70 *Chlamydia psittaci* infections

FAQ

- Q: How is a clinical case confirmed?

- A: A clinically compatible illness with fever, chills, headache, cough, and myalgia with (1) isolation of *C. psittaci* from respiratory tract specimens or blood or (2) 4-fold or greater increase in immunoglobulin G (IgG) by complement fixation (CF) or microimmunofluorescence (MIF) against *C. psittaci* between paired acute- and convalescent-phase serum obtained at least 2–4 weeks apart. A “probable case” of psittacosis requires a clinically compatible illness and either (1) supportive serologic test results (e.g., *C. psittaci* immunoglobulin M [IgM] ≥ 32 in at least 1 serum specimen obtained after onset of symptoms) or (2) detection of *C. psittaci* DNA in a respiratory tract specimen by polymerase chain reaction assay.
- Q: Does the source bird usually exhibit signs of disease?
- A: No. The bird is often asymptomatic; it may, however, show some signs of illness (e.g., anorexia, ruffled feathers, depression, or watery green droppings).

PSORIASIS

Leslie Castelo-Soccio

BASICS

DESCRIPTION

Skin disease characterized by a chronic relapsing nature and, most commonly, clinical features of scaly, erythematous papules and plaques with thick white scale, usually involving elbows, knees, and scalp (i.e., psoriasis vulgaris). Variants include guttate, erythrodermic, and pustular psoriasis.

EPIDEMIOLOGY

- No gender predilection
- Onset of psoriasis is bimodal, commonly presenting in the 3rd decade with a smaller 2nd peak of onset in the 6th decade; however, it can present at any age, with a mean age of onset in children of 8.1 years.
- Earlier onset is associated with more severe disease.

Prevalence

Psoriasis is universal in occurrence, but prevalence varies in different populations. The average prevalence in the United States is ~1–3%.

RISK FACTORS

Genetics

- Although psoriasis has a strong genetic influence, mode of transmission is not defined. It is likely multifactorial with more than one gene involved and is modified by environmental influence.
- 1/3 of patients with psoriasis report a relative with the disease.
- In family studies, 8.1% of children develop psoriasis when 1 parent is affected.
- When both parents have psoriasis, the affected percentage increases to 41%.
- In twin studies, 65% of monozygotic twins are concordant for the disease, whereas only 30% of dizygotic twins are concordant.

PATHOPHYSIOLOGY

- Plaque-type psoriasis is characterized by a thickened parakeratotic epidermis with an absent granular layer above dermal papillae containing dilated tortuous capillaries.
- Collections of polymorphonuclear leukocytes extend from the dermal papillae into the epidermidis stratum corneum (i.e., Munro microabscesses).
- A mixed perivascular infiltrate is confined to the papillary dermis.

ETIOLOGY

The pathogenesis is unknown. Well-defined trigger factors include the following:

- Trauma to normal skin, producing psoriasis in the area (i.e., isomorphic response, sometimes called the Koebner phenomenon)
- Infections (e.g., upper respiratory infections, *Streptococcus pyogenes*, human immunodeficiency virus)
- Stress
- Winter in colder climates in Northern Hemisphere
- Some drugs (i.e., systemic corticosteroids, lithium, NSAIDs, and antimalarials)

COMMONLY ASSOCIATED CONDITIONS

Leukocytosis and hypocalcemia are associated with pustular psoriasis.

DIAGNOSIS

HISTORY

- 1st appearance of eruption
- Area involved
- Recent illness, particularly sore throat
- Recent medications, particularly systemic steroids
- Any appearance of lesions with trauma to skin
- Joint pain
- Previous treatments and response
- Improvement with sun exposure
- Family history of psoriasis

- Signs and symptoms
 - Thick, flaky scales on skin
 - Psoriasis vulgaris
 - In psoriasis vulgaris, sharply demarcated erythematous plaques with white scale are located most commonly on the elbows, knees, scalp, lumbar area, and umbilicus, but they can cover any surface and large areas of the body.
 - Intertriginous regions are often involved, but scale is absent.
 - Guttate psoriasis
 - Form that more often presents in children and young adults as small papules (0.5–1.5 cm), with limited scale over the trunk and proximal extremities
 - Frequently associated with streptococcal infection
 - Erythrodermic psoriasis
 - Erythema with variable scale involving the majority of the body accompanied by chills is characteristic of erythrodermic psoriasis.
 - Generalized pustular psoriasis
 - Most serious variant
 - Sterile pustules as large as 23 mm arising on erythematous skin over large areas of the body. Usually, such appearance is accompanied by high fever.
 - A chronic and localized variant of pustular disease, however, involves only the palms and soles.
 - Note: Classic plaque psoriasis is easily diagnosed, but variants and less virulent cases require careful exam for physical clues.
- Nails are frequently involved, with pinpoint pits, hyperkeratosis, and oil spots.
- Areas where disease is hidden are the retroauricular portion of the scalp and the perianal region.
- Swollen or deformed joints suggest associated psoriatic arthritis.

PHYSICAL EXAM

- A complete cutaneous exam is necessary.
- Removal of scale on plaques produces bleeding points, a feature known as the Auspitz sign.

- The Koebner phenomenon may produce linear or geometric lesions corresponding to areas of trauma.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- An elevated uric acid level is a common finding.
- *S. pyogenes* infection is frequent in guttate disease, and throat culture is appropriate.
- Other laboratory values are generally within normal ranges. However, in more severe variants, anemia, elevated ESR, and decreased albumin levels may be found.

DIFFERENTIAL DIAGNOSIS

- Classic plaque psoriasis is easily diagnosed. Variants of psoriasis, including guttate, erythrodermic, and pustular disease, are more difficult to recognize.
- The differential diagnosis varies with the type of psoriasis and includes the following:
 - Nummular eczema
 - Cutaneous T-cell lymphoma
 - Tinea corporis
 - Pityriasis rosea
 - Pityriasis lichenoides et varioliformis acuta
 - Secondary syphilis
 - Atopic dermatitis
 - Drug eruption
 - Candidiasis
 - Seborrheic dermatitis

TREATMENT

GENERAL MEASURES

- Phototherapy
 - UVB
 - Administered on average 2–3 times weekly in a booth with bulbs that emit the appropriate wavelength of UV radiation

- Effective for guttate and plaque psoriasis
- Average treatment time: 3 months, with gradual increases in time of exposure. Sunscreen should be used on the face.
- Narrow-band UVB represents a form of monochromatic UVB, using 311-nm wavelengths; appears to be a somewhat more effective form of delivering UVB phototherapy using booth or handheld device
- PUVA (psoralen and UVB)
 - PUVA and oral medications (e.g., methotrexate, acitretin) should be reserved for severe cases and carefully monitored by a dermatologist.

ALERT

Possible conflicts with other drugs: Photosensitizing medication (e.g., tetracyclines, sulfa derivatives, phenothiazines, griseofulvin, among others) should be avoided with phototherapy.

- Topical
 - Topical corticosteroids
 - Mid- to high-potency topical corticosteroid ointments are applied twice daily.
 - Mid-potency preparations (e.g., 0.025% fluocinolone ointment, 0.1% triamcinolone acetonide) are preferred in children.
 - Low-potency corticosteroids (e.g., 1% and 2.5% hydrocortisone) are used on the face and intertriginous regions to prevent atrophy.
 - Agents can also be found in oils or solutions.
 - Anthralin
 - Anthralin, applied for 30 minutes and carefully washed off
 - Irritation and staining are common, so that the face and intertriginous regions cannot be treated with this approach.
 - Calcipotriene
 - Calcipotriene ointment is a vitamin D₃ derivative.
 - It is applied twice daily, avoiding the face and intertriginous regions.
 - Maximum weekly dosage in adults is 100 g.
 - Rare cases of hypercalcemia have been reported.

- Combination steroid/calcipotriene products exist.
- Tazarotene gel
 - A topical retinoid
 - Can be irritating when used as monotherapy
 - Often combined with topical steroids as adjunctive therapy applied once daily or twice daily
- Coal tar
 - A weak therapeutic agent as monotherapy
 - More effective when combined with UVB phototherapy
 - Used in various shampoo preparations as well as in solution that can be added to the bath
- Systemic agents
 - May be considered when the psoriasis is especially severe or when joint symptoms are prominent.
 - Methotrexate
 - Isotretinoin or acitretin
 - Cyclosporine
 - Biologic agents such as etanercept
 - Systemic corticosteroids should be avoided because withdrawal from steroids may be accompanied by a pustular psoriasis flare.

ISSUES FOR REFERRAL

- Pustules, a significant increase in degree or extent of erythema, or fever may require hospitalization and systemic therapy.
- Erythrodermic psoriasis may require hospitalization.
- Adult and pediatric patients with psoriasis have an increased prevalence of cardiovascular disease and metabolic syndrome. Patients should be monitored for blood pressure, glucose, weight, and lipids to decrease risk.

Initial Stabilization

- Therapy is delivered by topical medications, phototherapy, or systemic medications.
- Localized disease is treated with topical and more diffuse disease with phototherapy.
- Systemic medications for resistant cases

- Except in severe cases, therapy for children should be limited to topical medication and UVB phototherapy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Topical therapy is administered chronically, with breaks to minimize side effects.
- Remissions may occur in summer with sun exposure.
- The average treatment course with UVB therapy is 3 months and may be followed by an average remission period of 5 months.

PROGNOSIS

- Once psoriasis appears, it generally persists throughout life.
- Spontaneous remissions of variable length and frequency occur but are unpredictable.
- Response depends on potency of medication and frequency of treatment.
- Improvement with topical medication is obvious at 2 weeks and usually peaks at 2 months.
- Scrubbing by the patient to remove scales also irritates the disease.
- Psychological aspects of the disease, particularly in children, should be addressed.

CODES

ICD10

- L40.9 Psoriasis, unspecified
- L40.0 Psoriasis vulgaris
- L40.4 Guttate psoriasis

FAQ

- Q: Will my disease get worse?
- A: It is impossible to predict the course of any patient's disease because it is influenced by both heredity and everyday factors in the environment. Although there is no cure, with treatment, the disease can be kept under control. Remissions do occur and may be for prolonged periods of time.
- Q: When my disease is in remission, what can I do to prevent it from returning?
- A: Avoiding trauma and keeping skin moist are important. In the summer, controlled sun exposure is helpful. You may have to continue other treatments at less frequent intervals. Any cases of sore throat should be cultured and treated if streptococcal disease is present.
- Q: Will my other children get psoriasis?
- A: If neither parent has psoriasis, the chances are <10% that another child will develop the disease; if 1 parent is affected, the chances increase to 15%; if both parents are affected, the chances are 50%. Therefore, unless both parents are affected, it is more likely that other children will not get psoriasis.
- Q: Does stress make psoriasis worse?
- A: Some studies have suggested that flare-ups of psoriasis are associated with increased stress. It is difficult to evaluate whether stress is the cause or the result of the disease. Do all you can to

reasonably relieve stress, but do not focus on this as the cause of your psoriasis.

PUBERTAL DELAY

Angela P. Mojica • Lucy D. Mastrandrea

BASICS

DESCRIPTION

- Pubertal delay is the absence of secondary sexual characteristics (testicular enlargement in boys or breast development in girls) by an age $>2-2.5$ standard deviations (SD) than the population mean.
 - In the United States, this is considered to be ~ 13 years of age for girls and 14 years of age for boys.
 - Development of pubic hair is usually not considered in the definition because adrenarche (adrenal gland maturation) may occur independently of gonadarche.
- Pubertal delay may also occur if progression through puberty stalls or takes more than 4 years between first signs of puberty and completion.
- Most cases of pubertal delay can be ascribed to constitutional delay of growth and puberty (CDGP); however, missing the presentation of an underlying disease should be avoided.
- CDGP
 - Likely an extreme normal variant of pubertal development
 - Enter puberty late and usually reach normal adult height
 - More common in boys than in girls
 - Strong familial component

GENERAL PREVENTION

- Perform pubertal staging at regular intervals.
- Examination of growth charts at routine visits can alert providers to potential problems or changes in growth.
- Begin conversations about pubertal development with both patients and parents in late childhood. Realistic expectations regarding timing can avoid undue stress and unnecessary testing.
- Children with chronic health conditions should receive counseling regarding the effect their illness may have on their puberty. For example, children with cystic fibrosis generally have delayed puberty.

EPIDEMIOLOGY

- Approximately 2.5% of healthy teens will meet criteria for pubertal delay.
- CDGP explains 90–95% of pubertal delay.
- 50–75% of patients with CDGP have a positive family history.
- In contrast to boys, pubertal delay in girls more frequently represents underlying pathology
- Malnutrition is a risk factor for delayed puberty.

GENETICS

- Pubertal timing is highly influenced by genetic factors. This is evidenced by high correlation within ethnic groups, families, and between monozygotic twins.
- 50–80% of variation in timing can be explained by genetics.
- CDGP
 - Inheritance is often consistent with an autosomal dominant pattern.
 - No specific causative gene mutations have been identified.
- Hypogonadotropic hypogonadism is associated with mutations in single genes including GNRHR, KAL-1, FGFR-1, and GPR54.
- GPR54 (a G protein–coupled receptor) and its ligand (kisspeptin) play an important role as a signal for gonadotropin-releasing hormone (GnRH) release. Mutations in the GPR54 gene have been found in patients with isolated hypogonadotropic hypogonadism but not in those with CDGP.
- Pubertal delay as a result of underlying medical conditions is influenced by the pathophysiology of each disorder.

ETIOLOGY

Deficiency of gonadal sex steroids, estrogen in girls or testosterone in boys, is the underlying cause of delayed puberty. Several pathways to the common etiology exist:

- Hypogonadotrophic hypogonadism: delayed puberty as a result of a deficiency in secretion of GnRH or gonadotropin secretion
 - Functional: delay or transient decrease in GnRH or gonadotropin secretion; describes CDGP, hypothyroidism, chronic illness
 - Permanent: irreversible deficiency of GnRH, such as in Kallmann

syndrome or panhypopituitarism

- Hypergonadotrophic hypogonadism: gonadal failure as seen in Turner syndrome, Klinefelter syndrome, and anorchia

DIAGNOSIS

HISTORY

- A thorough history of past medical conditions, past growth patterns, and family history is essential.
- Family history of childhood growth patterns and age at pubertal onset of the parents (late menarche in the mother or delayed completion of adult height in the father)
- A complete review of systems to uncover an underlying chronic disorder, such as inflammatory bowel disease, thyroid disorder, celiac disease, or eating disorder, is necessary.
- Bilateral cryptorchidism or a small penis at birth and hyposmia or anosmia may suggest hypogonadotropic hypogonadism.
- A history of chemotherapy or radiotherapy may indicate primary gonadal failure.
- Request and examine a long-term growth chart:
 - CDGP will generally exhibit a consistent low percentile of growth throughout childhood, with linear growth deceleration in the peripubertal period. Growth rate is within the prepubertal normal range.
 - Gonadotropin or gonadal causes will generally present with normal growth in childhood, but no increase in growth rate during the expected pubertal spurt.
- Obtain history of progression of secondary sex characteristics:
 - Adolescents with complete gonadal or gonadotropin deficiencies will not enter puberty unless initiated by exogenous hormones; those with CDGP will progress at a normal rate after initiation of puberty.
 - In CDGP, both adrenarche and gonadarche occur later than average.
 - In isolated hypogonadotropic hypogonadism, adrenarche usually occurs at a normal age.

- Medication history may be useful (e.g., use of glucocorticoids or cytotoxins).
- Assess nutrition history to evaluate for chronic malnutrition or eating disorder.

PHYSICAL EXAM

A thorough physical exam is essential. Pay particular attention to the following elements:

- Thyroid examination
- Neurologic and funduscopic examinations to check for intracranial pathology
- Genital examination and sexual maturity rating (Tanner staging)
 - Breast exam for girls
 - Pubic hair
 - Penis/testicle exam for boys
 - Internal gynecologic examination for girls with amenorrhea may be indicated.
- The first sign of puberty in boys is when testicular length is >2.5 cm (4-cc volume).
- The first sign of gonadarche in girls is breast development.
- In girls, determine whether there is marked discordance between pubic hair and breast development (androgen insensitivity).
- Assess for physical signs of Turner syndrome or Klinefelter syndrome.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial workup: routine screening tests for chronic or systemic disease
 - CBC
 - ESR
 - Electrolytes, renal function
 - Thyroid-stimulating hormone
 - Gonadotropin level—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
 - Low levels suggest prepuberty or hypothalamic-pituitary failure.
 - High levels suggest gonadal failure or absence.
 - LH is a better marker of pubertal initiation than FSH.

- In delayed puberty, an FSH value above the upper limit of the normal range for the assay is a sensitive and specific marker of primary gonadal failure.
 - If hypergonadotropic, obtain karyotype:
 - XX is suggestive of ovarian failure.
 - XO or abnormal X chromosome is indicative of Turner syndrome or gonadal dysgenesis.
 - XXY is indicative of Klinefelter syndrome.
- Inhibin B—baseline levels may facilitate discrimination between constitutional delay and permanent hypogonadotropic hypogonadism.
- If all of the aforementioned studies are normal, and there is no evidence to support CDGP, reevaluate for cryptic chronic illness (including prolactinoma), substance abuse, eating disorder, or ongoing psychosocial stress until puberty progresses or the underlying cause of delay becomes clear.
- No test reliably distinguishes CDGP from isolated hypogonadotropic hypogonadism.
- Eventual pubertal progression confirms CDGP.

Imaging

- Bone age
 - An essential step in primary workup
 - Plain film of the epiphyseal growth centers in the left hand.
 - Epiphyses change in response to growth hormone, thyroxine, and steroids of adrenal or gonadal origin.
 - Bone age should be reviewed by a practitioner who is experienced in interpreting such radiographs.
 - Comparison to chronologic age can help to differentiate CDGP from organic disorders. A bone age that is >2 years delayed from chronologic age is consistent with CDGP. However, this degree of delay is not specific and can be found with other hypogonadotropic causes of delayed puberty or in gonadal failure.
- Pelvic ultrasound
 - Can be useful in locating intra-abdominal testicular structures or in determination of the presence or absence of müllerian structures
 - Indicated when testes are not palpated in patients with a male

phenotype or when müllerian structures cannot be confirmed on physical examination in patients with a female phenotype.

- MRI of the brain/pituitary
 - Useful in assessing pituitary or hypothalamic structures, mass lesions, pathologic calcifications, or increased intracranial pressure if a central cause of delayed puberty is suspected.
- Full neuroendocrine testing
 - Warranted in patients with hypothalamic-pituitary tumors causing hypogonadotropic hypogonadism
- Imaging in patients with the Kallmann syndrome commonly shows olfactory bulb and sulcus aplasia or hypoplasia.

DIFFERENTIAL DIAGNOSIS

- Increased serum gonadotropins (LH/FSH)
 - Congenital
 - Chromosomal abnormalities
 - Turner syndrome (gonadal dysgenesis)
 - Klinefelter syndrome
 - Disorders of sex development
 - Acquired
 - Primary gonadal failure
 - Cytotoxic chemotherapy or radiotherapy
 - Autoimmune gonadal failure
 - Vanishing testes syndrome
 - Trauma
- Normal or low serum gonadotropins
 - CDGP
 - Congenital
 - Gene defects (e.g., Kallmann syndrome)
 - Syndromes (Prader-Willi syndrome)
 - Acquired
 - CNS tumors/traumatic brain injury
 - Hypothalamic amenorrhea (strenuous exercise, eating disorders)
 - Chronic illness
 - Malnutrition
 - Primary hypothyroidism

- Hyperprolactinemia
- Drug-associated (psychotropics)

ALERT

- No test can make a definitive diagnosis of CDGP.
- Consultation with a specialist or experienced laboratory personnel is recommended before obtaining pituitary stimulation tests, as they may require special conditions.

TREATMENT

GENERAL MEASURES

Most patients with pubertal delay do not require pharmacotherapy but may benefit from psychological and social support.

MEDICATION

- In cases of presumed CDGP, estrogen/testosterone therapy can be used to affect hypothalamic maturation, thereby initiating endogenous puberty.
- Referral to an endocrinologist or adolescent specialist is usually recommended before the initiation of hormonal therapy to aid in diagnosis and management.

ONGOING CARE

In cases of permanent hypogonadism because of gonadal absence, failure, or gonadotropin deficiency, long-term hormonal therapy is necessary.

CODES

ICD10

- E30.0 Delayed puberty
- E28.39 Other primary ovarian failure
- E23.0 Hypopituitarism

FAQ

- Q: As ~95% of pubertal delay is constitutional or physiologic, when can I avoid an expensive workup and just observe the patient?
- A: Only the spontaneous onset of puberty confirms the diagnosis of constitutional delay. Anxiety from delayed puberty may preclude waiting. To make a presumptive diagnosis of CDGP, pathology must be ruled out:
 - Physical examination, including genital anatomy and sense of smell, must be normal.
 - There should be no signs or symptoms consistent with chronic disease.
 - History, including nutritional history and review of systems, must be negative.
 - Screening blood work must be negative.
 - Growth is slow for age, but height and growth rate are within prepubertal range.
 - A delay in bone age is characteristic but not diagnostic of CDGP.
- Q: When should patients with pubertal delay be seen by an

endocrinologist or adolescent specialist?

- A: Often, the initial workup of pubertal delay can be completed by the primary care provider. For complex stimulation tests, or if help is needed in interpreting test results, referral to an experienced specialist is warranted. If a specific chronic disease is suspected as the underlying cause, then referral should be made to the appropriate subspecialist.

PULMONARY EMBOLISM

Akinyemi O. Ajayi

BASICS

DESCRIPTION

Occlusion of a pulmonary vessel by a thrombus

EPIDEMIOLOGY

- Pulmonary embolism is seen more frequently in adults and tends to occur in postsurgical situations, especially when patients have been bedridden.
- ~10% of adults who present with an acute pulmonary embolus die within 1 hour of onset.
- Increasing incidence is secondary to increased central catheter use.
- Mortality rate can be as high as 30% if diagnosis is delayed.
- The incidence of new cases of pulmonary embolism presenting to a large, urban pediatric emergency department was 2.1 cases per 100,000 visits.

RISK FACTORS

- In children
 - Presence of a central venous catheter
 - Lack of mobility
 - Congenital heart disease
 - Ventriculoatrial shunt
 - Trauma
 - Solid tumors or leukemia
 - After-surgical procedures (especially reparative intervention for scoliosis repair)
 - Hypercoagulable condition
- In adults: most commonly due to the presence of a deep vein thrombosis, usually in the legs or pelvis

PATHOPHYSIOLOGY

- Thromboemboli may develop anywhere in the systemic venous system.
- Pulmonary embolism is characterized by the triad of hypoxemia, pulmonary hypertension, and right ventricular failure.
 - Diminished pulmonary perfusion causes a ventilation–perfusion mismatch, resulting in hypoxemia.
 - Hyperventilation occurs secondary to stimulation of proprioceptors in the lung.
 - Hypercapnia is seen with severe occlusion of the pulmonary artery (often not seen with smaller emboli).
- Pulmonary infarction is uncommon due to the presence of collateral pulmonary and bronchial arteries along with the airways providing additional sources of oxygen to the tissues.
- Death occurs with 85% obstruction of the pulmonary artery.

ETIOLOGY

Blood clots appear as a result of deep vein thrombosis or other disease states.

DIAGNOSIS

ALERT

Failure to make the diagnosis is the most common mistake.

- Pulmonary embolism must be suspected in critically ill children who have a central venous catheter in place and subsequently develop sudden respiratory failure.
- Because the symptoms of severe lung disease and pulmonary embolism are similar, the diagnosis might be missed if the index of suspicion is low.

SIGNS AND SYMPTOMS

- Pulmonary embolism should be suspected in children who present with the following:
 - Pleuritic chest pain
 - Shortness of breath
 - Hemoptysis
 - Cough

- Acute respiratory distress
- Apprehension or anxiety
- Syncope
- Cardiovascular shock
- Symptoms may be nonspecific and indicative of other disorders.

HISTORY

Ask about chest symptoms: The clinician must have a high index of suspicion and recognize risk factors to establish the correct diagnosis.

PHYSICAL EXAM

- Findings on physical examination are nonspecific.
- General
 - Fever
 - Diaphoresis
 - Nervousness or apprehension (altered mental status is uncommon)
- Cardiovascular
 - Increased intensity of the pulmonic component of S₂
 - Tachycardia
 - Gallop rhythm
 - New murmur
- Pulmonary
 - Tachypnea
 - Rales
 - Cyanosis (present with 65% obstruction of the pulmonary artery)
 - Pleuritic chest pain
 - Dyspnea
 - Cough
 - Hemoptysis
 - Wheezing (uncommon)
- Extremities
 - Deep venous thrombosis is frequently found in the adult population.
 - Phlebitis
 - Edema

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In general, blood tests are nonspecific and of no significant value in making the diagnosis of a pulmonary embolus.
- Arterial blood gases
 - Decreased PaO_2 and PaCO_2
 - Increased alveolar–arterial (A–a) gradient

Imaging

- Electrocardiogram
 - Useful in ruling out other conditions
 - May show sinus tachycardia or nonspecific ST-T wave changes
- Echocardiogram
 - Useful for identifying
 - Abnormalities of cardiac anatomy
 - Thrombi on catheter tips
 - If emboli are seen on echocardiogram, mortality rate is 40–50%. Additionally, if signs of right ventricular dysfunction are noted (e.g., right ventricular dilatation, abnormal right ventricular wall motion, or increased tricuspid regurgitation jet velocity), risk of poor outcome is greater.
- Spiral computed tomography (CT)
 - New diagnostic modality
 - Greater sensitivity than ventilation–perfusion scan in the diagnosis of pulmonary embolism due to the ability to image abnormal pulmonary pathology
- Chest x-ray
 - May be abnormal in 70% of patients with pulmonary embolus
 - Most frequent findings:
 - Parenchymal infiltrates
 - Atelectasis
 - Pleural effusions: seen in 33% of cases, mostly unilateral
 - Hampton hump (pyramidal shape pointing toward the hilum)
- Ventilation–perfusion scan
 - Results of a ventilation–perfusion scan performed to rule out a pulmonary embolus are reported in 1 of 5 categories, ranging from high probability to normal.
 - An abnormal ventilation–perfusion scan with normal ventilation and

decreased perfusion in the appropriate clinical setting is 90% specific for a pulmonary embolus.

- A normal result on ventilation–perfusion scan does not completely rule out pulmonary embolus, although if the patient is at low risk, a pulmonary embolus is highly unlikely.
- Pulmonary angiography
 - Most sensitive and specific test
 - Not done as frequently in children as in adults because of complications associated with the procedure
 - With the introduction of newer, improved catheters and safer contrast solutions, this test can now safely be performed in the pediatric population.
 - Indicated for cases
 - Intermediate-probability ventilation–perfusion scans
 - High-probability scans in patients who are poor candidates for anticoagulation, hemodynamically unstable, or require an embolectomy

Diagnostic Procedures/Other

- Pulmonary function testing
 - Results are nonspecific.
- Evaluation of the lower extremities
 - Diagnosing deep vein thrombosis via the following
 - Impedance plethysmography
 - Doppler technology
 - Venography

DIFFERENTIAL DIAGNOSIS

- Cardiac
 - Cardiac tamponade
 - Constrictive pericarditis
 - Restrictive cardiomyopathy
- Pulmonary
 - Chronic cough
 - Status asthmaticus
 - Pneumonia with empyema

- Pneumothorax

TREATMENT

GENERAL MEASURES

Initial Stabilization

- Stabilize patient before anticoagulation or thrombolytic therapy is begun:
 - Improve oxygenation.
 - Correct acidosis.
 - Stabilize blood pressure.
 - Analgesia for severe pleuritic chest pain. Avoid prescribing opiates in cases of cardiovascular collapse.
- Goal of therapy is anticoagulation and/or thrombolysis.
- In patients with an intermediate or high suspicion, begin anticoagulation before investigations.

MEDICATION

- Anticoagulation therapy to prevent further thrombus formation
 - Heparin
 - Bolus dose: 100–200 U/kg
 - Maintenance dose: 10–25 U/kg/h
 - Keep partial thromboplastin time (PTT) at 55–60 seconds.
 - Should be given for 7–10 days
 - Warfarin
 - Warfarin should be started 24–48 hours after heparin therapy is begun.
 - Maintenance dose: 2.5–10 mg/24 h
 - Keep prothrombin time (PT) twice normal and maintain the international normalized ratio (INR) between 2 and 3.
 - Should be continued for 36 months
- Thrombolytic therapy
 - Agents available
 - Urokinase
 - Tissue plasminogen activator (TPA): same efficacy as

streptokinase and lower incidence of allergic reactions

- Indications
 - Hemodynamically unstable
 - Large embolus
- Low-molecular-weight heparin has been used as prophylaxis or as treatment for preexisting conditions in both adults and children.
 - A synthetic, nonthrombocytopenic heparin pentasaccharide with pure antifactor Xa activity is currently being tested.
- Ticlopidine and clopidogrel have been used successfully to prevent thrombotic strokes and arterial thrombotic syndromes.
- Contraindications to anticoagulation therapy
 - Active internal bleeding
 - Recent cerebrovascular accident
 - Major surgery
 - Recent gastrointestinal bleed

SURGERY/OTHER PROCEDURES

- Embolectomy
 - Indicated when hemodynamic instability persists; reserved for patients who have failed thrombolytic therapy or in whom medical treatment is contraindicated
 - Late results are excellent if the patient has not suffered from a perioperative cardiac arrest, which is associated with early mortality.
- Percutaneous caval filtration
 - Indicated if commencement or continuation of anticoagulation is strongly contraindicated or if full anticoagulation has failed to prevent recurrent emboli
 - This should be considered in patients undergoing venous thrombolysis because up to 20% may develop embolization during treatment.

ONGOING CARE

Patients receiving warfarin therapy should have the usual follow-up for

those receiving an anticoagulant.

PROGNOSIS

- If treated promptly, prognosis is good.
- If treatment is delayed, especially if the patient is hemodynamically unstable, prognosis is poor.

CODES

ICD10

I26.99 Other pulmonary embolism without acute cor pulmonale

FAQ

- Q: Is it safe for children on warfarin to play contact sports?
- A: The general recommendation is that no contact sports should be allowed while children are on warfarin therapy because of the increased risk of bleeding.

PULMONARY HYPERTENSION

Richard M. Kravitz

BASICS

DESCRIPTION

Increased pulmonary vascular resistance

EPIDEMIOLOGY

Incidence

Incidence in children is unknown.

PATHOPHYSIOLOGY

- Structural alterations in pulmonary vessel architecture (remodeling)
- Smooth muscle hypertrophy
- Extension of blood vessel's smooth muscle into smaller vessels
- Inflammation

ETIOLOGY

- Hypoxemia-induced pulmonary hypertension
- Chronic lung disease
 - Cystic fibrosis
 - Bronchopulmonary dysplasia
 - Interstitial lung disease
 - Diaphragmatic hernia with secondary pulmonary hypoplasia
- Upper airway obstruction
 - Tonsillar and/or adenoid hypertrophy
 - Obesity
- Hypoventilation
 - Neurologically mediated process
 - Secondary to muscular weakness
- High pulmonary blood flow secondary to left-to-right shunting (seen in congenital heart disease)
 - Patent ductus arteriosus
 - Atrial septal defect

- Ventricular septal defect
- Left-sided cardiac disorders that increase pulmonary venous pressure
 - Left ventricular failure
 - Mitral valve stenosis
 - Obstructed anomalous pulmonary veins
- Occlusion of pulmonary vessels
 - Sickle cell disease
 - Veno-occlusive disease
 - Thromboembolism
- Pulmonary vasculitis
 - Systemic lupus erythematosus
 - Rheumatoid arthritis
 - Scleroderma
- Persistent pulmonary hypertension of the newborn
- Idiopathic cases (primary pulmonary hypertension)

DIAGNOSIS

HISTORY

- Dyspnea (usually earliest complaint reported)
- Fatigue
 - Seen early in course of illness with exercise or exertion (but not at rest)
 - Seen at rest in the later stages of the illness or in severe cases
- Exercise intolerance
- Feeding intolerance
- Failure to thrive
- Excessive sleeping
- Diaphoresis
- Chest pain
- Syncope
- Palpitations (late finding)
- Signs and symptoms pitfalls:
 - Signs and symptoms of pulmonary hypertension are not specific and can easily be missed.

- Consider obstructive sleep apnea as a possible cause of pulmonary hypertension (ask about snoring if suspecting pulmonary hypertension in the absence of overt cardiac or pulmonary disease).

PHYSICAL EXAM

- Typically governed by the signs and findings related to underlying lung or heart disease
- Tachypnea
- Arrhythmias
- Narrowed splitting of S₂ heart sound
- Increased P₂ heart sound
- Presence of S₃ and/or S₄ heart sounds
- Murmur of pulmonary or tricuspid insufficiency; tricuspid insufficiency more common
- Jugular venous distention
- Peripheral edema
- Hepatomegaly

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Arterial blood gases

- Measurement of PO₂ assesses degree of hypoxia.
- Evaluation of PCO₂ determines presence or absence of hypoventilation.

Imaging

Chest x-ray

- Will vary according to the underlying disorder and extent of pulmonary hypertension
- Degree of pulmonary hypertension correlates poorly with chest x-ray findings.
- In primary pulmonary hypertension
 - Cardiomegaly
 - Enlarged pulmonary artery
 - Peripheral lung appears underperfused (“pruning” of pulmonary vessels).

Diagnostic Procedures/Other

- EKG
 - Can be normal if cor pulmonale has not yet developed
 - If cor pulmonale present, EKG can demonstrate
 - Right QRS axis deviation
 - Right ventricular hypertrophy
 - Right atrial hypertrophy
- Echocardiogram with Doppler flow
 - Increased pulmonary artery pressure
 - Right ventricular hypertrophy
 - Paradoxical movement of the intraventricular septum
 - Pulmonic and tricuspid valve regurgitation
 - Right-to-left shunting via an open foramen ovale
- Cardiac catheterization
 - Most accurate measurement of pulmonary artery pressure is accomplished by right heart catheterization.
 - Criteria for pulmonary hypertension in children:
 - Mean pulmonary arterial pressure >25 mm Hg (at rest)
 - Mean pulmonary arterial pressure >30 mm Hg (with exercise)
 - Pulmonary vascular resistance >3 U/m²
 - Systolic pulmonary artery pressure $>1/2$ systolic systemic pressure
- Pressures should be measured before and after various vasodilators to assess potential reversibility of pulmonary hypertension.
- Caution: In patients with severe disease, catheterization is associated with increased risk of complications.

DIFFERENTIAL DIAGNOSIS

- Pulmonary
 - Asthma
 - Cystic fibrosis
 - Chronic obstructive pulmonary disease
 - Emphysema
 - Pulmonary arteriovenous malformations
- Miscellaneous
 - Congestive heart failure (CHF)
 - Noncardiogenic pulmonary edema

- Fatigue
- Syncope

TREATMENT

MEDICATION

- Oxygen
 - Acts as a vasodilator
 - Keep $\text{SaO}_2 \geq 95\%$
 - Supplemental oxygen may prove useful even with normal resting SaO_2 (supplemental oxygen will cover for desaturations associated with exertion, exercise, or illness).
 - Caution: Supplemental oxygen can sometimes cause hypercapnia by blunting the hypoxia-driven respiratory drive.
- Anticoagulation therapy (i.e., Coumadin)
 - Prevents clot formation in the narrowed pulmonary vessels
 - Helpful even in the absence of thromboembolic disease
- Vasodilators
 - Methods of action
 - ▢ Decreases pulmonary arterial pressures
 - ▢ Improves right-sided cardiac function
 - Available agents
 - ▢ Oxygen
 - ▢ Calcium channel blocker (i.e., nifedipine)
 - ▢ Nitric oxide (continuous inhalation)
 - ▢ Prostacyclin (continuous IV infusion) (i.e., epoprostenol)
 - ▢ Endothelin receptor antagonist, PO (i.e., bosentan)
 - ▢ Phosphodiesterase inhibitor PO (i.e., sildenafil)
 - Caution: Vasodilators should be used under close supervision because of their effect on systemic BP (systemic hypotension can be a significant problem).

ADDITIONAL TREATMENT

General Measures

- Provide for patient stabilization.

- Treat the primary disease process.
- Treat underlying hypoxia (supplemental oxygen).
- Treat underlying hypoventilation:
 - Useful for correcting hypoxia and hypercarbia secondary to hypoventilation
 - Available methods:
 - Noninvasive positive pressure ventilation (bilevel ventilation)
 - Mechanical ventilation (tracheostomy with mechanical ventilation)

SURGERY/OTHER PROCEDURES

- Tonsillectomy and/or adenoidectomy if obstructive sleep apnea is the underlying etiology
- Atrial septostomy may be considered when inadequate right-to-left shunting is present with syncopal episodes and/or right-sided heart failure
- Transplantation (lung or heart-lung transplantation): reserved for patients with refractory, severe pulmonary hypertension

ONGOING CARE

PROGNOSIS

- Depends on underlying disease, but generally poor
- In cases of primary pulmonary hypertension, improvement of pulmonary hypertension with administration of vasodilators during initial catheterization is associated with a better survival rate than if no response occurs.
- 10–40% mortality in treated patients
- Near 100% mortality if patient is untreated
- Treatment can be lifelong unless the primary cause of the pulmonary hypertension can be corrected.
- In acute pulmonary hypertension, response to most treatment modalities is almost immediate.
- Oxygen has been shown to reverse hypoxia-related remodeling of the airways after 1 month of therapy.

COMPLICATIONS

- Chronic hypoxia
- Exercise intolerance
- Right-sided heart failure (cor pulmonale)
- Death

CODES

ICD10

- I27.2 Other secondary pulmonary hypertension
- I27.0 Primary pulmonary hypertension
- P29.3 Persistent fetal circulation

FAQ

- Q: How many hours per day should supplemental oxygen be used?
- A: Studies have shown decreased mortality in patients using oxygen 24 hours per day compared with patients using supplemental oxygen for only part of the day.
- Q: Should the dosage of oxygen be adjusted during the day according to the patient's activity?
- A: Increasing supplemental oxygen should be considered for activities that require increased oxygen consumption (i.e., exercise, eating, and sleeping).
- Q: Can an echocardiogram replace the need for a cardiac catheterization?
- A: No. Although an abnormal echo can confirm the presence of pulmonary hypertension, it does not inform one of its severity or the (acute) response to therapy. Furthermore, a normal study does not rule out pulmonary hypertension (especially mild cases).

PURPURA FULMINANS

Victoria E. Price • Anthony Chan

BASICS

DESCRIPTION

- Hematologic emergency characterized by dermal hemorrhagic necrosis and disseminated intravascular coagulation (DIC)
- Associated with a congenital or acquired protein C and/or protein S deficiency
- Life-threatening condition that requires prompt diagnosis and judicious replacement therapy to decrease morbidity and mortality

EPIDEMIOLOGY

- Neonatal purpura fulminans related to homozygous protein C deficiency: 1 in 2–4 million births
- Clinical protein C deficiency: 1 in 20,000 individuals
- Homozygous protein S deficiency is exceptionally rare.
- Predicted prevalence of severe protein C deficiency is 1 in 40,000–250,000 individuals. Significantly less seen in practice, likely due to associated high rate of fetal loss and perinatal mortality

RISK FACTORS

Genetics

- Deficiencies of protein C and protein S are autosomally inherited with variable penetrance.
- Over 150 different genetic mutations of protein C have been described, leading to both qualitative and quantitative defects of the proteins.
- Homozygous protein C or S deficiency and compound heterozygous states are associated with severe deficiency, <1% normal activity level.
- Neonatal purpura fulminans is associated with a severe protein C or S deficiency.
- Coinheritance with other thrombophilias may also contribute to the risk of developing purpura fulminans.
- Heterozygous protein C and S deficiency are associated with a lifetime

increased risk of venous and arterial thrombosis.

PATHOPHYSIOLOGY

Common features of purpura fulminans:

- DIC: Endothelial injury from bacterial endotoxin or other trigger may initiate secretion of inflammatory cytokines or activation of coagulation and complement proteins.
- Purpura: due to perivascular hemorrhage
- Dermal vascular thrombosis: formation of microthrombosis in blood vessels of the skin, leading to hemorrhage in the skin (purpura), necrosis of skin, and gangrene

ETIOLOGY

- Acquired causes:
 - Severe acute bacterial infections: *Neisseria meningitidis* most common
 - Postinfectious fulminans: most commonly associated with varicella and *Streptococcus* infections. Caused by cross-reacting IgG antibodies that increase protein S clearance from the circulation. Consider in an otherwise well child with new-onset purpura fulminans and DIC.
 - Warfarin (Coumadin)-induced skin necrosis
 - DIC
 - Antiphospholipid antibodies
 - Cardiac bypass
 - Severe liver dysfunction
 - Galactosemia
 - Severe congenital heart disease
- Inherited protein C pathway defects
 - Predisposes to a reduced capacity to inhibit thrombin formation and therefore a hypercoagulable state
- Inherited defect of coagulation presenting as neonatal purpura fulminans
 - Protein C slows (“brakes”) the coagulation cascade at two steps: by degrading activated factor V and activated factor VIII.
 - Also plays a role in inflammatory cascade

- Protein S is a cofactor for protein C.

DIAGNOSIS

HISTORY

- Current bacterial sepsis: fever, weakness, dizziness, nausea, vomiting, onset of petechial rash
- Recent history of febrile illness
- Medications (e.g., warfarin)
- Family history suggestive of hypercoagulable state
- History of consanguinity
- Thromboses at an early age, such as stroke, deep vein thrombosis, pulmonary embolism
- Family members taking warfarin (Coumadin) or low-molecular-weight heparin or other anticoagulant
- Previous affected child with purpura fulminans or hypercoagulable state

PHYSICAL EXAM

- Signs of sepsis:
 - Fever
 - Hypotension
 - Tachycardia
 - Poor perfusion
 - Cool extremities
 - Decreased pulses
 - Shock
- Nonblanching purpura
- Acral purpura and necrosis: Check fingers, nose, toes, and penis for black areas.
- Skin lesions initially appear dark red and then become purple-black. Lesions may be mistaken as bruising.
- Bullae may form over purpuric skin.
- Skin lesions occur at previous sites of trauma (e.g., intravenous cannula insertion).

- Pain, ischemia, and edema of extremities or internal organ dysfunction may result from deep vein thrombosis or arterial thrombosis, depending on location and severity.
- Severe protein C deficiency is associated with cerebral vessel thrombosis, vitreous hemorrhage, and retinal detachment. These complications may occur in utero.
- Physical exam trick: Depress the purpuric area with a glass slide to determine whether it blanches.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Screening:

- CBC
 - Platelet count may be low.
 - Hemoglobin may be low.
- Smear screen: thrombocytopenia, schistocytes (evidence of microangiopathic hemolysis)
- Prothrombin time and international normalized ratio (INR): prolonged as in DIC
- Partial thromboplastin time: prolonged as in DIC
- Fibrinogen: decreased with consumption and fibrinolysis
- D-dimer: increased fibrinolysis as in DIC

Etiologic:

- Prior to initiation of treatment, collection of citrated plasma sample for functional activity assays for an accurate diagnosis. Confirm the assay that is used (chromogenic vs. functional), as the results may be discrepant.
- Protein C and S activity levels are undetectable in homozygotes.
- Antigen levels may be helpful if interfering factors (e.g., factor V Leiden mutation, antiphospholipid antibodies, direct thrombin inhibitors) are present.
- Genetic testing of the child and family to confirm diagnosis. Initiation of treatment should not depend on the return of these results.
- Protein C activity in patient, parents, and siblings
- Protein S antigen (total and free) in patient, parents, and siblings
- False positives: Protein C and S levels may decrease because of

consumption during a thrombotic episode that is not related to an underlying congenital deficiency. Low measurements often need to be repeated at baseline after recovery. Protein C and S levels may be below adult normal ranges for the first 3–6 months of life in healthy infants. Pediatric reference ranges should be used.

- Test for antiphospholipid antibodies: usually lupus anticoagulant or anticardiolipin antibody
- Factor V Leiden mutation assay

Imaging

To document presence and extent of suspected large vessel thrombosis: The most useful imaging strategy depends on location and clinical situation:

- Ultrasound with Doppler flow study
- CT scan
- MRI: better for visualization of vessels
- Angiography: most invasive; requires vascular injury for access
- Imaging is potentially useful to
 - Distinguish thrombosis from other pathology
 - Assess clot size prior to anticoagulant or thrombolytic therapy

DIFFERENTIAL DIAGNOSIS

- Infection
 - *N. meningitidis*, most common infectious cause of purpura fulminans
 - Streptococci
 - *Haemophilus* species
 - Staphylococci
 - Gram-negative bacteremia: *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*
 - *Rickettsia*: Rocky Mountain spotted fever
 - Varicella
 - *Plasmodium falciparum*
- Environmental
 - Warfarin-induced skin necrosis: 1 in 500–1,000 individuals starting warfarin therapy develop necrosis in subcutaneous fat.

- Thought to be caused by relative depletion of anticoagulant protein C (a vitamin K–dependent factor) during the initial phase of warfarin effect
- Malignancy: myeloid leukemia
- Congenital: inherited deficiencies of protein C and protein S
 - Only severe, homozygous, or compound heterozygous (<1% activity) deficiencies of proteins C and S are associated with purpura fulminans.
 - Milder, heterozygous deficiencies of protein C and protein S as well as other prothrombotic defects all give rise to hypercoagulable states but usually not neonatal purpura fulminans.
 - Patients with 1 or more risk factors for thrombosis may be more likely to develop purpura fulminans with an environmental stimulus.
- Immune mediated: heparin-induced thrombocytopenia: Antibody to heparin–platelet complex causes platelet activation, thrombocytopenia, and microthrombosis, including dermal vessels.
- Postinfectious purpura fulminans: autoimmune-mediated protein S and C deficiency
- Antiphospholipid antibody syndrome: Predisposition to thrombosis can include skin necrosis.
- Miscellaneous
 - Thrombotic thrombocytopenic purpura
 - Paroxysmal nocturnal hemoglobinuria
 - Henoch-Schönlein purpura

TREATMENT

GENERAL MEASURES

- If classical signs of purpura fulminans, therapy should be commenced emergently.
- Treat underlying cause.
- Anti-infective agents depending on underlying cause
- Manage DIC based on clinical and laboratory findings.

MEDICATIONS

- There is no protein S concentrate available. Fresh frozen plasma (FFP) 10–20 mL/kg every 12 hours or cryoprecipitate is used as replacement therapy.
- Protein C replacement therapy: FFP 10–20 mL/kg every 6–12 hours until protein C concentrate available. 1 mL/kg of FFP will increase plasma protein C concentrate by 1 IU/dL. Aim for trough protein C level of 10 IU/dL.
- Protein C concentrates (human plasma derived): initial dose of 100 U/kg followed by 50 U/kg every 6 hours. Aim protein C trough level of 50 IU/dL.
- Recombinant activated Protein C is no longer available.
- Anticoagulation therapy:
 - Start with replacement therapy in the case of severe protein C or S deficiency. Start with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). Warfarin should only be started after a few days of UFH/LMWH and overlap to avoid warfarin-induced skin necrosis.
- Maintenance therapy for congenital protein C or S deficiency: prophylaxis with warfarin alone (INR target 2.5–3.5) or protein C concentrate 30–50 IU/kg every 1–3 days with warfarin therapy (INR target 1.5–2.5).
- LMWH has been used for maintenance anticoagulation therapy (target anti-Xa 0.5–1.0 U/mL). The role of other new anticoagulants has not been defined.
- Venous access is challenging. Long-term subcutaneous administration of protein C concentrate is reported.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- When to expect improvement: related to underlying cause of purpura fulminans
- Signs to watch for:
 - Spread of purpura

- Hypotension
- Gangrene
- Treatment during the acute phase should continue until all lesions have resolved.
- Referral to ophthalmologist for management and follow-up of ocular lesions
- Monitor INR weekly on maintenance therapy.
- D-dimer can be used as a marker for adequate replacement therapy and anticoagulation. An increasing D-dimer may be the first sign of recurrent purpura fulminans.

DIET

Patients on warfarin therapy may need to avoid foods with high vitamin K content, especially if there is variation in the dose of warfarin required to maintain adequate anticoagulation.

PROGNOSIS

- Related to underlying cause of purpura fulminans
- Overall, poor for homozygous deficiencies of proteins C and S
- Report of cure of protein C deficiency by liver transplantation

COMPLICATIONS

- Skin necrosis and gangrene
- Scarring
- Acral amputations, from tips of digits to whole limbs
- Small and large vessel thrombosis
- Death

- P54.5 Neonatal cutaneous hemorrhage

FAQ

- Q: What is the risk of a 2nd affected child with protein C or S deficiency?
- A: If the diagnosis is confirmed by family studies that show both parents to be carriers of the deficiency and the affected child to be homozygous, there is a 25% chance that each subsequent infant would have purpura fulminans and a 50% chance that each child would be a carrier. However, other hypercoagulable states have been described that may be risk factors for purpura fulminans.
- Q: Should a child with purpura fulminans be followed by a specialist?
- A: Generally yes, with a pediatric hematologist, to assist in acute management of purpura, establishment of diagnosis, and management of long-term anticoagulation.

PYELONEPHRITIS

Michael H. Hsieh

BASICS

DESCRIPTION

Acute pyelonephritis (upper urinary tract infection [UTI]) is a clinical diagnosis that can feature fever, a positive urine culture, and urinary symptoms (e.g., dysuria, frequency/urgency, and/or flank pain).

Histologically, acute pyelonephritis results in acute renal parenchymal (interstitial) inflammation secondary to bacterial invasion.

EPIDEMIOLOGY

- UTIs are more likely to involve the upper renal tracts in children <3 years of age.
- UTIs are more common in females, except in uncircumcised males <3 months of age.

Incidence

Cumulative incidence of UTI during the first 6 years of life:

- 6.6% for girls
- 1.8% for boys

Prevalence

- 5–7% of febrile infants <8 weeks of age
- 1% of all school-aged children
- 1–3% of girls between 1 and 5 years of age
- 0.03% in school-aged boys

RISK FACTORS

- Previous history of UTI
- Sibling with a history of UTI
- Female sex
- Indwelling urinary catheter
- Structural abnormalities of the kidneys and lower urinary tract
- Vesicoureteral reflux (VUR): present in ~30–40% of children with

febrile UTIs

- The majority (>95%) of VUR associated with febrile UTIs is low to moderate grade (grades I–III). Although, there is a stronger statistical association of febrile UTI with high-grade (grade >IV) VUR.
- Uncircumcised boys <3–6 months of age

PATHOPHYSIOLOGY

Specific factors related to development of pyelonephritis:

- Host related
 - Anatomic abnormalities (e.g., obstruction)
 - Functional abnormalities (e.g., bladder and bowel dysfunction, VUR)
- Pathogen related
 - Adherence factors (P and type 1-fimbriae, adhesins)
 - Virulence factors (e.g., lipopolysaccharide, capsular antigen)
 - Formation of antibiotic- and immune clearance-resistant intracellular bacterial pods within urothelium
- Adhesion of bacteria to uroepithelium induces cytokine release and a subsequent inflammatory response.
- Patchy infiltration of the medullary parenchyma by polymorphonuclear leukocytes and lymphocytes leads to degradation of extracellular matrix, tubular disruption, and interstitial edema.
- Parenchymal scarring may result as a consequence of the infection.

ETIOLOGY

- Enterobacteriaceae: *Escherichia coli* most frequent cause (90% of initial infections and in up to 66% of recurrent infections); *Proteus*, *Klebsiella*, *Enterobacter* spp. also implicated
- Gram-positive organisms cause 10–15% of cases: *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*, *Enterococci* spp.
- Other organisms: *Pseudomonas*, *Haemophilus influenzae*, *Streptococcus* group B

COMMONLY ASSOCIATED CONDITIONS

- Struvite kidney stones: associated with urease-producing bacteria (e.g., *Proteus* sp.)

- Anatomic or physiologic abnormality of the collecting system: found in up to 50% of infants with pyelonephritis

DIAGNOSIS

HISTORY

- Fever may be the only presenting complaint.
- In the neonate, inquire caregivers about vomiting, lethargy, poor feeding, irritability, fever, hypothermia, trembling, and jaundice.
- Older children are more likely to present with flank pain, dysuria, frequency, urgency, and incontinence.
- Important factors that predispose to the development of UTI that should be specifically inquired about:
 - Constipation
 - Incorrect toilet training
 - Perineal skin irritation
 - Antibiotic exposure
 - Uncircumcised males
 - Previous UTIs
 - Investigations already performed
 - A family history of UTIs or reflux nephropathy
 - A history of structural abnormalities of the kidneys and/or lower urinary tract
 - Symptoms suggestive of bladder and bowel dysfunction, such as that the bladder always feels full, infrequent use of the toilet, double-voiding, and urgency incontinence
 - Previous surgery or trauma to the back
- Lower motor milestones
- Signs and symptoms:
 - Fever
 - Chills
 - Flank pain
 - Urinary symptoms: dysuria, frequency, urgency

PHYSICAL EXAM

- Findings may be nonspecific.
- Fever, irritability, rigors, lethargy
- Flank tenderness
 - Gentle posterior punch test will reveal tenderness at the costovertebral angle.
 - May be related to underlying renal tract abnormality, such as hydronephrosis; cystic kidney disease; spina bifida, apparent or occult (as evidenced by a dimple); pilonidal sinus; or hemangioma
- Bimanual palpation of kidneys to assess tenderness and size
- Careful neuromuscular exam of lower limbs and back to evaluate for the presence of neurologic abnormalities associated with neurogenic bladder
- Assess rectal tone.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Collect urine using sterile methods (e.g., midstream in toilet-trained children, catheter or suprapubic aspiration for infants).
- Urine dipstick for measurement of leukocyte esterase and nitrites as a rapid screen for UTI
- WBC casts on urine microscopy are diagnostic.
- As a screening test, an unspun clean-catch urine specimen with bacteria on stained microscopic exam correlates (80–90%) with culture results exceeding 100,000 colonies/mL.
- Urine for culture and sensitivity: A positive culture result is defined by the growth of a single pathogenic organism of 100,000 colonies/mL in a clean-catch specimen, $\geq 1,000$ colonies/mL in a catheter-acquired specimen, or any growth in a suprapubic specimen.
- CBC with an elevated WBC count
- Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels are often increased.
- Serum procalcitonin is an emerging biomarker of pyelonephritis.

Imaging

- Renal ultrasound to rule out obstruction and assess renal size and parenchyma if no previous imaging obtained

- Voiding cystourethrogram (VCUG) to rule out anatomic anomalies including obstruction (e.g., posterior urethral valves) and VUR
- ^{99m}Tc-dimercaptosuccinic acid (DMSA) test can be done to confirm the presence of acute pyelonephritis and to look for renal scarring. This is a sensitive and specific test that some clinicians believe to be the imaging study of choice for diagnosing acute pyelonephritis and renal scarring.
- MRI is an emerging imaging modality for pyelonephritis that avoids ionizing radiation.

Diagnostic Procedures/Other

- Imaging evaluation of the urinary tract after a UTI should be individualized based on the child's age, sex, and clinical presentation.
- All children <24 months of age should have an ultrasound.
- It is controversial whether to routinely perform a VCUG in children aged 2 months–2 years with a 1st febrile UTI.
- After the urine is sterile, a VCUG can be performed; there is no need to wait 4 weeks.
- Administer antibiotic prophylaxis before VCUG.

ALERT

- False-positive test results:
 - May be due to nonsterile collection techniques (bagged urine specimen) or allowing urine to stand unrefrigerated
- False-negative test results:
 - The rapid test for nitrites requires urine to stay in the bladder for several hours and is therefore not useful in infants who do not store urine in the bladder.
 - Precollection antibiotic exposure

DIFFERENTIAL DIAGNOSIS

- Cystitis
- Sterile pyuria
 - Vulvovaginitis
 - Balanitis
 - Systemic viral illness
 - Postvaccination

- Pregnancy
- Appendicitis
- Cystic renal disease
- Tuberculosis
- Lower lobe pneumonia

TREATMENT

MEDICATION

- Initiate broad-spectrum antibiotics. Children who appear toxic, are dehydrated, are <2 months of age, or vomiting should receive IV antibiotics until afebrile for at least 24 hours, then change to an oral formulation.
- In total, 7–14 days of oral and/or IV antibiotic therapy are required.
- Consider low-dose antibiotic prophylaxis until an imaging evaluation is completed for patients with 1st time UTIs.
- Children with frequent symptomatic recurrences of UTI and those with high-grade vesicoureteric reflux may benefit from long-term antibiotic prophylaxis.
- Antibiotics such as co-trimoxazole (Bactrim), amoxicillin–clavulanate (Augmentin), and the 2nd-generation cephalosporins are appropriate initial therapy depending on local resistance patterns.
- Familiarity with local antibiotic patterns of resistance is particularly important in treating hospital-acquired infections.
- Antipyretics (e.g., acetaminophen)

ALERT

- Removing struvite or other infected calculi during active infection may precipitate bacteremia/urosepsis.
- High index of suspicion is required for pyelonephritis associated with cystic renal disease, as urine cultures may be negative when the infection is intracystic.

INPATIENT CONSIDERATIONS

IV Fluids

- May be necessary when children are hospitalized with fever and

vomiting to maintain hydration and urine output.

- Underlying anatomic or functional urinary collecting system abnormality should be evaluated/treated by a urologist.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Requirements for testing: Educate caregivers in the symptoms and signs of UTI.

PROGNOSIS

- Fever usually resolves in 3–5 days.
- Ongoing fever or persistent flank pain requires further evaluation to exclude a drug-resistant organism, kidney stone, kidney abscess, or urinary tract obstruction.
- Diagnosis and treatment of any underlying bladder and bowel dysfunction and constipation are required for successful management of UTIs in children.
- Outcome of acute pyelonephritis is usually good but may result in parenchymal scarring.
- Pyelonephritis associated with struvite renal stones requires removal of the infectious stones after antibiotic treatment is completed.
- Risk factors for renal damage include obstruction, reflux with dilation, young age, delay in treatment, number of episodes of pyelonephritis, and bacterial virulence factors.

COMPLICATIONS

- Acute:
 - Reduced concentrating ability, hyperkalemic renal tubular acidosis (transient mineralocorticoid resistance)
 - Bacteremia: highest risk in young infants (23% of children <2 months of age)
 - Perinephric abscess formation
- Chronic:
 - Focal renal scarring, hypertension, proteinuria, azotemia,

- N10 Acute tubulo-interstitial nephritis
- N11.9 Chronic tubulo-interstitial nephritis, unspecified

FAQ

- Q: Should a DMSA scan be used to help diagnose acute pyelonephritis?
- A: Routine use of the DMSA scan to diagnose acute pyelonephritis is controversial because disagreement exists about the therapeutic implications of a positive test result, and such routine testing is expensive. Children with hypertension and previous UTIs require a DMSA scan to look for renal cortical scarring.
- Q: Does renal parenchymal scarring occur without reflux?
- A: Yes. The causal relationships among reflux, acute pyelonephritis, and renal parenchymal scarring are complex.

PYLORIC STENOSIS

Pradeep P. Nazarey

BASICS

DESCRIPTION

Hypertrophy of the muscular layers of the pylorus with elongation and thickening, leading to projectile nonbilious emesis and gastric outlet obstruction

EPIDEMIOLOGY

- Usually presents between the 3rd and 10th week of life
- Male-to-female ratio 4:1, with first-born males more affected.
- More common in Caucasians

Incidence

~2–4 per 1,000 live births in Western populations

PATHOPHYSIOLOGY

- Marked muscle hypertrophy and hyperplasia primarily involving the circular layer and hyperplasia of the underlying mucosa
- Growth of abnormally contorted and thickened nerve fibers and/or lack of neural elements
- Net result is either partial or complete obstruction of the pyloric channel.

ETIOLOGY

- No definitive causative factors have been identified despite considerable research.
- Genetic predisposition evidenced by variability among races, male preponderance, and genetic syndromes with pyloric stenosis
- Children of affected fathers are affected 3–5%, whereas affected mothers are associated with a 7–20% incidence.
- Several growth factors and gastrointestinal (GI) peptides, including gastrin and elevated acid levels, as well as increases in substance P, EGF, TGF α , and IGF-1, have been implicated.

- Erythromycin estolate given for postexposure prophylaxis for pertussis may cause strong gastric and pyloric contractions that induce hypertrophy. Lactating mothers exposed to erythromycin show babies with increased incidence of pyloric stenosis.
- Decreases in nerve differentiation, reduced density of neural elements, and deficiency of nitric oxide–induced muscle relaxation have been implicated.

COMMONLY ASSOCIATED CONDITIONS

Increased occurrence of esophageal atresia and malrotation was noted in 5% of infants with pyloric stenosis.

DIAGNOSIS

HISTORY

- Emesis
 - Otherwise healthy full-term infant that initially vomits intermittently
 - Over time (approximately 2 weeks), frequency slowly progresses to emesis with nearly every feeding.
 - Emesis becomes forceful or projectile.
 - Color of vomitus will resemble the feeds and is nonbilious.
- Infants look well appearing but act hungry.
- There may be a history of prescription of antireflux medications or formula changes that have no effect on symptoms
- Parents describe a decrease in the frequency of wet diapers.
- As dehydration progresses, infants will become less vigorous and increasingly lethargic.

PHYSICAL EXAM

- Dehydration
 - Infants may have decreased skin turgor, flat fontanelles, and dry mucous membranes.
 - Infants are usually tachycardic and may be hypotensive.
- Abdominal exam
 - Visible peristalsis may be appreciated just after the infant feeds, which is seen as a waveform proceeding from the left upper

quadrant toward the pylorus in the right upper quadrant.

- A palpable, hard, mobile, and nontender mass in the epigastrium to the right of the midline, referred to as an “olive” (palpable 45–75% of cases)
- Palpation should be attempted after the stomach has been emptied and with the infant quiet and comfortable and can take time.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hypochloremia and metabolic alkalosis
- Hypokalemia
- 2–5% of infants have indirect hyperbilirubinemia associated with jaundice.

Imaging

- Ultrasound
 - Primary modality for diagnosis
 - Ultrasonography identifies the hypertrophic pyloric musculature and identifies wall thickness and channel length.
 - Can see “shoulder sign,” which is bulging of hypertrophic muscle into lumen of antrum
 - To confirm the diagnosis, muscle thickness should be >3 mm and pyloric length >15 mm.
- GI studies
 - An upper GI study may be an adjunct if qualified ultrasonographer is unavailable.
 - Can see “string sign” of contrast going through narrowed pyloric channel

DIFFERENTIAL DIAGNOSIS

- Gastroesophageal reflux
- Gastroenteritis
- Milk protein allergy
- Anatomic considerations
 - Malrotation
 - Webs
 - Pyloric atresia

- Duplications

TREATMENT

INPATIENT CONSIDERATIONS

Initial Stabilization

- Early identification of electrolyte abnormalities and correction with appropriate IV fluids
- Bolus with 10–20 mL/kg of NS
 - Followed by initiation of maintenance fluids of D.45NS + 2 mEq KCl/100 mL at 6 mL/kg/h
 - Goal urine output is >2 mL/kg/h
- Surgery is definitive treatment but is not emergent or urgent. Electrolyte anomalies and alkalosis must be corrected prior to OR.
- Postop feedings usually resume within 4–6 hours after surgery, with spitting up or vomiting common.
- Discharge within 1–2 days

SURGERY/OTHER PROCEDURES

- Pyloromyotomy (Ramstedt procedure): longitudinal incision and spreading of the antropylic muscle either through an RUQ or umbilical incision
- Laparoscopic pyloromyotomy is safe, feasible, has been gaining traction, and is favored by many surgeons over an open approach.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Vomiting may persist for several days after surgery.

ALERT

- Do not fail to appreciate that alkalosis must be corrected prior to surgery to prevent difficulty with extubation as well as risks of postop apnea and death.
- Infants should undergo aggressive fluid resuscitation.

PROGNOSIS

Morbidity and mortality rates are low; surgery is curative with virtually no recurrence.

COMPLICATIONS

- Dehydration
- Electrolyte abnormalities, primarily hypochloremic, hypokalemic metabolic alkalosis that results from loss of hydrochloric acid and fluid caused by persistent vomiting
- Postoperative complications
 - Incomplete pyloromyotomy
 - Difficult extubation after surgery
 - Postoperative apnea
 - Mucosal injury; may lead to leak and sepsis if not immediately recognized and repaired

CODES

ICD10

Q40.0 Congenital hypertrophic pyloric stenosis

FAQ

- Q: What is the best initial imaging study to help make the diagnosis?
- A: An abdominal ultrasound is the best initial imaging study to obtain,

as the pylorus can be well visualized.

- Q: Why is so much chloride lost?
- A: The chloride loss occurs with the loss of gastric acid, which contains hydrochloric acid.
- Q: What plan should I follow when replacing electrolytes?
- A: Correct the deficiency of fluids with 1.5–2× maintenance fluid volumes. Correct chloride loss with normal saline, and correct potassium loss with potassium chloride.

RABIES

Sergio E. Recuenco

BASICS

DESCRIPTION

Fatal acute viral encephalomyelitis transmitted from animals to humans through bites or exposure to saliva or nervous tissue from a rabid animal. Only mammals are able to contract and transmit the disease.

EPIDEMIOLOGY

- An estimated 55,000 deaths are due to rabies every year in the world, most of them in Asia and Africa. Many of the affected countries do not have proper surveillance systems for rabies.
- Only 1–3 human cases reported annually in the United States. Imported cases infected overseas add 1–3 more cases annually.
- The dog is the main animal reservoir in most of world. In the United States and most developed countries, canine rabies had been eliminated.
- Wildlife such as bats, raccoons, skunk, and foxes are main reservoirs in North America, with frequent spillover to cats, dogs, and other domestic animals.
- All of the continental United States is enzootic for bat rabies, whereas transmission among terrestrial reservoirs occurs in specific geographic regions such as the Eastern United States (raccoon); south central, north central areas, and the state of California (skunk); south west (fox); Alaska (Arctic fox); and Puerto Rico (mongoose).
- Hawaii is considered rabies-free.

Incidence

- From 2003 to 2013, there were 24 cases of rabies acquired in the United States, 19 of these were associated with bat rabies strains, 3 with raccoon rabies, 1 with mongoose rabies, and 1 of unknown origin.
- 30% of the cases were 18 years old or below.
- A total of 5 rabies cases were due to organ transplant.

- The real burden of human rabies exposure in the United States is unknown, but 36,000 individuals are estimated to receive postexposure prophylaxis (PEP) every year across the country.
- Wildlife accounts for 92% of all animal rabies cases; raccoons continue as the most frequent species (32%), followed by bats (27%), skunks (25%), foxes (6%), and other wildlife (2%).

RISK FACTORS

- Travel to areas where canine rabies is endemic
- Recent scratch or bite from known animal reservoir species including bats or other wildlife; exposure from an unvaccinated domestic animal (e.g., cat, dog) without the ability for appropriate management
- Transmission from transplanted corneas, vessels, and solid organs has occurred.
- Working with animals (e.g., veterinarians) or working in a laboratory with the virus
- Outdoor occupations and recreational activities that increase contact with high-risk species
- Mass exposures to potentially rabid animals (e.g., bats, cats) may occur in summer camps, county fairs (e.g., rabid goat), petting zoos (e.g., rabid sheep), schools, and public events.

GENERAL PREVENTION

- Targeted to humans and domestic animals
- Immunoprophylaxis: Preexposure rabies prophylaxis (Pre-EP) is offered to those at high risk (e.g., veterinarians, animal handlers, trappers, travelers to high-risk regions).
- Avoid unnecessary contact with wild animals in the United States and overseas.
- Pets should be vaccinated and kept updated on their immunizations.

PATHOPHYSIOLOGY

- Except for rare cases, the rabies virus enters the body through a bite that breaks the skin and introduces infected saliva:
 - From there, the virus gains access to muscle, where it is sequestered.
 - The virus then enters the peripheral nerves, where it moves

- centripetally to the CNS at a rate of ~3 mm/h.
- Once in the CNS, infection spreads rapidly throughout many areas of the brain.
 - Neurologic manifestations progress rapidly from sensorial alterations to coma.
 - Leads to autonomic instability, the mechanisms of which are still poorly understood, which leads to acute death
 - Average incubation period is 2–3 weeks to 2–3 months and, in rare cases, is suspected to be several to many years, with the longest documented incubation being 8 years.

ETIOLOGY

The 14 known members of the Lyssavirus genus, rhabdovirus family (rabies virus, Lagos bat virus, Mokola virus, Duvenhage virus, Aravan virus, Irkut virus, Khujand virus, European bat lyssavirus types 1 and 2, West Caucasian bat virus, Australian bat lyssavirus, Shimoni bat virus, Ikoma virus, and Bokeloh virus) are suspected to be capable of causing human rabies death. Lyssaviruses are single-stranded RNA viruses, and all except Mokola had been associated with bats. Most cases are due to the rabies virus, with rare cases due to the other lyssaviruses.

DIAGNOSIS

HISTORY

- Behavior of animal: Although signs of rabies in animals vary greatly, atypical behavior for the animal is the norm (e.g., passive animals become aggressive, nocturnal animals roam in daylight).
 - Excessive salivation and lack of coordination may be present.
- Probably due to long incubation periods, some human rabies cases lack a history of animal contact probably because the contact may have seemed trivial at the time (i.e., from a small bat).
- Assessment for postexposure prophylaxis considers risk of rabies in the species, clinical presentation of the exposing animal, route and severity of exposure, and availability of the animal for observation or testing.
- Signs and symptoms

- Prodrome: 2–10 days with vague and insidious symptoms (e.g., sore throat, malaise, anxiety, change of behavior, hallucinations, fever). Other prodromal symptoms observed are itching, pain, or tingling at the site of the bite.
- Acute neurologic phase: furious (80%) versus paralytic (20%) rabies
 - Furious rabies: agitation, hyperactivity, bizarre behavior, nuchal rigidity, sore throat, and hoarseness. The pathognomonic sign is hydrophobia and, at times, aerophobia.
 - Paralytic rabies: Initial finding is flaccid paralysis in the limb that was bitten; subsequently spreads to other limbs. Cranial nerve involvement can give complete lack of facial affect.
 - Coma: Onset follows acute neurologic phase; may persist up to 2 weeks and is followed by death almost universally

PHYSICAL EXAM

- Although neurologic findings can vary, cranial nerve paralysis (e.g., palate, vocal cords) is common. Therefore, hoarseness and stridor may occur.
- Meningismus is also fairly common, along with involuntary movements. Beyond this, findings depend on type of presentation (furious vs. paralytic).
- Imaging (e.g., MRI, CT) is unremarkable or unspecific.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Existing diagnostic methods for rabies virus infection are not useful before the onset of clinical signs. However, after signs appear, human antemortem laboratory diagnosis is possible with a set of 4 samples: serum, CSF, skin biopsy of at the hairline at the back of the neck, and fresh saliva. All 4 samples need to be taken on the same day and shipped express on dry ice. The following standard methods are used to rule out rabies:
 - Reverse transcription PCR for rabies RNA detection in saliva and skin
 - Direct fluorescent antibody test (DFA) on cryostat sections of the

skin biopsy

- Virus-neutralizing antibody detection in CSF and serum with RFFIT
- Indirect fluorescent antibody test on CSF and sera to detect IgM and IgG that may bind to rabies virus antigens present in infected cell culture
- Postmortem diagnosis is made by DFA and PCR in samples from brainstem, cerebellum, and sometimes other samples.

DIFFERENTIAL DIAGNOSIS

- Other causes of encephalitis to consider: herpes simplex virus, enterovirus, West Nile virus, and other arbovirus encephalitis; Rocky Mountain spotted fever and other rickettsial encephalitis; Japanese encephalitis; Guillain-Barré syndrome; limbic encephalitis; tetanus; acute disseminated encephalitis; Bartonella encephalitis
- Other conditions can mimic rabies: delirium tremens, cocaine overdose, amphetamine overdose, and acute psychosis
- Case reports of rabies wrongly diagnosed as cerebral malaria exist in countries with high malaria risk.

TREATMENT

MEDICATION

- Immunization: Both passive and active immunization should be initiated concurrently when an exposure is identified. Local or state health departments can advise about the risk of specific animal exposures.
- Passive
 - Human rabies immune globulin (HRIG) derived from the plasma of volunteers hyperimmunized with rabies vaccine
 - The present recommendation for HRIG vaccination is 20 IU/kg instilled locally into the tissue at the site of the bite.
 - Remaining HRIG can be given IM, avoiding the arm in which the rabies vaccine (RV) is administered.
 - In cases of multiple wounds, to ensure that all wounds receive an injection of HRIG, dilution in saline (2–3-fold) is acceptable.

- HRIG is only administered the day 0 of the PEP schedule simultaneously to the first dose of RV. In case not available at the same time of first dose of RV, still can be administered until day 7; after that, it is not necessary.
- Active
 - Two RVs are licensed in the United States: human diploid cell rabies vaccine (HDCV) and purified chick embryo cell vaccine (PCEC).
 - For Pre-Ep, the recommended schedule is 1 mL of RV IM dose in the deltoid area on days 0, 7, and 21 or 28. No HRIG is used.
 - For PEP, the current schedule in the United States is 1 mL of RV IM in the deltoid region on days 0, 3, 7, and 14. For immunocompromised patients, an additional dose on day 28 is given. The anterolateral thigh can be used in infants or young children.
- Discontinue the vaccine series if fluorescent antibody testing of the brain of the biting animal is conducted and result is negative, or if it is a cat, dog, or ferret healthy after a period of 10 days of observation after the bite.

INPATIENT CONSIDERATIONS

Initial Stabilization

Local wound care immediately after bite

- The 1st step in preventing infection is washing out the virus mechanically or inactivating it before it has a chance to attach to and enter susceptible cells.
- The wound should be flushed with copious amounts of soap and water or saline solution.
- For puncture wounds, insertion of a catheter (i.e., angiocatheter) and irrigation with fluid by means of an attached syringe should be performed. If irrigation is too painful, infiltration of the area with local anesthetic can help.

For symptomatic patients after incubation period

- Request antemortem rule out rabies tests.
- Palliative and supportive care should be made available in an intensive care unit.

- Consider experimental therapies (e.g., induced coma) in selected patients (e.g., early rabies confirmation, young age).

ONGOING CARE

PROGNOSIS

- After the patient CNS is infected with the rabies virus, prognosis is poor. There is no medical therapy available once the encephalitis onset, and after that, PEP is no longer indicated.
- Without PEP before clinical presentation, the disease is fatal with very rare survivors.
- 10% of patient survival had been observed following intensive care and induced coma (see www.mcw.edu/rabies) attempted in about 50 of cases. Three of 7 survivors using this regimen are still alive; the other patients survived the acute illness but died of complications during rehabilitation.

CODES

ICD10

- A82.9 Rabies, unspecified
- Z20.3 Contact with and (suspected) exposure to rabies

FAQ

- Q: Does a wild squirrel or rabbit bite necessitate rabies prophylaxis?
- A: In general, rodents (e.g., squirrels, rats, mice, hamsters, gerbils, etc.), lagomorphs (e.g., rabbits and hares), and marsupials are not known to serve as natural rabies reservoirs. They should not be considered rabid unless they exhibit unusual behavior.
- Q: Is there any evidence of human-to-human spread?
- A: No. However, health care workers or others exposed to a patient with known or suspected rabies should receive vaccination if they have suffered a bite wound or if mucosal surfaces or open wounds have been exposed to the patient's body fluids.
- Q: Are there any countries that require “routine rabies vaccination”?
- A: Yes, Nepal. Recently, Peru and Ecuador started mandatory vaccination programs restricted to very high-risk areas in Amazonia.
- Q: What if a severe allergic reaction occurs during postexposure rabies prophylaxis?
- A: The reaction should be treated at the time as you would any systemic anaphylactic reaction. PEP should continue after that using a different RV and taking additional precautions. The two RVs licensed in the United States (PCECV, HDCV) are interchangeable if indicated.
- Q: If a bat is found in the house, should the family members receive immunoprophylaxis?
- A: If a bat is found in the room of a sleeping person, previously unattended child, or mentally compromised person, it should be tested. If the bat escapes, prophylaxis should be considered case by case. The injury inflicted by a bat bite or scratch may not be obvious.

RECTAL PROLAPSE

Joel Friedlander

BASICS

DESCRIPTION

There are three types of rectal prolapse:

- Complete: Full thickness of rectum prolapses through anus (2 layers of rectum with an intervening peritoneal sac, which may contain small bowel).
- Incomplete/mucosal: prolapse limited to only 2 layers of mucosa
- Concealed: internal intussusception of upper rectum into lower, with no extrusion into the anus

EPIDEMIOLOGY

- Most cases occur in children <4 years of age around time of toilet training; equal incidence in boys and girls
- In older children and adults, strong (6-fold) female predilection
- Common in developing countries, perhaps because of poor nutrition and parasitic infection; less common in the Western world

RISK FACTOR

- Cystic fibrosis
 - Typically presents between 6 months and 3 years of age in patients with cystic fibrosis (CF)
 - Incidence is 20%.
 - Presentation in children with CF >5 years of age is rare.

ETIOLOGY

Exact etiology uncertain, but the following are usually related findings and predisposing conditions:

- Excessive straining with bowel movements from constipation and toilet training (hips and knees flexed) is the most common cause in the Western world.
- Diarrhea; may be more of a cause in tropical and subtropical countries

- Infections: hookworms and other parasitic infections
- Malnutrition; can cause loss of the ischiorectal fat pad
- Complication of past surgery, such as imperforate anus repair
- Complete prolapse is rare in children, but when it occurs, it may be related to poor fixation of rectum to sacrum and to weak pelvic and anal musculature.
- CF
- Ulcerative colitis
- Hirschsprung disease
- Ehlers-Danlos syndrome
- Meningomyelocele
- Pertussis
- Rectal polyp
- Pneumonia
- Anorexia
- Rectal neoplasm

Genetics

- Inheritance patterns depend on associated underlying etiologies.
- No known inheritance pattern for idiopathic rectal prolapse.

DIAGNOSIS

HISTORY

- Signs and symptoms:
 - Protrusion of rectal layers through anus, usually found during defecation or attempted defecation
 - Although the history of rectal prolapse may be evident, it is often difficult to elicit on examination, and by the time the patient is seen after a prolapse at home, it may already be spontaneously reduced. Thus, the assumption of the diagnosis may have to rest primarily on the parental history.
 - Although usually benign, rectal prolapse is distressing to both the parents and the child.
- Assess for symptoms of CF, risk factors for CF, or for symptoms of

other associated conditions (infection, malnutrition, etc.).

- Suggest pictures to be taken by family when it occurs.
- Often reduces spontaneously; if not, can instruct parents to attempt reduction manually
- Rectal prolapse may cause some discomfort during bowel movements.
- Trauma to the recurrently prolapsed mucosa may lead to ulceration and mucus discharge.

PHYSICAL EXAM

- Usually, prolapse is not seen on examination while the patient is at rest, unless it is irreducible (dark or bright red mass protruding from child's anus without discomfort).
- May see poor anal tone and/or large anal orifice, especially within hours after the prolapse
- In complete rectal prolapse, concentric mucosal rings can be seen, whereas incomplete (mucosal) prolapse reveals radial folds.
 - If clinician sees >5 cm of rectum emerging, it is most likely a complete prolapse.
 - Asking the patient to strain may allow the mucosa to prolapse. However, this may be challenging in young patients.
- If prolapsed mucosa visualized, insert a finger around the prolapsing apex of the intussusception, between it and the lining of the anal canal.
- Will appear different from a polyp, which is generally plum-colored and does not involve the entire anal circumference

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Sweat test
 - All children with rectal prolapse should have a sweat test to rule out CF.
 - Complete CF genetic testing can be considered but is more costly.
- Stool cultures for bacterial and parasitic infestations
- Other tests for the aforementioned conditions as clinically indicated

Imaging

- Evacuation proctography
 - A barium enema is given, and movement of barium is observed

- under fluoroscopy during defecation.
- This study may reveal an internal prolapse not easily recognizable on physical examination.
- This study is not commonly used in children because full cooperation is essential.
- Consider AP/lateral lumbosacral imaging to evaluate for spinal fusion anomalies.

DIFFERENTIAL DIAGNOSIS

- Tumors
- Prolapsing rectal tumor
- Trauma
- Sexual abuse (e.g., result of anal penetration)
- Metabolic
- CF: From 10 to 50% of patients diagnosed with CF, >4 years of age have experienced rectal prolapse (either at the time of the diagnosis or as a past event), but few individuals with rectal prolapse have CF.
- Anatomic abnormality (such as absence of Houston valves in infants)
- Solitary rectal ulcer syndrome: An uncommon benign condition usually affecting older children that involves rectal bleeding on defecation is common.
- Prolapsing polyp
- Large hemorrhoids
- Colonic intussusception
- Constipation
- Ehlers-Danlos syndrome
- Hirschsprung disease
- History of imperforate anus
- Pertussis/pneumonia
- Ulcerative colitis
- Meningomyelocele

TREATMENT

MEDICATION

- Stool softeners (i.e., docusate, polyethylene glycol) to relieve constipation or medication with the associated condition
- In patients with CF, optimization of pancreatic enzyme supplementation. Associated with significant improvement in rectal prolapse in this population

ADDITIONAL TREATMENT

General Measures

- Rectal prolapse in children <4 years of age has strong tendency to resolve spontaneously over time (90%).
- Patients who develop rectal prolapse at >4 years of age have less certain prognosis.
- Patients who present with a prolapsed rectum should undergo manual reduction in a prone position:
 - Parents should be provided with gloves and lubricant and taught how to reduce the prolapse.
 - The prolapsed bowel may be grasped with lubricated gloved fingers and pushed back in with gentle steady pressure.
 - If the bowel has become edematous, firm steady pressure for several minutes may be necessary to reduce the swelling and allow for reduction.
 - Digital rectal examination should always follow this procedure to verify complete reduction.
 - If the prolapse immediately recurs, it may be reduced again and the buttocks taped together for several hours.
- The prolapse will resolve more successfully and quickly if the patient is treated for constipation:
 - This should include both dietary manipulations (e.g., increased fiber, hydration) and improved defecation methods.
 - It also will usually require the use of supplemental aids such as laxatives (polyethylene glycol).
- A small child should try to defecate with his or her hips at 90 degrees, his or her buttocks at toilet seat level, and on an appropriately sized toilet.
- In the rare case of stool infection with diarrhea as the underlying etiology, the appropriate therapy for that infection should be instituted.

SURGERY/OTHER PROCEDURES

Numerous (>130) approaches have been attempted and advocated with varying degrees of enthusiasm, suggesting that none is perfect. Across all procedures, including as follows, efficacy is higher in older patients >4 years old:

- Perianal sutures: poor results and high complication rate
- Delorme procedure: Rectal mucosa is excised, and underlying rectal muscle is plicated with sutures.
- Laparoscopic suture rectopexy: Rectal wall is exposed and then sutured to the fascia of the sacral promontory; 5% full thickness recurrence rate
- Abdominal rectopexy: Rectum is mobilized and attached to the sacrum by prosthetic material. Although the procedure provides good results, it has a high complication rate of constipation (>50%).
- Anterior resection rectopexy: resection of the sigmoid loop and upper rectum; good results, but again, high complication rate
- Perineal resection: perineal rectosigmoidectomy with a coloanal anastomosis; good results
- Circumferential injection procedures (90–100% success rate): injection of phenol, oil, hypertonic saline, dextrose 50% solution (500 g/L), or ethyl alcohol to promote adhesion and stabilization of the rectum
- Lockhart–Mummery operation (near 100% success): Mesh pack is placed temporarily in the retrorectal space (8–10 days) to promote adhesions that stabilize rectum.

INPATIENT CONSIDERATIONS

Initial Stabilization

Palliative

- Reassurance of patient and/or family and caregivers
- Teaching around techniques of manual reduction
- Education regarding pros and cons of surgery, which may appear to offer more definite solution, but are not without risk and may lead to further complications. In most cases, it may be more prudent to allow time and medical management to solve the problem.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Ongoing Treatment

- Treatment of constipation should continue indefinitely, or until the child has demonstrated regular bowel habits on a high-fiber diet on his or her own without evidence of prolapse for at least several months.
- Intermittent parental observation to ensure child is avoiding straining with defecation

DIET

- Increase consumption of liquids.
- Add larger amounts of fiber to diet (goal: 5 g + age in years = total g/day fiber intake).

PROGNOSIS

- With proper medical management, there is an excellent prognosis, defined as resolution without surgery.
- May require months to years on a good dietary and behavioral regimen

COMPLICATIONS

- In some older patients who may also have an overactive external sphincter, the need to generate high rectal pressures to defecate, together with the rectal prolapse, may cause venous congestion and solitary rectal ulcer syndrome.
- Repetitive trauma to mucosa can produce proctitis.
- Surgical complications of repair
- Frequent recurrence

CODES

ICD10

K62.3 Rectal prolapse

FAQ

- Q: What should I do if my child has a rectal prolapse but I cannot reduce it?
- A: You should wrap the prolapse in moist towels and bring your child to the emergency department. Physicians there will try to reduce it. Rarely, if a prolapse is irreducible and left for a period of time, it can cause bowel ischemia and may require surgery.
- Q: My child has rectal prolapse and now he is supposed to have a sweat test to determine whether he has CF. Is this very likely?
- A: No. Although it is important to rule out this disease, most patients with rectal prolapse do not have CF. However, many children with CF suffer from rectal prolapse.
- Q: My child, who has rectal prolapse, is in day care. How will I know if he is having the prolapse?

- A: You should inform someone in the school (a teacher or guardian) of his condition, and he or she should check the child for prolapse after a bowel movement. Although, if present, it usually resolves spontaneously, the teacher should inform you so you can do a manual reduction, if necessary.

REFRACTIVE ERROR

Leah G. Reznick

BASICS

DESCRIPTION

- Refractive errors are abnormalities in the optical components of the eyes that cause light not to be focused on the retinal plane. In order for a person to have clear vision, light entering the eye must precisely focus on the retina.
 - Uncorrected refractive errors blur vision in one or both eyes.
 - If left untreated in children, uncorrected refractive errors may cause permanent vision loss from amblyopia and strabismus (see “[Amblyopia](#)” and “[Strabismus](#)”).
- Refractive errors are measured in diopter units.
- Refractive errors can be classified in three groups based on the optic effects ([Appendix, Figure 1](#)):
 - Myopia (near-sightedness): Objects are focused in front of the retinal plane. Near vision is clearer and distance vision is more blurry. Optical correction is with concave lenses (negative power).
 - Hyperopia (far-sightedness): Objects are focused behind the retinal plane and optical correction contains convex lens (plus power).
 - Astigmatism: Unequal curvature of the cornea causing the cornea to be more curved in one direction than another (aspherical). The shape of the cornea is more like a football than a basketball in astigmatism.
 - Images are blurred at near and far distances.
 - Astigmatism can occur concomitantly with myopia and hyperopia.
- Other terms related to refractive error include the following:
 - Emmetropia: No refractive error. Objects are focused on the retinal plane.
 - Anisometropia: Unequal refractive error between the two eyes that increases the risk of amblyopia

- Accommodation: the changing of the shape of the eye's lens to focus clearly at near or all of the time in hyperopes

EPIDEMIOLOGY

Prevalence of refractive errors varies during childhood as the optical components change with development. At birth, usual median refractive error is low hyperopia, approximately +2.00 diopters. In adults, the median is emmetropia; approximately 30% require optical correction.

Prevalence

- In children aged 5–17 years, the prevalence of visually significant refractive error varies on type.
 - Myopia = 0.7–5.0%
 - Hyperopia = 4.0–9.0%
 - Astigmatism = 0.5–3%
- The prevalence and type of refractive error varies among ethnic groups. For example, people of Native American, Chinese, and Japanese descent have an increased prevalence of myopia.

RISK FACTORS

Genetics

- Both genetic and environmental factors are important in refractive status. ~60% of myopia can be predicted by parental degree of refraction.
- There is an increased prevalence of visually significant refractive errors in individuals with prematurity, autism, and cerebral palsy.
- Some genetic syndromes or medical problems associated with refractive errors include the following:
 - Myopia is associated with Stickler, Marfan, Down, and Ehlers-Danlos syndromes.
 - Hyperopia is associated with Senior-Loken syndrome, WAGR (Wilms tumor, aniridia, genitourinary malformations, mental retardation) syndrome, and Down syndrome.
 - Astigmatism is associated with Down syndrome, craniofacial abnormalities, and albinism.
 - Environmental factors associated with refractive error include prematurity, eye surgery, and trauma.

GENERAL PREVENTION

- Early detection and correction of refractive errors is important to prevent amblyopia and strabismus. A child should be able to perform a visual acuity examination by age 4 years.
- Children with significant refractive errors are often asymptomatic. All children should be screened for visual acuity in each eye.
- Glasses may not improve vision alone because of amblyopia (maldevelopment of the brain's ocular cells). Patients with suspected amblyopia should be rechecked even if wearing glasses.

PATHOPHYSIOLOGY

- The three most important determinants of refractive error include the cornea, lens, and axial length of the eye. The cornea and lens bend light to meet the retina in order to create a sharply focused image. The optical power of the cornea and lens must match the actual eye length (distance from cornea to retina). If the cornea and lens do not bend light to hit the retina, there is a refractive error and can blur the vision.
- Small amounts of hyperopia are normal for children. With small hyperopic errors, a child's eye can easily bring objects into clear focus by adjusting the shape of the lens (accommodation). These children have no problems seeing at far or near distances.
- With larger amounts of hyperopia (greater than +3.50 diopters), a child's vision may be blurred at distance and near because accommodation may be limited or cause esotropia (see "[Strabismus](#)").
- The refractive components evolve as the eye develops over childhood. The cornea, lens, and eye length should simultaneously develop to lead to emmetropia. Factors determining the normal and abnormal growth of eye are not completely understood.
- There are likely genetic and environmental factors determining the growth of the eye. There may be an association with increased level of education and increased incidence of myopia. Epidemiologic data suggest that increased amount of time spent outdoors protects against the development of myopia.

COMMONLY ASSOCIATED CONDITIONS

Refractive errors are frequently associated with other ocular conditions.

- Anisometropia is associated with nasolacrimal duct obstruction.
- Myopia is associated with childhood glaucoma, deprivation amblyopia, retinopathy of prematurity, retinal dystrophies, coloboma, and retinal detachments.
- Hyperopia is associated with esotropia, Leber congenital amaurosis, and aphakia (absence of lens).
- Astigmatism is associated with ptosis, coloboma, glaucoma, retinopathy of prematurity, lid hemangioma, nystagmus, and limbal dermoid.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Blurred vision
- Headache
- Squinting
- Torticollis
- Strabismus

HISTORY

- Age of onset of vision loss
- History of headaches, squinting, or subjective vision problems
- Associated ocular abnormalities, trauma, injury, or surgery
- History of strabismus, amblyopia
- History of prematurity, genetic disorders
- Family history of strabismus, amblyopia, congenital cataract, ocular or systemic genetic disease

PHYSICAL EXAM

- Age appropriate vision screening is the most effective diagnostic tool for detecting refractive errors.
- Vision must be tested with each eye separately (patch or occluder over one eye).
- In children younger than 3 years of age:
 - Monocular testing for fixing and following will determine visual behavior for each eye.

- Brückner (simultaneous red reflex) examination with the direct ophthalmoscope can objectively identify high refractive errors (distorted or darkened red reflex) or anisometropia (asymmetric brightness of red reflex).
- In children age 3 years or older:
 - Subjective visual acuity should be testing with matching or identifying optotypes on a vision chart (Allen figures, HOTV, Lea, or Snellen).
 - A failed vision screening or untestable vision after 2 attempts warrants a referral to an eye care provider.
- Vision screenings are important at regular intervals throughout childhood to prevent vision loss.
- Strabismus is frequently a secondary sign of refractive error in children and can be detected by cover test, Hirschberg corneal light reflex test, or Brückner test.
- Photoscreening, which uses the principle of red reflex testing, is also effective in detecting high or asymmetric refractive errors.

DIFFERENTIAL DIAGNOSIS

- Decreased binocular or monocular vision can be caused by a number of structural abnormalities of the eye as well as decreased cortical visual development. In any child with vision loss, refractive error needs to be evaluated as the cause or one of many factors contributing to decreased vision.
- True refractive error needs to be measured by only after instilling cycloplegic eye drops with retinoscopy (objective technique to measure refractive error). Without these drops, a child's lens will accommodate (change shape) and give a false amount of refractive error.

TREATMENT

GENERAL MEASURES

- Refractive errors are treated by corrective lenses. Young children typically use glasses and teenagers may use contact lenses.

- The following guidelines for prescribing glasses have been developed to improve visual acuity and reduce the risk of amblyopia and strabismus.
 - Myopia: >3.00 diopters for age 2–3 years and >1.00 diopter or more in school-age children
 - Hyperopia: $+4.50$ diopters or more for age 2–3 years, $+3.00$ diopters or more in school-age children, or $+1.50$ diopters or more anisometropia
 - Astigmatism: >2.00 diopters in age 2–3 years or >1.50 diopters in school-age children
- If hyperopic correction is needed for treatment but is not well accepted by the child, a brief period of cycloplegia with topical atropine can increase usage of glasses.
- In suspected amblyopia, vision should be retested to measure visual improvement after glasses have been worn for several weeks
- Hyperopic patients may develop esotropia when their glasses are taken off. Full-time glasses usage will prevent loss of vision and depth perception when children have accommodative esotropia.

ONGOING CARE

Because refractive error depends on the eye's shape and the eye's shape changes as a child grows, the refractive error will evolve over time. Because this process is dynamic, children require at least an annual vision evaluation and refraction to assess whether they need a change in their glasses. They also need to be evaluated for amblyopia and strabismus.

PROGNOSIS

If a child has a significant refractive error, his or her visual acuity will likely improve with optical correction. Refractive error rarely leads to significant functional limitations for daily activities and school. If refractive errors accompany other vision problems such as amblyopia or strabismus, other treatments may be needed to improve visual acuity. Special frames for athletic activities should be considered for children if standard glasses are interfering with those activities.

COMPLICATIONS

In children, the most significant complications of uncorrected refractive errors are strabismus and amblyopia.

- Accommodative esotropia
 - For children with moderate to high hyperopia, their eyes will normally accommodate (change shape of lens) to bring objects into focus.
 - This accommodative process may involuntarily cause overconvergence of the eyes and thus esotropia.
 - Small amounts of convergence normally occur with accommodation so that both eyes can be looking at a near target. But in children with accommodative esotropia, they cannot control the degree of convergence and develop esotropia when focusing at both distance and near.
- Refractive amblyopia is poor cortical visual development resulting from a poorly focused image in one or both eyes.
 - Anisometropia (unequal refractive error) is the most frequent cause of unilateral amblyopia (~35%). The brain learns to see well from the eye that has the least amount of refractive error but does not develop equal vision from the eye that has a higher refractive error.
- Bilateral high refractive errors may cause bilateral amblyopia from chronically poor visual input from both eyes.
- High myopia (>5 diopters) can lead to retinal thinning and eventual retinal detachment. It is also associated with increased risk of glaucoma and cataracts as an adult.

CODES

ICD10

- H52.7 Unspecified disorder of refraction
- H52.10 Myopia, unspecified eye
- H52.209 Unspecified astigmatism, unspecified eye

FAQ

- Q: Will my child always need glasses?
- A: Not necessarily. As children grow, the shape of the eyes change. Because the need for glasses depend on the eye's shape, it is unclear whether the child will continue to need glasses to have normal vision as his or her eye develops. If optical correction remains necessary, contact lenses and refractive surgery are also possible in older children or adults.
- Q: Will wearing glasses weaken my child's eyes?
- A: No. Glasses change the way light enters the eye to focus on the retina and optimize vision. Glasses do not weaken the eyes or vision. Glasses are important to prevent amblyopia and permanent vision loss.
- Q: If my child wears glasses and his or her vision improves, can my child stop wearing glasses?
- A: In the majority of children, they will need to continue to wear glasses to clarify the blur from their refractive error. The glasses are

improving their visual acuity.

- Q: Is my child too young for glasses?
- A: If a child needs glasses to improve his or her visual acuity, then a child is never too young to wear them. Small frames are designed for children as young as a few months. If glasses improve vision, a child usually quickly accepts correction.
- Q: My child can see well. Why does he need glasses?
- A: Some children with hyperopia can see charts well, but the accommodation (i.e., focusing) necessary to overcome the refractive error may cause eye strain, fatigue, and esotropia. Others may need glasses for unilateral refractive error and seem to see well with both eyes open. In these children, wearing correction may treat or prevent problems even though they may seem to see well without correction.
- Q: Everyone in my family has needed glasses for myopia in childhood. Is there anything we can do for my child that will prevent the development of myopia?
- A: Unfortunately, few environmental factors have been clearly identified to affect the development of myopia. Reading, particularly at an early age; excessively close visual targets (holding books or toys too close to the face); and light exposure during nighttime have been suggested as factors in myopia development. Increased hours spent outdoors may prevent myopic progression. Avoiding long periods of reading, avoiding intensive near work, using a reasonable reading distance (i.e., 16–18 inches), and avoiding use of night-lights may reduce some environmental stimuli.

RENAL ARTERY STENOSIS

Danielle Soranno • Michelle Denburg

BASICS

DESCRIPTION

Narrowing of 1 or both renal arteries and/or their more distal branches, resulting in decreased perfusion, increased renin release, increased vascular resistance, and systemic hypertension

EPIDEMIOLOGY

- Hypertension in infants and young children is often secondary to some identifiable cause. Of those with secondary hypertension, most have intrinsic renal disease (e.g., renal scarring, dysplasia, chronic nephritis).
- Up to 5% of adults with hypertension have renal artery stenosis (RAS).
- RAS accounts for ~10% of secondary hypertension in children. Its importance clinically is not its frequency but its potential curability.

RISK FACTOR

- Any condition associated with thromboembolic events (such as a complication of an umbilical artery catheter in newborns)
- Renal trauma including renal artery surgery (e.g., transplantation)
- Extrinsic compression of the renal artery (e.g., Wilms tumor, neuroblastoma, or pheochromocytoma).

GENERAL PREVENTION

Reduce risk factors, such as thromboembolic events, which can lead to renal artery narrowing.

PATHOPHYSIOLOGY

Arterial narrowing leads to diminished perfusion of the affected kidney, leading to signals in the juxtaglomerular apparatus, which lead to renin release and results in increased vascular resistance and blood pressure (BP).

ETIOLOGY

- Majority are caused by fibromuscular dysplasia (FMD), a noninflammatory vascular disease of unknown etiology.
 - Primarily affects females and affects up to 4 in 100 adults
 - The renal vasculature is the most common arterial bed affected.
 - FMD can concurrently affect other vascular beds including carotid, vertebral, and intracranial vascular beds.
- Arterial narrowing by atheroma is common in adults but rare in children.

COMMONLY ASSOCIATED CONDITIONS

- RAS may occur in many other conditions, including congenital anomalies (e.g., renal artery hypoplasia), neurocutaneous disorders (neurofibromatosis [type 1], tuberous sclerosis), vasculitis (Wegener, polyarteritis nodosa, Kawasaki disease, Takayasu arteritis, moyamoya disease), syndromes (Williams, Marfan, Alagille), and infections (e.g., congenital rubella and fungal infection [immunocompromised hosts]).
- Nephrotic syndrome may accompany renal artery stenosis and is probably secondary to it.
- RAS has been associated with multicystic dysplasia in the contralateral kidney.

DIAGNOSIS

HISTORY

- Ask about prior BP determinations, family history of hypertension, previous renal disease, symptoms of hypertension, and preexisting conditions associated with renal artery stenosis.
- Signs and symptoms:
 - Symptoms of hypertension in infants are not specific and include irritability, poor feeding, and vomiting.
 - In children, symptoms include headache, nausea/vomiting, visual disturbance, dizziness, and seizure.
 - Many affected children remain asymptomatic and 1/3 of children with RAS are diagnosed incidentally.

PHYSICAL EXAM

- BP assessment
 - Consider RAS in a child with very high BP readings (i.e., at or above the 99th percentile).
 - Obtain multiple, manual BP readings using an appropriate-size cuff in the right upper extremity with patient relaxed at baseline heart rate and compare to the BP nomogram for age, sex, and length/height percentile.
 - Avoid using automated devices (oscillometers).
 - Most accurate readings are obtained with either a mercury column or an aneroid sphygmomanometer.
- Determine the BP in all extremities. A gradient from the upper to lower extremities should prompt evaluation for aortic coarctation or midaortic syndrome.
- Examine the skin for lesions suggestive of vasculitis or neurocutaneous disorder (e.g., café au lait macules).
- Assess the child's facies and habitus for features of associated syndromes.
- View the optic fundi for hypertensive vascular changes.
- Auscultate the lower back and abdomen for the presence of a bruit (suggesting turbulent flow).
- In infancy, signs of heart failure may be present.

DIAGNOSTIC TESTS & INTERPRETATION

ECG or echocardiogram to assess for left ventricular hypertrophy and function

Lab

- BUN and creatinine to evaluate for renal insufficiency
- Electrolytes to assess possible hyperaldosteronism with hypokalemia and metabolic alkalosis. Hyponatremia may sometimes occur.
- ESR or CRP to screen for vasculitis

Imaging

- The definitive diagnostic test remains the selective renal arteriogram. If the diagnosis is made, angioplasty may be part of the same procedure. Angiography should not be delayed in any child in whom the diagnosis

is strongly suspected.

- Renal ultrasound with Doppler to identify a smaller kidney and/or increased resistance to flow is simple and not invasive, but it is neither sensitive nor specific. Length discrepancy of >1 cm in children can increase suspicion for RAS.
- Contrast-enhanced CT or MR angiography also is not completely diagnostic and is not therapeutic.
- Nuclear renal scans using dimercaptosuccinic acid (DMSA) or MAG-3 enhanced with captopril (and more recently angiotensin receptor blockers [ARB]) also are not diagnostic for all children.
- Diagnostic accuracy of various imaging studies including with magnetic resonance angiography (MRA), computed tomography angiography (CTA)

Technique	Sensitivity (%)	Specificity (%)
Ultrasound	73–85	71–92
DMSA with ACE	52–93	63–92
CTA	64–94	62–97
MRA	64–93	72–97

DIAGNOSTIC PROCEDURES/OTHER

- Avoid excessive investigation in children whose BP is minimally or episodically elevated and therefore in whom the diagnosis of renal artery stenosis is less likely.
- Selective renal vein renin determinations suggest unilateral stenosis if the affected side is 1.5 times the contralateral (normal) side. However, the procedure is invasive and requires catheterization of the femoral vein.
- Random renin determinations have little value and may be misleading. If obtained, renin levels should be interpreted in the context of the urine sodium concentration.

Pathologic Findings

- FMD is a segmental sclerotic process involving smooth muscle hyperplasia of the media layer of the artery. It is unilateral in 75%.
- Stenosis is usually distal in the renal artery, sometimes involving intrarenal branches.
- The stenotic area(s) of the artery may be associated with distal

aneurysms.

- In neurofibromatosis, arterial narrowing is at the vessel's ostium and usually involves the intimal layer.

DIFFERENTIAL DIAGNOSIS

- RAS should be suspected and investigated in children with severe, progressive, and/or difficult-to-manage hypertension.
- The differential diagnosis consists of other causes of significant hypertension, including increased intracranial pressure, coarctation of the aorta, midaortic syndrome, rapidly progressive glomerulonephritis, vasculitis, and pheochromocytoma.

TREATMENT

Treat children who are symptomatic immediately (e.g., severe headaches, seizures, blurred vision, facial palsy).

MEDICATION

- Hypertension accompanying RAS is often difficult to control and may worsen over time. Multiple medications given in high doses are common until the diagnosis is made and angioplasty can be done.
- Because RAS results in increased renin levels, renin-angiotensin blockade with ACE inhibitor therapy (e.g., enalapril, lisinopril) and/or angiotensin receptor blockers (ARBs, e.g., losartan) is often effective. In children where bilateral renal artery stenosis is known or suspected, ACE inhibitor and ARB therapy must be avoided to prevent acute renal failure. 50% of children will have bilateral disease. Renal function should be checked before and after initiation of ACE inhibition or ARB therapy.
- If BP is easy to control on monotherapy, may consider medical management alone rather than angioplasty.
- β -Blockers, calcium channel blockers, diuretics, and direct vasodilators (e.g., minoxidil, hydralazine) are all possibly effective.

ADDITIONAL TREATMENT

General Measures

- If renal artery stenosis is suspected, begin the diagnostic evaluation and pharmacotherapy together.
- If BP is very high, use bed rest until BP is better controlled.

ISSUES FOR REFERRAL

- Cardiology follow-up for echo changes, if indicated
- Ophthalmologic follow-up for resolution of vascular changes, if indicated

SURGERY/OTHER PROCEDURES

- Actual surgery on the stenotic renal artery has been replaced by angioplasty, which has been successfully carried out in very young infants. Stents are occasionally used.
- Surgery must sometimes be performed, especially in children with neurofibromatosis where the stenosis is frequently at the renal artery's ostium.

INPATIENT CONSIDERATIONS

Initial Stabilization

- If symptomatic, use potent, rapidly acting medications such as labetalol or nicardipine.
- Be prepared to have difficulty adequately controlling the BP using a single medication.

Admission Criteria

- Children who present with a BP at or above the 99th percentile
- Children who appear to have symptomatic hypertension
- Children with progressive renal insufficiency

Nursing

- Obtain BP levels frequently and carefully.
- Notify MD if high or low limits exceeded.
- Monitor intake of salt, I&O, and weight.

Discharge Criteria

BP in the 90–95th percentile

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- The child's BP must be followed closely, both before and after the angioplasty. Response to angioplasty may be immediate but may require continued antihypertensive therapy at some level for weeks to months.
- Medical therapy should be monitored closely. Until correction, the need for progressively higher doses and/or additional medications is common.
- Disposition
 - Close follow-up by the primary care provider, mainly for monitoring BP, and a specialist comfortable with the evaluation and treatment of childhood hypertension.
 - Patient and/or family must be familiar with medication, exercise program, and diet.

Patient Monitoring

- Long-term follow-up of the BP is most important. If on no medications, the BP should be checked monthly, preferably somewhere the child is comfortable and the correct cuff is employed. Begin to space visits after 6 months.
- Checking renal growth on serial renal ultrasounds is important (e.g., at 6 months postangioplasty and then yearly). If the child is fully grown, check ultrasound at 6 months.
- Check renal function annually.

DIET

Limit salt intake.

PROGNOSIS

Long-term outcome of percutaneous angioplasty is excellent; most children require no long-term antihypertensive medications. Percutaneous angioplasty is less successful in neurofibromatosis than in other causes of RAS.

COMPLICATIONS

- Rate of restenosis of the renal artery, either ipsilateral or contralateral, is 22–39%.

- When renal artery stenosis causes severe hypertension, it may cause encephalopathy, severe headache, seizures, or stroke.
- If untreated, chronic hypertension may cause end-organ damage, including heart and kidney.
- Angiography may lead to contrast-induced renal failure. The procedure may also cause injury to the kidney and/or renal artery.
- Rare cases of subarachnoid hemorrhage secondary to coexisting intracranial aneurysm may occur.

CODES

ICD10

- I70.1 Atherosclerosis of renal artery
- Q27.1 Congenital renal artery stenosis
- I15.0 Renovascular hypertension

RENAL TUBULAR ACIDOSIS

Elaine Ku • Anthony A. Portale

BASICS

DESCRIPTION

- Renal tubular acidosis (RTA) is characterized by hyperchloremic metabolic acidosis in the setting of normal or near-normal glomerular filtration rate (GFR).
- The acidification defect can be localized to the proximal tubule (type II RTA) resulting in incomplete bicarbonate reabsorption, or the distal tubule (type I or type IV RTA) resulting in impaired net acid secretion.
- Type I and II RTA are associated with hypokalemia; type IV is associated with hyperkalemia.
- Timing of onset and severity of presentation are variable, depending on the underlying cause of the acidification defect.
- Type I RTA is associated with nephrocalcinosis, osteopenia, rickets and sometimes hearing loss.
- Four different types of RTA are recognized:
 - Type I (classic, hypokalemic, distal)
 - Type II (proximal)
 - Type III (characteristics of both proximal and distal RTA, rare inherited disorder associated with mental retardation, osteopetrosis, and cerebral calcification)
 - Type IV (hyperkalemic, distal)
 - Associated with aldosterone deficiency or resistance to its renal effect

EPIDEMIOLOGY

RTA is a rare disorder. Increased prevalence is observed in areas where consanguinity is common.

ETIOLOGY

- Genetic causes of proximal RTA:
 - Mutation in carbonic anhydrase II

- Mutation in sodium bicarbonate cotransporter
- Genetic causes of distal RTA:
 - Mutation in anion exchanger 1 (AE1) in alpha-intercalated cell
 - Mutation in H⁺-ATPase
 - Mutation in carbonic anhydrase II
- Genetic causes of Fanconi syndrome/proximal RTA:
 - Lowe syndrome
 - Dent disease
 - Cystinosis
 - Tyrosinemia
 - Galactosemia
 - Hereditary fructose intolerance
 - Wilson disease
 - Fanconi-Bickel syndrome
 - Mitochondrial disorders
- Acquired causes of proximal RTA:
 - Drugs:
 - ▢ Ifosfamide
 - ▢ Cisplatin/oxaliplatin
 - ▢ Valproic acid
 - ▢ Carbonic anhydrase inhibitor (e.g., acetazolamide)
 - ▢ Topiramate
 - ▢ Aminoglycosides
 - ▢ Antiretroviral therapy (tenofovir)
- Acquired causes of distal RTA type I:
 - Autoimmune disorders
 - Drugs:
 - ▢ Lithium toxicity
 - ▢ Amphotericin
 - ▢ Ifosfamide
- Acquired causes of distal RTA type IV:
 - Aldosterone resistance/deficiency
 - ▢ Diabetic renal disease
 - ▢ Obstructive uropathy
 - ▢ Adrenal insufficiency

- Drugs:
 - Nonsteroidal anti-inflammatory medications
 - Heparin
 - Potassium-sparing diuretics
 - Angiotensin-converting enzyme inhibitor or angiotensin receptor blocker
 - Calcineurin inhibitors (e.g., tacrolimus or cyclosporine)
 - Trimethoprim
 - Pentamidine

PATHOPHYSIOLOGY

- With ingestion of a typical Western diet, healthy adults generate ~1 mEq/kg net acid per day and infants and children ~2–3 mEq/kg/day.
- Under physiologic conditions, the proximal tubule is responsible for reclaiming 85–90% of filtered bicarbonate.
 - Bicarbonate reclamation in the proximal tubule is achieved by a sodium–hydrogen ion antiporter, which secretes hydrogen ion into the urine resulting in generation of bicarbonate within the cell. Cellular bicarbonate is then transported into the bloodstream via an Na-HCO₃ transporter on the basolateral membrane.
- The distal tubule normally reclaims the remaining 10–15% of filtered bicarbonate and secretes a net amount of acid, both via hydrogen ion secretion.
 - In the distal tubule, hydrogen ion secretion occurs primarily via H⁺-ATPase.
 - Secreted hydrogen ions are buffered in the urinary lumen primarily by ammonia and excreted as ammonium ions.
- In proximal RTA, mutations in the basolateral sodium bicarbonate cotransporter or in carbonic anhydrase prevent adequate bicarbonate reclamation in the proximal tubule.
 - Unreclaimed bicarbonate enters the distal nephron, which has limited capacity for bicarbonate reclamation, resulting in bicarbonaturia and non-anion gap metabolic acidosis (usually serum bicarbonate does not decrease below 16 mEq/L).
- In distal RTA, mutations in the basolateral anion exchanger or the H⁺-ATPase prevent bicarbonate transport into the bloodstream and

hydrogen ion secretion into the lumen, respectively, resulting in impaired net acid secretion and non-anion gap metabolic acidosis.

- Proximal RTA can be associated with Fanconi syndrome in which there is general proximal tubular dysfunction leading to bicarbonaturia, glucosuria, phosphaturia, and tubular proteinuria.
- Distal RTA type I is associated with urine pH >5.5
- Distal RTA type IV is associated with either low aldosterone levels or aldosterone resistance and presents with hyperkalemic non-anion gap metabolic acidosis.

DIAGNOSIS

HISTORY

- Failure to thrive in infants and children
- Polyuria
- Constipation
- Anorexia
- Symptoms of hypokalemia:
 - Muscle weakness
 - Constipation
- Kidney stones
- Intellectual disability
- Propensity for fractures

PHYSICAL EXAM

- Constitutional: failure to thrive
- Head: frontal bossing
- Ears: deafness (associated with some forms of RTA)
- Neurologic: developmental and cognitive delay
- Skin: decreased turgor, prolonged capillary refill

DIAGNOSTIC TESTS & INTERPRETATION

- Serum electrolytes
 - To identify metabolic acidosis with normal anion gap, and hypokalemia or hyperkalemia
 - Magnesium level (can be low in Fanconi syndrome)

- Phosphorus level (can be low in Fanconi syndrome)
- Serum creatinine: to evaluate GFR
- Urine electrolytes
 - Urine anion gap, calculated as (urine sodium + urine potassium – urine chloride): typically >10 in distal RTA (type I or IV)
 - Urine phosphorus: Fractional excretion is high in Fanconi syndrome, resulting in hypophosphatemia.
- Urinalysis
 - Urine pH is high in distal RTA, often >6.8 and can be elevated or normal in proximal RTA.
 - Look for glucosuria in setting of normal serum glucose.
- Urine spot for calcium/creatinine ratio: Look for hypercalciuria (normal values are age-dependent).
- 24-hour urine collection for citrate (typically low)

Imaging

- Renal ultrasound: Evaluate for nephrocalcinosis and kidney stones.
- Long bone films to look for signs of rickets or osteopenia

DIFFERENTIAL DIAGNOSIS

- Renal insufficiency (earlier stages)
- Diarrhea
- Urinary diversion via bowel conduits
- Acetazolamide use

TREATMENT

MEDICATION

- Alkali supplementation given as sodium or potassium bicarbonate or citrate (typically requires 5–8 mEq/kg/24 h in distal RTA and 5–15 mEq/kg/24 h in proximal RTA)
- Thiazide diuretics (in proximal RTA) to induce volume depletion which can be sensed by the proximal tubule, resulting in increased proximal tubular reabsorption of bicarbonate
- Mineralocorticoid supplementation (for those with select causes of type IV RTA)

ADDITIONAL TREATMENT

General Measures

- Vitamin D supplementation as needed
- Phosphorus supplementation as needed (if concurrent Fanconi syndrome)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Frequent monitoring of serum electrolytes
- Close follow-up of linear growth
- Renal ultrasound to monitor for evidence or progression of nephrocalcinosis

PROGNOSIS

- Can rarely progress to chronic kidney disease over time depending on etiology of RTA (as in cystinosis) or if associated with nephrocalcinosis
- May be associated with development of nephrolithiasis

CODES

ICD10

N25.89 Other disorders resulting from impaired renal tubular function

FAQ

- Q: Can RTA be diagnosed in the setting of renal failure?
- A: No. Typically, RTA is diagnosed in the setting of relatively preserved renal function. Renal function associated with non-anion or anion gap acidosis typically occurs when GFR is $<30 \text{ mL/min/1.73 m}^2$.
- Q: Does a urine pH <5.5 exclude RTA?
- A: A low urinary pH excludes distal RTA but could still be consistent with a proximal RTA. However, urine pH as tested on urine dipsticks or formal urinalysis can be unreliable depending on duration between time of sample delivery and analysis.
- Q: What are the available forms of alkali supplementation?
- A: Alkali supplementation is best provided as a combination of sodium and potassium citrate or bicarbonate (except in distal RTA type IV, in which potassium alkali is avoided).

RENAL VENOUS THROMBOSIS

Daniel Ranch

BASICS

DESCRIPTION

- Most common non–catheter-related thromboembolism in the neonatal period
- May also be associated with nephrotic syndrome, hypercoagulable states, and oral contraceptive use
- May present with a clinical triad of flank mass, gross hematuria, and thrombocytopenia

EPIDEMIOLOGY

- Most commonly seen in the newborn period
- Slight male predominance
- In neonates, most cases are unilateral, with the left kidney more frequently affected.

Incidence

- Not well-defined due to lack of data
- Ranges from 0.5 to 2.3 per 100,000 live births

Prevalence

Accounts for 16–20% of thromboembolic events in newborns

RISK FACTORS

- Maternal diabetes mellitus
- Birth asphyxia
- Dehydration/blood loss
- Polycythemia
- Cyanotic heart disease
- Hypercoagulable states
- Nephrotic syndrome
- Venous catheter
- Sepsis

- Oral contraceptive use
- Renal transplant recipient

Genetics

- ~50% of affected neonates have at least 1 hereditary prothrombotic risk factor.
- Factor V Leiden, protein C/S, and MTHFR mutations and lupus anticoagulant

GENERAL PREVENTION

- Maintaining a high index of suspicion in patients at risk (i.e., infant of diabetic mother, child with nephrotic syndrome)
- Counseling regarding the importance of adequate fluid intake and avoidance of dehydration, especially in newborn infants
- Prophylactic anticoagulation may be indicated in certain populations, although conclusive data is lacking.

PATHOPHYSIOLOGY

- Thrombus formation is initiated by endothelial cell injury from hypoxia or other insults.
- In neonates, non–catheter-related renal vein thrombosis is believed to originate in the arcuate or interlobular veins, as evidenced by early ultrasound findings.
- Thrombosis may extend to the main renal veins and inferior vena cava.
- Neonates also have decreased levels of protein C, protein S, antithrombin, and plasminogen, which may make them more susceptible to thrombosis.
- Lower renal blood flow may also predispose neonates to venous thrombosis.
- In older children, thrombosis may be associated with nephrotic syndrome, hypercoagulable states, or cyanotic heart disease.
- Renal venous thrombosis can result in renal enlargement, decreased renal venous flow, and increased arterial resistive indices.
- Adrenal hemorrhage and left varicocele may also result from renal venous thrombosis.

DIAGNOSIS

HISTORY

- More than half of neonatal cases present within 3 days of birth and almost all within the 1st month of life.
- Macroscopic hematuria is seen in about half of affected infants.
- The classic triad of flank mass, gross hematuria, and thrombocytopenia is present in less than 25% of patients.
- Signs and symptoms:
 - Palpable flank mass
 - Abdominal/flank pain
 - Hematuria
 - Dehydration/shock
 - Edema
 - Fever
 - Hypertension
 - Varicocele

PHYSICAL EXAM

- Palpable enlarged kidney can be found in about half of neonates.
- Abdominal/flank tenderness
- Periorbital/peripheral edema
- Left varicocele
- Hypertension

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urinalysis
 - Macroscopic or microscopic hematuria
 - Proteinuria
- Complete blood count
 - Thrombocytopenia is seen in about half of affected neonates.
 - Hemolytic anemia may be present on peripheral blood smear.
- Coagulation tests
 - Prothrombin time and partial thromboplastin time may be prolonged.

- Fibrin split products may be elevated.
- Plasma fibrinogen levels may be decreased.
- Tests for hypercoagulable states, such as factor V Leiden or lupus anticoagulant, should be performed.
- Renal function tests
 - Increased blood urea nitrogen (BUN) and/or creatinine may be present due to acute kidney injury.
 - Electrolyte abnormalities may exist depending on the underlying disease and degree of renal insufficiency.

Imaging

- Ultrasonography
 - Pathognomonic echogenic streaks may be seen with early clot formation.
 - Progresses to renal enlargement and increased parenchymal echogenicity
 - Later findings include loss of corticomedullary differentiation and calcified thrombi in the renal veins.
- Doppler ultrasound
 - Demonstrates decreased or absent renal venous flow
 - May see increased arterial resistive indices

DIFFERENTIAL DIAGNOSIS

- Renal tumors (Wilms, mesoblastic nephroma)
- Pyelonephritis/renal abscess
- Hematoma
- Cystic kidney disease
- Obstructive uropathy
- Thrombotic microangiopathy (hemolytic uremic syndrome [HUS], thrombotic thrombocytopenic purpura [TTP])

TREATMENT

MEDICATION

- The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines for Antithrombotic Therapy in Neonates and

Children (9th edition) recommend the following:

- For unilateral renal vein thrombosis (RVT) in the absence of renal impairment or extension into the inferior vena cava (IVC), either (1) supportive care with radiologic monitoring for extension of thrombosis (if extension occurs, anticoagulation is suggested) or (2) anticoagulation with unfractionated heparin (UFH)/low-molecular-weight heparin (LMWH) or LMWH in therapeutic doses rather than no therapy. If anticoagulation is used, a total duration of between 6 weeks and 3 months rather than shorter or longer durations of therapy.
- For unilateral RVT that extends into the IVC, anticoagulation with UFH/LMWH or LMWH for a total duration of between 6 weeks and 3 months
- For bilateral RVT with evidence of renal impairment, anticoagulation with UFH/LMWH or initial thrombolytic therapy with tissue plasminogen activator (tPA) followed by anticoagulation with UFH/LMWH
- However, the overall evidence supporting these recommendations is weak. Also, no recommendations exist for patients with unilateral RVT and renal impairment or patients with prothrombotic risk factors.

ADDITIONAL TREATMENT

General Measures

- Treatment of the underlying disease process, if present
- Management of acute kidney injury (i.e., fluid imbalance, electrolyte abnormalities, hypertension)

ISSUES FOR REFERRAL

Patients with renal venous thrombosis should be evaluated by a nephrologist and hematologist.

SURGERY/OTHER PROCEDURES

- Surgery is rarely indicated, except possibly for malignancy-related cases or refractory hypertension or infection.
- Local thrombolytic therapy via an angiocatheter has been reported for severe IVC thrombosis and bilateral RVT causing renal failure.

INPATIENT CONSIDERATIONS

Initial Stabilization

Supportive therapy for the underlying process, correction of fluid/electrolyte imbalance, and pain control

Admission Criteria

- Admission for treatment of an underlying cause, if present
- Renal impairment
- Pain management
- Thrombolytic therapy

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Long-term monitoring for development of hypertension, renal atrophy, or chronic renal insufficiency

PROGNOSIS

- Treatment with anticoagulants may not change renal outcomes.
- RVT has a low mortality rate but may result in significant complications.
- Patients require long-term follow-up to screen for development of hypertension, renal atrophy, proteinuria, or renal insufficiency.
- Hypertension develops in ~20% of patients with neonatal RVT.
- Chronic kidney disease has been reported to develop in up to 71%.
- However, end-stage renal disease is uncommon and is more commonly associated with bilateral RVT.
- Death is uncommon and is usually related to the underlying disease process.
- Certain findings may be linked to worse outcomes, such as the following:
 - Kidney size >6 cm at presentation
 - Decreased overall renal perfusion by Doppler ultrasound
 - Subcapsular bleeding
 - Patchy hypoechogenicity or

- Irregular pyramids

COMPLICATIONS

- Hypertension
- Renal atrophy
- Proteinuria
- Renal insufficiency

CODES

ICD10

I82.3 Embolism and thrombosis of renal vein

FAQ

- Q: Which population is most susceptible to renal vein thrombosis?

- A: Neonates have the highest risk, especially those with a history of maternal diabetes mellitus, birth asphyxia, or dehydration.
- Q: What is the classic presentation of renal vein thrombosis?
- A: Flank mass, gross hematuria, and thrombocytopenia. However, this “triad” is present in less than 25% of patients, so a high degree of suspicion must be maintained.
- Q: How is renal vein thrombosis diagnosed?
- A: Renal Doppler ultrasound can show renal enlargement, increased echogenicity, or absent renal venous flow.
- Q: What are the current treatment recommendations for renal vein thrombosis?
- A: Supportive therapy and monitoring is recommended, except for bilateral involvement, IVC extension, or evidence of renal impairment. The role of anticoagulation is otherwise still controversial.

RESPIRATORY DISTRESS SYNDROME

Julie M. Noguee • Lawrence M. Noguee

BASICS

DESCRIPTION

Respiratory distress syndrome (RDS) is an acute, developmental lung disease affecting primarily premature infants. Disease is characterized by alveolar collapse due to a lack of pulmonary surfactant owing to lung immaturity that results in increased work of breathing, hypoxemia, and respiratory acidosis. The term hyaline membrane disease (HMD) is often used synonymously.

EPIDEMIOLOGY

- RDS is the most common lung disease in premature infants, affecting approximately 60–80,000 infants per year in the United States.
- Risk increases with the degree of prematurity; nearly 100% of infants born at <26 weeks' gestation affected.
- For near-term infants delivered operatively without benefit of labor, the risk of developing RDS increases roughly 2-fold for every week <39 weeks' gestation.

RISK FACTORS

- Prematurity
- Low birth weight
- Maternal diabetes
- Delivery without labor
- Absence of antenatal steroid administration
- Male gender
- Caucasian race
- Perinatal depression

PATHOPHYSIOLOGY

- Insufficient or dysfunctional surfactant results in alveolar instability and atelectasis, causing hypoventilation and ventilation–perfusion

mismatch, leading to hypoxemia and respiratory acidosis.

- The lack of surfactant in conjunction with pulmonary immaturity also leads to transudation of fluid and alveolar edema.
- Surfactant inactivation from transudation of proteins or other substances into the alveolus
- Increased work of breathing generates high negative intrathoracic pressures to overcome alveolar collapse. Retractions result from the highly compliant newborn rib cage combined with poorly compliant lungs.
- Expiratory grunting is due to glottic closure at the end of expiration to prevent end-expiratory atelectasis and maintain functional residual capacity.
- Infants with a well-developed pulmonary arterial muscular bed can develop secondary pulmonary hypertension, with hypoxemia leading to pulmonary vasoconstriction.

GENERAL PREVENTION

- Prevention of prematurity
- Maternal antenatal steroids

DIAGNOSIS

HISTORY

- Gestational age, birth weight
- Lack of antenatal steroids
- Delivery history: maternal diabetes, perinatal asphyxia, route of delivery, absence of labor, 2nd-born twin
- Resuscitation: need for supplemental oxygen, positive pressure, intubation, surfactant

PHYSICAL EXAM

- Assessment of color (cyanosis), grunting, nasal flaring, accessory muscle usage
- Vital signs (including respiratory rate to assess for tachypnea) and pulse oximetry (to assess for hypoxemia)
- Pulmonary exam, including shallow or decreased breath sounds,

symmetry of breath sounds, and inspiratory rales

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood gases (BGs): Arterial BGs allow for accurate determination of pH, PaCO₂, and PaO₂ to avoid hyperoxia as well as hypoxemia.
- Capillary BGs obtained from appropriately warmed extremities can provide accurate determinations of pH and Pco₂, but poor perfusion to the extremity or inadequate warming may result in inaccurate determinations.
- Oxygenation may be determined noninvasively through pulse oximetry.

Imaging

- Chest radiography
 - Classic findings include hypoinflation, diffuse reticulogranular or “ground-glass” appearance, and air bronchograms.
 - Lateral films may be helpful for determination of air leak.
- Other imaging modalities (CT, ultrasound) are generally unnecessary for the diagnosis and management of RDS but may be indicated if there is suspicion for other pulmonary pathology.

DIFFERENTIAL DIAGNOSIS

Common

- Transient tachypnea of the newborn (TTN)
- Infection (sepsis, pneumonia)
- Air leak (may also be a complication of RDS)
- Meconium aspiration syndrome

Unusual

- Pulmonary hypoplasia
- Congenital heart disease
- Primary ciliary dyskinesia
- Genetic surfactant dysfunction

TREATMENT

GENERAL MEASURES

Diet

Sufficient glucose infusion to prevent hypoglycemia. Hydration and nutrition for expected increased caloric needs with early initiation of IV nutrition while working to establish enteral nutrition

Supportive Care

- Radiant warmer or incubator for warmth
- Blood pressure support with volume expansion and/or pressors to maintain perfusion and normal blood pressure for gestational age

MEDICATION

- Exogenous surfactant
 - Both modified mammalian-derived surfactants and synthetic surfactants have been shown to reduce morbidity and mortality from RDS.
 - Exogenous surfactant is delivered directly into the trachea through the endotracheal tube and thus currently requires that the infant be intubated, although alternative delivery methods are being explored.
 - Timing of surfactant
 - Prophylactic: as soon as infant is stabilized, usually less than 15 minutes of life, based on the risk for RDS without demonstrating that the infant has disease. Prophylaxis is usually reserved for those infants at highest risk for RDS, such as <26 weeks' gestation.
 - Rescue: after the diagnosis of RDS is established; usually after first hour and before 48 hours of life
 - Additional doses are considered for persistently high FiO_2 requirements ($\text{FiO}_2 > 0.3\text{--}0.4$) or for ongoing need for mechanical ventilation. Consultation with a neonatologist is recommended.

ALERT

- Occasionally, the surfactant material may clog the endotracheal tube, causing acute airway obstruction with resultant hypercapnia and hypoxemia, necessitating suctioning or removal and replacement of the endotracheal tube.
- Surfactant therapy can also result in acute improvements in pulmonary

compliance. Monitor physical exam, SpO₂, blood gasses, and tidal volumes to avoid inadvertent overventilation.

- Caffeine citrate
 - Used for apnea of prematurity and may be helpful in RDS if it is able to minimize the duration of mechanical ventilation

ADDITIONAL THERAPIES

- Continuous positive airway pressure (CPAP)
 - Can be delivered via nasal prongs or mask either using a ventilator, dedicated apparatus, or through “bubble CPAP”
 - CPAP prevents end-expiratory atelectasis and can be started in the delivery room.
- Humidified high-flow nasal cannula (HFNC)
 - May achieve CPAP benefit with easier handling of the patient and less risk of pressure necrosis of nasal septum
 - Pressure delivery variable
- Mechanical ventilation
 - May be required for infants with significant respiratory acidosis and hypoxemia. Can be initiated following intubation for surfactant delivery
 - High-frequency ventilation (oscillatory or jet) may be valuable in very severe cases or with air leak (jet).

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Very low-birth-weight and extremely low-birth-weight infants should receive follow-up in specialty clinics that can provide for their specialized needs, including neurodevelopmental, pulmonary (for those with bronchopulmonary dysplasia [BPD]), and ophthalmology (for those with retinopathy of prematurity).
- Immunizations are extremely important preventive measures to prevent subsequent respiratory morbidity and mortality. See chapter on “[Bronchopulmonary Dysplasia](#)” for recommendations for passive immunization against respiratory syncytial virus with palivizumab

(Synagis).

PROGNOSIS

Natural history: disease severity worsens over the first 24–72 hours, with improvement occurring after 5–10 days of age. With antenatal steroids, CPAP, newer modes of mechanical ventilation, and surfactant replacement therapy, more rapid improvement is often seen, and mortality from RDS is rare. Outcome is usually related to the degree of prematurity and its related complications.

COMPLICATIONS

Air-leak: pneumothorax, pneumomediastinum, pulmonary interstitial emphysema, pneumopericardium

ALERT

- Emergency treatment of pneumothorax: Acute tension pneumothorax can occur as a complication of RDS and its management can be life threatening, even in larger or term infants. Needle aspiration may provide temporary stabilization, and chest tube placement may be necessary.
- Pulmonary hemorrhage: typically occurs between 1 and 3 days of age with sudden respiratory deterioration and pink or red frothy fluid or bright red blood in the endotracheal tube. Associated with diffuse opacification of the lung fields and marked decrease in pulmonary compliance.
- Complications related primarily to prematurity that are often associated with RDS:
 - Patent ductus arteriosus: Pulmonary edema and high-output congestive heart failure may develop as a consequence of left-to-right shunting through the ductus.
 - Bronchopulmonary dysplasia: a chronic disease of multifactorial etiology involving abnormal lung development and abnormal repair following lung injury due in part to RDS as well as edema, infection, and other factors causing inflammation

CODES

ICD10

P22.0 Respiratory distress syndrome of newborn

FAQ

- Q: Should all babies with a diagnosis of RDS be started on antibiotics?
- A: It is important to consider sepsis/pneumonia in all infants with a diagnosis of RDS, particularly infection with group B *Streptococcus* (GBS). Risk factors to be considered include maternal GBS colonization, evidence of chorioamnionitis, intrapartum antibiotic use, and route of delivery. Antibiotics may sometimes be held if the risk factors for sepsis are low compared to those for RDS, such as in a baby delivered electively by caesarean section for maternal indications. However, as congenital pneumonia can radiographically appear identical to RDS, it is often common practice to screen for sepsis in all infants with RDS by performing blood cultures and looking for other laboratory evidence of infection including complete blood counts with

differentials and acute-phase reactants such as C-reactive protein, and start empiric antibiotic therapy with ampicillin or penicillin in combination with an aminoglycoside. Duration of antibiotics is typically 48 hours depending on results of blood cultures as well as the clinical picture and other laboratory data. Therapy may be narrowed if a specific organism is identified.

- Q: What is the most worrisome acute complication of RDS?
- A: Acute air leak (primarily tension pneumothorax) can be life threatening, even in near-term or full-term infants with RDS, and such infants should be cared for in centers that are prepared to properly handle this emergent situation in a timely fashion (i.e., availability of a provider who can perform an emergent needle aspiration and chest tube placement). In smaller infants, pulmonary hemorrhage can also be life threatening.
- Q: Because the risk of a baby developing RDS for a baby born at 26 weeks' gestation is so high, should such babies automatically receive prophylactic surfactant?
- A: Not necessarily. Early prospective, randomized, placebo-controlled studies did demonstrate that mortality from RDS was reduced with prophylactic surfactant in preterm infants ≤ 26 weeks' gestation. However, those studies were conducted in an era before widespread use of antenatal steroids and early use of CPAP. Recent prospective, randomized trials of different approaches to extremely low-birth-weight infants in the delivery suite have demonstrated that such infants treated with early and continued CPAP alone may have outcomes comparable to those immediately intubated and treated with surfactant replacement therapy.
- Q: As some surfactant preparations are prepared from cow lungs, is there an increased risk that babies receiving such surfactants will develop a milk protein allergy?
- A: It is very unlikely that surfactant treatment with preparations derived from animal lungs increases the risk of immune responses. The two proteins in replacement surfactants are present in low amounts and are extremely hydrophobic and unlikely to generate an immune response given the limited number of surfactant doses (usually

maximum of 4) administered. They are also not structurally related to proteins found in human milk, and their amino acids sequences are highly conserved between species, such that it is unlikely that they would be seen as foreign antigens by the baby's immune system.

RESPIRATORY SYNCYTIAL VIRUS (SEE ALSO: BRONCHIOLITIS)

David K. Hong • Alan R. Schroeder

BASICS

DESCRIPTION

- An enveloped, nonsegmented RNA virus of the family Paramyxoviridae and in the subfamily Pneumovirinae along with human metapneumovirus. There are 2 subgroups, A and B, differentiated by the major attachment G protein, a large surface glycoprotein. The fusion or F protein is relatively homologous between the 2 subgroups.
- It is the most common cause of bronchiolitis, a lower respiratory tract disease that primarily affects the small airways.

EPIDEMIOLOGY

- Incubation period is 2–8 days.
- Virus is detected in secretions 4 days prior to clinical symptoms. Typically shedding of infectious virions is 3–8 days but can be as long as 3–4 weeks in immunocompromised.
- Transmission occurs by direct contact of nasopharyngeal or ocular mucosa with infected secretions or fomites.
- Nosocomial spread can occur because the virus can survive on surfaces and hands for several hours.
- In the United States, epidemics typically occur between November and April and last for roughly 18–20 weeks.
- In tropical climates, respiratory syncytial virus (RSV) seasons are less predictable and can circulate year-round.
- One antigenic strain predominates during any given epidemic, but both subtypes can circulate concurrently.

Incidence

- Peak incidence is the first 2 years of life. 20–30% of infected infants develop lower respiratory tract disease.

- Annual rate of RSV-associated hospitalization is roughly 3/1,000 in children <5 years of age and 17/1,000 in children <6 months of age.

Prevalence

- 50% of children are infected by their 1st birthday. 100% of children are infected by age of 2 years.
- Reinfection can occur during the same RSV season and is common during the first few years of life.
- Subsequent infections are typically milder.

RISK FACTORS

Those at greatest risk for severe infection include:

- Children <1 year of age, especially those <6 months of age
- Children born prematurely (<35 weeks gestation)
- Children with underlying cardiopulmonary disease (e.g., chronic lung disease of prematurity, congenital heart disease)
- Those with primary immune deficits
- Patients on immunosuppressive medications (e.g., transplant patients, oncology patients)

GENERAL PREVENTION

- There is currently no RSV vaccine. A formalin-inactivated RSV vaccine tested in the 1960s caused enhanced illness after reexposure to wild-type RSV likely due to an overexuberant immune response.
- Because RSV can survive on surfaces, strict hand washing can minimize nosocomial spread.
- Contact isolation with routine usage of gowns and gloves has been shown to decrease RSV nosocomial spread.
- Patients with RSV infection should be isolated in private rooms.
- Palivizumab, a humanized monoclonal antibody directed against the highly conserved F protein of RSV, is the only product available for the prevention of RSV infection in certain high-risk children.
 - Children who should receive palivizumab:
 - Children <2 years of age who receive medical therapy for chronic lung disease
 - Infants with a history of prematurity (birth at <32 weeks gestation)

- Children for whom palivizumab should be considered:
 - High-risk premature infants born between 32 and 35 weeks' gestation
 - Infants with congenital heart disease, congenital airway abnormalities, or neuromuscular disease
- Palivizumab is given IM (15 mg/kg) every 30 days for 5 doses usually from November to April.
- Specific recommendations are available from the American Academy of Pediatrics (AAP) Committee on Infectious Diseases and Committee on Fetus and Newborn.

PATHOPHYSIOLOGY

- The G protein is the major surface glycoprotein responsible for attachment of virus to cells.
- The F protein aids in viral entry into cells and is responsible for fusion of adjacent cells to form a syncytia.
- Infection is initiated in nasopharynx and then can move to the lower respiratory tract.
- Infection of smaller airways leads to edema and necrosis of epithelial cells and infiltration of inflammatory cells, resulting in airway obstruction and air trapping.
- Severe RSV infection has been associated with recurrent wheezing later in life. It is unclear whether RSV infection causes subsequent wheezing or if patients predisposed to severe wheezing are more likely to have severe RSV disease.

DIAGNOSIS

HISTORY

- Initial symptoms include copious nasal discharge, cough, and fever.
- Cough is the most common symptom typically progressing over 1–2 days.
- Concerning findings on history:
 - Apnea, severe coughing with possible cyanotic episodes
 - Poor oral intake

- Decreased urine output (e.g., fewer wet diapers)
- Trouble breathing

PHYSICAL EXAM

- Profuse rhinorrhea
- Acute otitis media or otitis media with effusion
- Signs of dehydration (dry mucus membranes, delayed capillary refill time)
- Conjunctivitis
- Varying levels of respiratory distress:
 - Mild: suprasternal retractions, mild tachypnea
 - Moderate: subcostal or intracostal retractions
 - Severe: severe retractions, grunting, RR >60, lethargy
- Air trapping resulting in hyperexpansion of lungs can lead to a barrel-shaped chest, palpable liver, or spleen below the costal margin.
- Pulse oximetry may reveal hypoxemia.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- A definitive diagnosis of RSV can be made by viral culture but requires up to 5 days.
- Rapid diagnostic antigen assays from nasopharyngeal specimens are used for RSV detection, usually with a sensitivity of 80–90%:
 - Enzyme immunoassay
 - Immunofluorescent assay
- Reverse transcriptase-polymerase chain reaction (RT-PCR) assays are commercially available and may have superior sensitivity to rapid antigen testing. However, these assays detect viral RNA that may persist in nasal secretions after patient is no longer shedding infectious virus.
- Because concurrent serious bacterial infections are not common, complete blood counts or blood cultures are not indicated.
- Given reported 3% incidence of concurrent urinary tract infections (UTIs), urinalysis and urine culture can be considered for infants with persistent fever.

Imaging

- Chest x-rays should not be routinely obtained in children with RSV.
- Often reveals hyperinflation, increased bronchial markings, and areas of atelectasis/infiltrates, findings which may not alter the treatment plan or may in some cases lead to unnecessary antibiotics.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Influenza virus
 - Parainfluenza virus
 - Human metapneumovirus
 - Adenovirus
 - Coronaviruses
 - *Mycoplasma pneumoniae*
- Environmental: foreign body in upper airway
- Tumors: mass compressing upper airway
- Congenital: laryngomalacia or tracheomalacia

TREATMENT

MEDICATION

- β -Adrenergic agents: Bronchodilators should not be used routinely. However, there are some data to suggest that they may lead to transient improvement in respiratory scores in some patients, but no data that suggests that this impacts hospitalization rates or length of stay.
- Racemic epinephrine: Racemic epinephrine has been demonstrated to reduce hospital admission rates compared to placebo and to shorten length of stay when compared to albuterol.
- Select patients may benefit from a trial of bronchodilators, but this remains controversial. Careful attention should be paid to the clinical exam before and after administration to support their ongoing use.
- Corticosteroids are not useful in bronchiolitis and should not be used.
- Ribavirin: has in vitro antiviral activity against RSV, but ribavirin aerosol treatment for RSV infections should not be used routinely in the treatment of children with bronchiolitis. There may be some benefit in severely ill patients such as immunocompromised patients with

severe disease.

- Antibiotics are rarely indicated because concurrent bacterial disease (lung or blood) is uncommon in patients with RSV bronchiolitis. However, 3% of patients with bronchiolitis and fever have urine culture findings consistent with UTI.
- There is limited evidence that nebulized hypertonic saline (3%) may reduce length of hospital stay and improve clinical symptoms.

ADDITIONAL TREATMENT

General Measures

- Supportive care: hydration therapy and supplemental oxygen as needed if oxygen saturation persistently falls below 90%
- Cardiorespiratory monitoring and pulse oximetry should be used for infants at risk for apnea and hypoxemia.
- In severe cases, respiratory support with continuous positive airway pressure (CPAP) or mechanical ventilation is required.

INPATIENT CONSIDERATIONS

Initial Stabilization

Apnea or severe respiratory distress with impending respiratory failure may require intubation and mechanical ventilation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Lower respiratory tract symptoms usually arise 2–3 days after initial symptoms.
- Symptoms usually peak from 5 to 7 days, but 20% of children can have symptoms for 3 weeks.
- Recurrent apneic episodes are rare, and home monitoring is usually not indicated.
- Fever commonly resolves over 2–3 days.

Patient Monitoring

Signs to watch for:

- Increased respiratory rate and increased work of breathing

- Lethargy, altered mental status
- Signs and symptoms of dehydration (dry mucous membranes, decreased urine output)

PROGNOSIS

- Most children have a mild to moderate disease course requiring only supportive care.
- Approximately 1–3% of children will require hospitalization. Most children recover with no sequelae.
- Infants born prematurely or with underlying cardiopulmonary disease are at increased risk for more severe and longer duration of disease.
- Reinfections occur throughout life with an incidence of about 5% per year.
- There are some data to suggest that patients with severe RSV bronchiolitis may have more episodes of recurrent wheezing in the 1st year of life. It is unclear whether severe RSV infection causes long-term airway hyperresponsiveness.

COMPLICATIONS

- Dehydration
- Apneic episodes in young infants (can occur in all causes of bronchiolitis, not just RSV)
- Hypoxemia
- Hypercarbia
- Respiratory failure
- Pneumonia, rarely bacterial
- Croup
- Acute otitis media
- Asthma

CODES

ICD10

- B97.4 Respiratory syncytial virus causing diseases classd elswhr
- J21.0 Acute bronchiolitis due to respiratory syncytial virus
- J20.5 Acute bronchitis due to respiratory syncytial virus

FAQ

- Q: How did my child get this illness?
- A: RSV bronchiolitis is caused by respiratory syncytial virus, an extremely common virus which is passed from one person to another by contact with nasal secretions and through airborne transmission of droplets.
- Q: For how long is my child contagious?
- A: Viral shedding occurs for 24 hours prior to the onset of clinical symptoms and for up to 21 days from the onset of symptoms.
- Q: Will my child develop asthma because of the wheezing that is occurring now?
- A: There is an association between severe RSV bronchiolitis and recurrent wheezing episodes during the 1st year of life. However, it is not clear whether RSV causes asthma later in life.
- Q: How do I prevent my child from being infected with RSV?
- A: Unfortunately, there is no vaccine against RSV. In high-risk infants (infants born prematurely with chronic lung disease, congenital heart disease) palivizumab can be administered during RSV season to

prevent severe lower respiratory tract disease.

RETINOBLASTOMA

Sheila Thampi • Paul Stewart

BASICS

DESCRIPTION

Retinoblastoma is a malignant tumor of the retina. Due to current treatment options, survival rates are high in developed countries. Primary management focuses on the best treatment approach to spare the child's life, while secondary goals focus on sparing vision and reducing risk of secondary malignancies.

EPIDEMIOLOGY

- Retinoblastoma is the most common intraocular malignancy in children.
- Hereditary retinoblastoma commonly presents with bilateral disease or multiple tumors in unilateral disease
- Median age at diagnosis for unilateral disease is 24 months and less than 12 months for bilateral disease.
- 25% of patients will present with bilateral disease.
- No association with race, gender, or laterality of eye involvement
- The greatest disease burden is found in countries with the largest populations and high birth rates such as Asia and Africa.

Incidence

- In the United States, there are about 4 cases per million children per year, with a higher incidence in children younger than age 5 years.
- Approximately 300 new pediatric cases of retinoblastoma are diagnosed each year in the United States.
- Retinoblastoma represents 3% of all pediatric malignancies.

RISK FACTORS

- Hereditary retinoblastoma, in which patients have a germline Rb gene mutation
 - 25–45% of all retinoblastoma cases are hereditary.
- Family history of retinoblastoma in parents or siblings warrants early

screening and continued follow-up to monitor for development of disease.

PATHOPHYSIOLOGY

- Tumor development requires loss of function of the RB1 gene, which resides on chromosome 13.
- Constitutional loss of one RB1 allele predisposes a patient to cancer. Loss of the second allele or other mutations of retinal cells will initiate formation of retinoblastoma.
- Sporadic or nonhereditary retinoblastoma has no germline RB1 mutation but instead requires biallelic inactivation of the RB1 gene in a single retinal cell.
- There are 3 common growth patterns:
 - Intraretinal (growth only in the retina)
 - Endophytic (inner surface of retina to vitreous)
 - Exophytic (outer surface of retina to subretinal space)
 - Tumor cells that break off from the primary mass will invade the vitreous and grow independently in the vitreous.
- Children with loss of RB1 with large chromosomal deletions of surrounding genes are at risk for developmental anomalies such as facial dysmorphism and mental and/or motor impairment.
- Initial classification of tumor extent is imperative for assessment of prognosis and outcomes.
- International Classification of Retinoblastoma (ICRB), also known as the ABC classification system, is predictive of treatment success following systemic chemotherapy and focal laser treatment. However, the older Reese-Ellsworth classification system is still commonly used.
 - ICRB groups eyes from less advanced disease, group A, to most advanced disease, group E.
 - ICRB predicts high-risk retinoblastoma seen in group D or E eyes.
- High-risk features on histology include tumor invasion of the optic nerve and massive choroidal invasion. High-risk features will lead to metastases in about 24% of patients if not treated with systemic chemotherapy as compared to 4% of those treated with systemic chemotherapy.
- Patients with bilateral retinoblastoma are at risk for involvement of the

pineal gland, termed trilateral retinoblastoma.

ETIOLOGY

Mutations in the RB1 gene lead to predisposition of retinal tumors.

DIAGNOSIS

HISTORY

Parents often report noticing a white color in the pupil on photographs, eye(s) turning in or outward, and poor vision.

PHYSICAL EXAM

- Most common presenting signs include the following:
 - Leukocoria
 - Strabismus
 - Poor vision (poor tracking)
- Proptosis is worrisome for more advanced disease.
- Associated bone pain should be evaluated for metastatic disease.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC to look for leukopenia, anemia, or thrombocytopenia
 - CBC should be evaluated to determine bone marrow involvement.
 - If cytopenias are noted, then evaluation of the bone marrow is indicated.
- Extraocular spread noted on imaging warrants evaluation of the cerebrospinal fluid.
- Chromosome analysis should be performed, particularly in patients with bilateral eye involvement or developmental delay.

Imaging

- Brain and orbit MRI can aid in distinguishing between retinoblastoma and Coats disease and will assess for trilateral disease. CT scan can provide information regarding tumor calcification but due to radiation is used less frequently.
- Ophthalmic ultrasonography can demonstrate retinal masses and calcifications.

- A technetium bone scan will show areas of intense primary tumor uptake and screen for bone metastasis and should be performed if concern for metastasis noted on exam.

Diagnostic Procedures/Other

- A biopsy is not performed due to risk for dissemination.
- The diagnosis of retinoblastoma is based on ophthalmologic exam.
- An experienced pediatric ocular oncologist should perform the exam under anesthesia (EUA).
- Early involvement of pediatric oncology should be initiated.

DIFFERENTIAL DIAGNOSIS

- Coats disease
- Persistent fetal vasculature
- Vitreous hemorrhage
- Congenital cataract
- Coloboma
- Toxocariasis
- Astrocytic hamartoma
- Retinopathy of prematurity

TREATMENT

CHEMOTHERAPY

- Systemic chemotherapy is currently the most common form of treatment for retinoblastoma, as it allows preservation of the globe and prevention of systemic metastasis.
- Systemic chemotherapy is combined with local retinal therapy for adequate treatment.
- Systemic chemotherapy may prevent development of trilateral retinoblastoma.
- Most common chemotherapeutic agents used for retinoblastoma include carboplatin, etoposide, and vincristine (CEV).
- Intra-arterial chemotherapy (IAC) is a newer modality for treatment of retinoblastoma and provides direct retinal chemotherapy via the ophthalmic artery.

- Less commonly used approaches to deliver chemotherapy include periocular or intravitreal injections.

RADIOTHERAPY

- Retinoblastoma is a radiosensitive tumor.
- Radiation therapy can be provided by external beam therapy or plaque therapy (brachytherapy) and is a useful method to preserve vision.
- Use of radiation is generally avoided due to risk of secondary malignancies, particularly in children with hereditary retinoblastoma.

SURGERY/OTHER PROCEDURES

- Local retinal therapy with cryotherapy or laser photocoagulation is an important modality of treatment.
- Enucleation, removal of the eye, provides definitive treatment for retinoblastoma. Advanced eyes (group E) are usually managed with enucleation to prevent metastatic spread. Unilateral cases with less advanced disease also are frequently managed with enucleation.

PHYSICAL THERAPY

- Physical therapy is not commonly required for children with retinoblastoma.
- Occupational therapy or speech therapy can help children cope with loss of vision or hearing changes that develop due to side effects of chemotherapy.

ONGOING CARE

ISSUES FOR REFERRAL

- Children suspected to have retinoblastoma should be immediately referred to a children's hospital with expertise in these tumors. Prompt evaluation by an ocular oncologist is required for early diagnosis.
- Multidisciplinary teams include ocular oncologists, pediatric oncologists, nurses, pharmacists, and social workers.
- Children with bilateral retinoblastoma should be referred to a pediatric geneticist for genetic testing for RB1 mutations.

PROGNOSIS

- Five-year overall survival in the United States is excellent at 96.5%.
- All forms of metastatic spread: Leptomeningeal disease, trilateral or pineal involvement, and distant metastases require aggressive therapy and still result in poor overall survival.

COMPLICATIONS

- Surgical
 - Surgical site wound infections after enucleation
 - Complications associated with orbital implants (infection, bleeding, conjunctival erosion, wound dehiscence)
- Acute systemic chemotherapy toxicity
 - Myelosuppression
 - Ototoxicity
 - Infections
 - Renal dysfunction
 - Peripheral neuropathy
- Radiation
 - Skin erythema
 - Risk of cataract development
 - Vascular endothelium damage
 - Vitreous hemorrhage
 - Facial and temporal bone hypoplasia
 - Secondary malignancy
- IAC toxicity
 - Myelosuppression
 - Redness or swelling of the eyelid
 - Vitreous hemorrhage
 - Choroidal atrophy
 - Rare risk of stroke or blindness
- Late effects
 - Hearing loss and nephrotoxicity from carboplatin
 - Secondary malignancy from radiation or chemotherapy (i.e., etoposide).

Patient Monitoring

- Patients should be followed regularly by an ocular oncologist for EUAs

to monitor for reoccurrence.

- Patients should be followed by a pediatric oncologist with serial MRI of the brain and orbit and additional imaging based on sites of disease at presentation.
- Patients should be monitored for long-term side effects/complications of therapy, ideally within the context of a survivorship clinic.

CODES

ICD10

- C69.20 Malignant neoplasm of unspecified retina
- C69.21 Malignant neoplasm of right retina
- C69.22 Malignant neoplasm of left retina

FAQ

- Q: Are children with retinoblastoma at risk for developmental delays?
- A: Children who carry RB1 gene mutations should be followed closely for developmental delays with speech and/or motor skills. Children with deletions in chromosome 13 have been described to have an array of developmental delays in association with retinoblastoma.
- Q: Do siblings of children with retinoblastoma need to be evaluated?
- A: Given the high possibility of hereditary RB1 mutations, children of siblings or parents with retinoblastoma should be evaluated at an early age and followed by an ophthalmologist.
- Q: Do I need to worry about other cancers in my child who has

retinoblastoma?

- A: Children with the hereditary form of retinoblastoma (RB1 gene mutation, bilateral disease, or family history) are at increased risk for other cancers such as osteosarcoma.
- Q: Is my child with retinoblastoma blind?
- A: The size and location of the tumor(s) will determine your child's vision. Advanced retinoblastoma (group D or E) is more likely to have total retinal involvement and poor vision.

RETINOPATHY OF PREMATURITY

Michael X. Repka

BASICS

DESCRIPTION

Retinopathy of prematurity (ROP) is an abnormal pattern of retinal vascularization of preterm infants leading in some cases to permanent visual loss and blindness as well as many other eye problems.

EPIDEMIOLOGY

- ROP is the leading cause of blindness among children in the developed world:
 - 0.2% of all infants born in the United States
 - 20% of infants born <1,500 g
- 1,300 develop severe disease requiring treatment annually in the United States.
- Birth weight and ROP (incidence of ROP stage 1 or greater)
 - <750 g: 90%
 - 750–<1,000 g: 78%
 - 1,000–1,250 g: 47%
 - >1,250 g:<1%
- Gestational age and ROP (incidence of any ROP stage 1 or greater with BW <1,251 g)
 - ≤27 weeks: 83%
 - 27–31 weeks: 55%
 - ≥31 weeks: 29%

RISK FACTORS

- Gestational age
- Hyperoxia
- Hypoxia
- Acidosis
- Hypercarbia
- Apnea

- Bradycardia
- Nutritional deficiencies
- Ambient light
- Intraventricular hemorrhage
- Lower birth weight
- Lower gestational age
- Multiple gestation
- Born at another facility and transferred

PATHOPHYSIOLOGY

- Normal retinal vascularization begins at the optic disc at about 16 weeks postmenstrual age and is typically completed at about term.
- Preterm delivery exposes the actively growing vessels to unusual conditions. These alter production of vascular endothelial growth factors. In some cases, the vascular growth stops and then resumes normally, whereas in other cases, the retinal blood vessels grow abnormally off the surface of the retina.
- The timing for development of acute ROP is related to postmenstrual age and not chronologic age or birth weight. It is rare to see any disease prior to 32 weeks postmenstrual age. Fewer than 10% of babies smaller than 1,250 g birth weight will have disease sufficiently severe to have treatment.

DIAGNOSIS

HISTORY

- All infants with birth weight less than 1,500 g or gestational age less than 30 weeks are at risk.
- Other children with significant oxygen exposure are also referred for retinal evaluations.
- Each nursery needs a protocol to identify and document the infants needing examinations, both initial and follow-up. Reasons for exam deferral should be included in the medical record.

ALERT

A common error in ROP management is failure to perform exams on the

required schedule. The most vulnerable time for this lapse is during a transition to another unit or another facility or after discharge to home.

PHYSICAL EXAM

- Requires a retinal examination with pupillary dilation, binocular indirect ophthalmoscopy, sterile eyelid speculum, and scleral depression
 - Topical anesthesia may be used.
 - Pupillary dilation is obtained using 1% phenylephrine/0.2% cyclopentolate solution (Cyclomydril) administered as a single drop to each eye, repeated in 5–10 minutes.
 - Administer at least 30 minutes and preferably 1 hour prior to the exam.
 - The dilating eye drops are associated with delay in gastric emptying.
 - Careful monitoring is needed following the drop administration and the eye examination.
 - Bradycardia and emesis are common following mydriatic eye drop administration and eye examination.
- The results of the examination should be recorded in a manner defined by the International Classification of Retinopathy of Prematurity. A retinal drawing is suggested:
 - Zone I: posterior circular area of the retina centered on the optic disc with a radius twice the distance from disc to fovea
 - Zone II: peripheral ring of retina extending from zone I to anterior edge of the nasal retina and estimated temporally
 - Zone III: temporal retina beyond zone II
- Diagnostic retinal examinations and/or imaging should commence unless the infant is too unstable.
 - At 31 weeks for those infants born at 26 weeks postmenstrual age or earlier
 - By 4 weeks postnatal age for infants >26–30 weeks postmenstrual age
- Exams typically are ordered every 2 weeks.
- Additional examinations may be requested by neonatology for infants outside the consensus birth weight and postmenstrual age criteria.

- Subsequent examinations are determined by the ophthalmologist.
 - Exams typically ordered every 2 weeks
 - When there is prethreshold disease, weekly or even more frequent exams are conducted.
 - When there is zone III disease, the exam interval may be lengthened.
 - Exams continue until retinal vascularization into zone III is recorded.
 - If VEGF inhibitors have been used for treatment, the exams may need to be extended substantially past term. Exams continue until retinal vascularization into zone III is recorded.
- ROP is typically symmetric, with similar exams in both eyes seen in 85% of infants.
- Eye examinations performed in the office setting may require monitoring depending on the infant's medical status.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Wide-field digital camera with images of posterior pole, as well as superior, inferior, nasal, and temporal retinas, allows documentation and review of the findings as well as consultation.
- The images are reviewed either in real-time or using store-forward technology for evidence of referral-warranted ROP, at which time indirect ophthalmoscopy must be performed to determine if the patient has reached the treatment threshold or be monitored.
- Some facilities are using telemedicine as a substitute, rather than a supplement, for a clinical exam.
 - Skilled nursery personnel are needed to handle the camera and obtain useful images.
 - Plan for image review and urgent treatment referral when needed.

Diagnostic Procedures/Other

- Ophthalmic ultrasonography
 - If difficult to obtain adequate indirect ophthalmoscopy, B-mode ultrasound of the eye can be useful to determine progression of ROP to retinal detachment and to monitor the detachment.

DIFFERENTIAL DIAGNOSIS

- Norrie disease
- Incontinentia pigmenti
- Familial exudative vitreoretinopathy
- Trauma
- Stickler syndrome
- Cyanotic congenital heart disease in rare cases
- Idiopathic

TREATMENT

SURGERY/OTHER PROCEDURES

- Each nursery needs a policy in place for where and how treatment is to be performed.
 - Treatment should be performed within 48 hours if at all possible.
- Treatment is recommended when a particular stage of disease called type 1 occurs. Type 1 is ROP in zone I or II with PLUS characteristics (dilation and tortuosity of retinal arteries and veins), any stage in zone I, and stage 2 or 3 in zone II. Ideally, the treatment is completed within 48 hours, depending on the stability of the infant.
- Standard care treatment of ROP is ablation (destruction) of the peripheral nonvascularized retina using a laser incorporated into a binocular indirect ophthalmoscope.
 - Requires airway management, topical eye drop anesthesia, and either sedation or general anesthesia
 - 25% have unfavorable visual outcomes at 6 years.
 - 9% have unfavorable structural outcomes at 6 years.
 - 83% of treatments performed in infants ≤ 27 weeks' gestation
- Cryotherapy of the peripheral retina that has not been vascularized (anterior) has been shown to be effective compared to observation.
 - Used less frequently today because of pain, tissue damage, and difficulty treating more posterior disease
 - Improves the chance of favorable structural outcomes at age 15 years from 48 to 70%
- Vitreoretinal surgery including vitrectomy is performed after retinal

ablation or intravitreal injection has failed and the infant has progressed to stage 4 or 5 ROP (retinal detachment).

- Rarely associated with visual outcome of 20/200 or better (16%)
- Retinal reattachment in about 30%

MEDICATION

- Oxygen restriction: Restriction of oxygen to 85–89% saturation measured by pulse oximetry has been associated with a reduction in the risk of severe ROP but was associated with an increased mortality rate.
- Oxygen supplementation: In the Stop-ROP trial, supplemental oxygen for infants with prethreshold disease appeared to reduce the rate of progression but was associated with increased risk for pulmonary disease.
- Vascular endothelial growth factor (VEGF) inhibitors (e.g., bevacizumab)
 - Intravitreal injection of a small dose of one of these drugs is currently of great interest.
 - In a clinical trial, a single dose of bevacizumab was more effective than laser ablation for zone I disease.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Infants with treated ROP and more severe stages of ROP without treatment typically require lifelong ophthalmologic monitoring.
 - Substantially increased risk for the development of multiple eye conditions
 - Retinal detachment
 - Strabismus
 - Amblyopia
 - Myopia
 - Glaucoma
 - Optic nerve atrophy
 - Cerebral visual impairment

- Infants with prethreshold ROP have moderately increased risk of the ophthalmic conditions mentioned above. Referral managed with typical practice.
- A history of treatment for ROP is correlated with a high risk of disability on motor, communication–social, self-care, and continence scales on the Wee-FIM (Functional Independence Measure for Children).

PROGNOSIS

- If ROP treatment was required, visual outcomes reported at 15 years:
 - 25% with 20/20–20/40
 - 50% with 20/20–20/200
 - 33% with less than 20/200

FAQ

- Q: Does intrauterine growth retardation (IUGR) affect the chance for development of ROP?
- A: The chance for development of ROP in an infant with IUGR is more related to the postmenstrual birth age rather than the birth weight. However, in as much as the IUGR infant is sick, that could increase the risk over infants of similar postmenstrual age at birth.
- Q: When should a missed exam be made up?
- A: In most cases, it is safe to wait a week unless there has been recent evidence of stage 2 or worse disease in which case the exam should be completed as soon as the infant is stable for the dilated exam.
- Q: Does acute ROP ever need to be retreated?
- A: Following ablative therapy, about 10% of eyes will need additional treatment to untreated areas of the retina if the PLUS disease has not begun to diminish. This typically occurs about 10–14 days. The rate for retreatment after VEGF inhibitor therapy is not yet well established.

RETROPHARYNGEAL ABSCESS

Camille Sabella

BASICS

DESCRIPTION

A relatively rare but potentially life-threatening infection occurring in the potential space between the posterior pharyngeal wall and prevertebral fascia

EPIDEMIOLOGY

Children <6 years of age are most at risk, with 50% of the cases occurring in those <48 months of age.

Incidence

Most large children's hospital centers report 1–5 cases per year.

PATHOPHYSIOLOGY

- Most infections result from pharyngitis or supraglottitis and occur because of suppuration of the retropharyngeal lymph nodes, which lie in 2 paramedial chains and drain various nasopharyngeal structures and sinuses.
- These lymph gland chains disappear in childhood; thus, retropharyngeal abscesses are most common in infancy and early childhood.
- Cellulitis of the retropharyngeal area leads to formation of a phlegmon, which matures into an abscess.
- Other sources of infection in this space, often seen in older children and adolescents, include penetrating trauma of the posterior pharynx (e.g., foreign object aspiration, dental procedures, attempts at intubation).
- Extension of infection into this space can arise from vertebral body osteomyelitis or a dental abscess.

ETIOLOGY

- Infectious: Cultures frequently reveal multiple organisms.

- The predominant organisms isolated include the following:
 - Streptococcus (group A and others)
 - Staphylococcus aureus
 - Various anaerobic species (e.g., Bacteroides, Peptostreptococcus, Fusobacterium)
- Many of the isolates are β -lactamase producers.

DIAGNOSIS

HISTORY

- Symptoms may be present from hours to days before correct diagnosis is established. Many patients will have been taking oral antibiotics for presumed pharyngitis/sinusitis.
- Ask about neck trauma, especially penetrating injuries, recent surgery (especially dental), and history consistent with aspiration of a foreign object.
- Physicians must maintain a high index of suspicion. The presentation of a retropharyngeal abscess can be subtle, with the most frequent initial diagnostic impression usually epiglottitis or severe pharyngitis.
- Signs and symptoms:
 - Most frequent symptoms include sore throat, decreased oral intake, muffled voice, drooling, stiff or painful neck, fever, dysphagia, and stridor.
 - Fever
 - Stridor (seen in up to 50% of children in 1 study but only 5% in a more recent series)
 - Drooling
 - A tender cervical neck region/mass and restricted range of motion
 - Classic diagnostic finding of a bulging posterior pharyngeal wall; may be absent or difficult to appreciate in an ill, apprehensive child

PHYSICAL EXAM

- Classic presentation is the young child who develops fever, neck stiffness, torticollis, neck mass, and acute cervical lymphadenitis.
- Infants and children often appear ill, but the manifestations are

subacute and may be subtle.

- Other findings may include the following:
 - Muffled voice
 - Drooling
 - Fever
 - Dysphagia
 - Stridor

DIAGNOSTIC TESTS & INTERPRETATION

Lab

CBC may reveal an elevated total leukocyte level, with a significant left shift.

Imaging

- Lateral neck x-ray
 - Widening of retropharyngeal space and at times an air–fluid level
 - Negative plain neck film does not rule out retropharyngeal abscess.
- CT scan (contrast-enhanced) of the neck
 - Superior to plain film
 - Can usually differentiate abscess from local cellulitis/adenitis, although the sensitivity and specificity of this study for defining abscess vs. cellulitis are less than 70%

DIFFERENTIAL DIAGNOSIS

- Pharyngitis
- Peritonsillar or lateral wall abscess
- Epiglottitis/supraglottitis
- Penetrating foreign body
- Cervical osteomyelitis

TREATMENT

MEDICATION

- Start empiric broad-spectrum antibiotics, active against *Staphylococcus aureus*, *Streptococcus pyogenes*, other non–group A streptococci, and anaerobic organisms.

- Ampicillin-sulbactam or clindamycin are good initial choices. Vancomycin may be added for suspected methicillin-resistant *S. aureus* infections in a child with severe infection.
- Antibiotics may be tailored based on microbiologic and susceptibility data.

ADDITIONAL TREATMENT

General Measures

- Urgent consultation with an otolaryngology surgical team is warranted for airway management and possible surgical drainage; a team experienced in pediatric airway management is critical.
- Recent data suggest that up to 50% of patients can be successfully managed without surgical intervention.
- Patients with a well-defined abscess on admission CT are most likely to require surgical intervention.
- Patients treated with antibiotics alone must be followed closely for signs of worsening clinical status.

ISSUES FOR REFERRAL

After diagnosis is confirmed, urgent consultation with experienced surgical staff who have expertise in management of a pediatric airway is mandatory.

INPATIENT CONSIDERATIONS

Initial Stabilization

Emergency therapy requires maintaining patent airway; be wary of sudden spontaneous drainage of the abscess, with catastrophic aspiration.

ONGOING CARE

PROGNOSIS

Excellent with appropriate antibiotics, expectant care, and surgery, if needed, at optimal time

COMPLICATIONS

- Spontaneous rupture with aspiration of infected material, with subsequent asphyxia or overwhelming pulmonary infection

- Hemorrhage from extension into local arteries and/or venous thrombosis from involvement of major neck vessels
- Extension of the infection inferiorly can occur, leading to mediastinitis, a subdiaphragmatic or psoas abscess.

CODES

ICD10

J39.0 Retropharyngeal and parapharyngeal abscess

FAQ

- Q: What is the age group most at risk of having a retropharyngeal abscess?
- A: They are most common in preschool children; the paramedical chains of lymph nodes in the retropharyngeal area regress during childhood and adolescents. Thus, prior to their regression, these nodes

filter lymph from the nasopharynx and paranasal sinuses and are responsible for retropharyngeal abscesses.

REYE SYNDROME

Jayaprakash A. Gosalakal

BASICS

DESCRIPTION

- Acute encephalopathy and fatty degeneration of the liver which may be idiopathic or secondary
- “Classic” Reye syndrome is associated with aspirin (acetylsalicylic acid) therapy, whereas Reye-like syndromes are due to metabolic disorders or other etiologies.
 - Acute, noninflammatory encephalopathy that is documented clinically by (a) an alteration in consciousness and, if available, (b) a record of the CSF containing ≤ 8 leukocytes/mm³ or a histologic specimen demonstrating cerebral edema without perivascular or meningeal inflammation
 - Liver enlargement documented by either (a) a liver biopsy or an autopsy considered to be diagnostic of Reye syndrome or (b) a 3-fold or greater increase in the levels of the serum glutamic-oxaloacetic transaminase (SGOT), serum glutamic-pyruvic transaminase (SGPT), or serum ammonia
 - No more reasonable explanation for the cerebral and hepatic abnormalities

EPIDEMIOLOGY

- Peak incidence age 6 years
- Most children range from 4 to 12 years of age.
- Association with ingestion of aspirin-containing medicines by children with varicella or influenza B
- In 1982, the U.S. Surgeon General issued an advisory on the use of salicylates and Reye syndrome.
- Reye-like illness is often associated with fatty acid oxidation defects and other inborn errors of metabolism.

Incidence

- Peak incidence of 555 cases in children in the United States in 1980
- From 1994 to 1997, there were no more than 2 cases of Reye syndrome annually.
- Reye-like illness due to metabolic causes should be suspected now in all cases with this presentation.

PATHOPHYSIOLOGY

- Mitochondrial injury of unknown etiology in a viral-infected host results in dysfunction of oxidative phosphorylation and fatty acid oxidation.
- Mitochondrial toxins, usually salicylates, exacerbate the condition when ingested after mitochondrial injury.
- Multiple factors may sometimes be involved, including complex metabolic problems affecting the mitochondria.
- Postmortem
 - Liver: grossly yellowish-white due to increased triglyceride levels; foamy cytoplasm with increased microvesicular fat, decreased glycogen
 - Brain: marked edema with increased intracellular fluid and loss of neurons
 - Abnormal-looking mitochondria can be detected in many tissues.
 - Multiple organ involvement may be present in fatty acid oxidation or other defects.

DIAGNOSIS

HISTORY

- Prodromal illness: upper respiratory infection (73%)—influenza B, influenza A, and varicella
- Abrupt-onset vomiting within 47 days of initial illness
- Natural history: neurologic deterioration in which delirium may progress to seizures, coma, or death
- Underlying history of inborn errors of metabolism or family history of conditions like medium-chain acyldehydrogenase deficiency should be sought.

PHYSICAL EXAM

- Slight liver enlargement without jaundice
- Absence of focal neurologic signs
- Neurologic exam varies with stage of disease:
 - Stage 0: alert, wakeful
 - Stage 1: difficult to arouse, lethargic, sleepy
 - Stage 2: delirious, combative, with purposeful or semipurposeful motor responses
 - Stage 3: unarousable, with predominantly flexor motor responses, decorticate
 - Stage 4: unarousable, with predominantly extensor motor responses, decerebrate
 - Stage 5: unarousable, with flaccid paralysis, areflexia, and pupils unresponsive
 - Stage 6: treated with curare or equivalent drug and therefore unclassifiable
- Organomegaly may be present in Reye-like illness.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Ammonia test: Result may be normal at the onset of vomiting. Serum level >45 g/dL suggests higher mortality.
- CSF: normal except for elevated intracranial pressure
- Hypoglycemia is often present.
- Ketonemia may be present.

Imaging

EEG: characteristic of metabolic encephalopathy with generalized slow-wave abnormalities

Diagnostic Procedures/Other

- Liver and muscle function testing: elevated levels of transaminases, creatinine kinase, lactate dehydrogenase, and ammonia; increased PT
- Metabolic workup: Abnormalities of organic and amino acids may be present if symptoms are caused by a metabolic disorder.
- Cultured fibroblasts for fatty acid oxidation defects

DIFFERENTIAL DIAGNOSIS

- It is important to distinguish between so-called classic Reye syndrome, associated with aspirin (acetylsalicylic acid) therapy, and Reye-like syndromes, often due to metabolic disorders and other causes as mentioned subsequently. All cases who present with Reye syndrome should be investigated for metabolic disorders.
- Metabolic diseases: In a report by Hou et al., Reye-like syndrome was secondary to hereditary organic acidemias (n = 13), urea cycle defects (n = 4), mitochondrial disorders (n = 3), fulminant hepatitis (n = 2), tyrosinemia (n = 1), and valproate-associated hepatotoxicity (n = 1). In the United Kingdom, 12% of Reye syndrome cases between 1981 and 1996 were subsequently reclassified as metabolic disorders.
- CNS infections (e.g., meningitis, encephalitis)
- Toxins
- Drug ingestion (e.g., salicylates, valproate)

ALERT

Failure to recognize early and control or prevent cerebral edema is associated with increased mortality.

TREATMENT

GENERAL MEASURES

Vitamin K, fresh frozen plasma, and platelets as needed for treatment of secondary coagulopathy

INPATIENT CONSIDERATIONS

Initial Stabilization

- Should be tailored based on severity of presentation
- IV glucose to counteract effects of glycogen depletion
- Fluid restriction in patients with cerebral edema (1,500 mL/m²/day), along with mannitol to increase serum osmolality and induce cerebral dehydration

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Cerebral function at presentation is the best predictor of outcome. Evaluate for metabolic diseases if not done already.

PROGNOSIS

- Most patients suffer only mild illness without progression.
- Patients with milder disease (stages 0, 1, 2) tend to recover completely.
- Patients with stage 3 disease are equally likely to recover completely or die.
- Patients with stage 4 or 5 disease usually do not survive.

COMPLICATIONS

- Elevated intracranial pressure secondary to cerebral edema
- Cardiovascular collapse
- Overall mortality of 31%

CODES

ICD10

G93.7 Reye's syndrome

FAQ

- Q: Is Reye syndrome fatal?
- A: ~30% of children will die, usually due to cerebral edema. Mortality rates are best predicted by neurologic state at the onset of presentation.
- Q: How can the neurologic findings of Reye syndrome be differentiated from those of meningitis?
- A: Aside from elevated intracranial pressure, the lumbar taps of patients with Reye syndrome are at best unremarkable. Elevated leukocyte count is not seen in these cases.
- Q: What additional recommendations are suggested for children on chronic aspirin therapy?
- A. When annual influenza vaccine supply is limited, according to the CDC, vaccination efforts should focus on delivering vaccination to specific subpopulations, including children “receiving long-term aspirin therapy and who therefore might be at risk for experiencing Reye syndrome after influenza virus infection.”

RHABDOMYOLYSIS

Erica Winnicki • Farzana Perwad

BASICS

DESCRIPTION

- Rhabdomyolysis is defined as skeletal muscle breakdown resulting from injury.
- Injury may result from many causes including trauma, infection, medications or inherited disorders
- Classic presentation is with a triad of myalgia, weakness, and dark urine.
- Characterized by elevated creatinine kinase (CK) and myoglobinuria
- Release of intracellular contents from damaged muscle cells may cause severe electrolyte disturbances including life-threatening hyperkalemia, hyperphosphatemia, and hypocalcemia.
- The resulting myoglobinuria can cause obstruction of renal tubules and pigment-induced acute kidney injury (AKI), the most serious complication of rhabdomyolysis.

EPIDEMIOLOGY

- Rhabdomyolysis is more common in adults than children, where it is commonly due to illicit or prescription drugs or due to trauma.
- Rhabdomyolysis may be a common clinical problem in a catastrophic disaster (e.g., an earthquake).
- Rhabdomyolysis accounts for 7–10% of cases of AKI in the United States.

RISK FACTOR

Genetics

Many unusual causes of rhabdomyolysis, including muscle enzyme deficiencies, muscular dystrophy, and disorders of mitochondrial metabolism, are heritable disorders.

ETIOLOGY

- There are numerous potential causes of rhabdomyolysis, which can be sporadic or recurrent, traumatic, or nontraumatic.
- Muscle trauma is a common cause in both adults and children. This may occur from crush or compression injury (crush syndrome), compartment syndrome, or electric shock.
- The most common cause in children is infection, specifically viral infections. Some of the associated infections include viral (influenza A and B, Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus), certain bacterial infections (*Legionella* species, group A beta-hemolytic streptococci, *Salmonella*), and protozoa (Malaria).
- Exertion-related rhabdomyolysis may be a common cause for young athletes. Specifically, exercise which is novel, intense, or prolonged, and especially in the presence of extremely hot weather may cause rhabdomyolysis. Seizure, tetany, and alcohol withdrawal syndrome are other causes of exertion-related rhabdomyolysis.
- Certain inherited disorders should be considered with recurrent rhabdomyolysis. Myopathies involving muscle enzyme or energy substrate deficiencies include disorders of lipid metabolism (e.g., carnitine palmitoyltransferase II deficiency), disorders of glycogenolysis (e.g., phosphorylase kinase deficiency, McArdle disease), disorders of glycolysis (lactate dehydrogenase deficiency), and mitochondrial deficiency disorders. Usual triggers for rhabdomyolysis in such conditions are fasting, exertion, or viral illness.
- Rhabdomyolysis is more likely to occur after exertion in association with the dystrophinopathies, which include all forms of muscular dystrophy.
- Illicit drug use including alcohol (alcohol withdrawal syndrome), cocaine, heroin, amphetamines, phencyclidine (PCP), and ecstasy
- Causative prescription medications include lipid-lowering drugs (statins, fibrates) and antipsychotic medications (mostly due to neuroleptic malignant syndrome).
- Prolonged immobilization or loss of consciousness leading to muscle hypoxia. Certain metabolic and electrolyte disorders may result in rhabdomyolysis. These include hypokalemia, hypophosphatemia, hypocalcemia, and hyperosmolar states such as diabetic ketoacidosis.

- Body temperature changes (hyperthermia and hypothermia) may cause rhabdomyolysis.
- Malignant hyperthermia is a rare inherited condition that results in hyperthermia, muscle breakdown, and subsequent rhabdomyolysis on receiving halogenated hydrocarbon-containing anesthetics or muscle relaxants such as succinylcholine.
- Neuroleptic malignant syndrome is a rare neurologic disorder characterized by hyperthermia, rhabdomyolysis, and autonomic changes in patients receiving neuroleptic or antipsychotic medications.
- Other implicated toxins include snake bite, spider venom and vespid venoms, quail, and some mushrooms.
- The list of causes of rhabdomyolysis above is not exhaustive. Any child with sudden onset of muscle pain, tenderness, or weakness should be suspected of having rhabdomyolysis, and any child with dark urine suspected of myoglobinuria.
- The insult may lead to muscle cell destruction with release of intracellular contents including proteins and electrolytes and sequestration of fluids by damaged muscle leading to severe hypovolemia.
- Rhabdomyolysis leads to AKI by direct toxicity of myoglobin to the renal tubules, renal tubular obstruction, and renal ischemia from hypoperfusion.
- Rhabdomyolysis has also been associated with diverse conditions, including status asthmaticus, diabetes mellitus, and thyroid disease. It may also occur in Kawasaki disease, hemolytic uremic syndrome, and adrenal insufficiency, associations which are rare but must not be missed.

DIAGNOSIS

HISTORY

- Prior history of any illness or insult associated with rhabdomyolysis should be sought. Rhabdomyolysis may follow certain illnesses (e.g., influenza), insults (e.g., crush injury, severe exertion), and medications (e.g., statins).

- Symptoms of muscle pain or weakness may result from rhabdomyolysis and help suggest diagnosis if present.
- Signs of reddish-brown discoloration of the urine may be present.

PHYSICAL EXAM

- Palpate muscles for tenderness and, less commonly, swelling or fullness.
- Test for motor strength.
- Elicit reflexes to exclude neuropathy.
- Examine skin and mucous membranes for signs of vasculitis.
- Look for signs suggestive of child abuse.
- Examine for signs of a concomitant precipitating illness.
- The clinical picture is generally consistent with volume depletion given the sequestration of fluids in injured muscle tissue.

Lab

- Serum CK level, specifically the CK-MM isoenzyme, which is found in skeletal muscle, will be elevated to greater than 4–5 times the upper limit of normal. CK levels usually rise within 12 hours of the injury and peak within 2–3 days. If the CK levels continue to rise, it should raise suspicion for ongoing muscle damage or development of compartment syndrome.
- Serum electrolytes including calcium and phosphorus must be measured given the potential for severe derangements. Abnormalities may include hyperkalemia, hyperphosphatemia, and/or hypocalcemia. There may be metabolic acidosis with a wide anion gap in those conditions associated with lactate production.
- Creatinine level may be elevated out of proportion to that of BUN, secondary to conversion of liberated muscle creatine to creatinine.
- CBC and smear should be obtained because many of the metabolic disorders causing rhabdomyolysis cause a hemolytic anemia as well.
- Patients with rhabdomyolysis are at increased risk for disseminated intravascular coagulation (DIC) secondary to thromboplastin released from the injured myocytes. Therefore, PT/INR, PTT, platelets, and fibrinogen levels should be obtained.
- Serum uric acid may be elevated from release of purines from muscle

- cells and may contribute to renal tubule obstruction.
- Other muscle enzyme levels (myoglobin, aldolase, lactate dehydrogenase, AST, ALT) will be elevated secondary to muscle injury but are not necessary for diagnosis.
 - Urinalysis
 - Urine may appear brown and test positive for blood on dipstick without red blood cells on microscopy.
 - Granular pigmented casts are common. Low fractional excretion of sodium (<1%) is found in those with AKI.
 - Myoglobin is not generally measured; however, urine myoglobin can be quantitatively measured using an immunoassay. Serum CK levels are more sensitive to assess the degree of ongoing rhabdomyolysis.
 - Other tests:
 - EKG may reveal changes associated with acute hyperkalemia, such as peak T waves, prolongation of PR, absent P wave with prolonged QRS interval, or even ventricular tachycardia/fibrillation in severe untreated hyperkalemia.
 - Metabolic and genetic testing if recurrent or otherwise suspected metabolic myopathy

Imaging

Imaging is not generally required for the diagnosis. Note that use of radiocontrast in imaging studies as part of diagnostic evaluation can worsen acute kidney injury.

Other Diagnostic Procedures

Muscle biopsy: necessary to diagnose metabolic myopathies; should wait several weeks after the clinical event to perform. A biopsy will demonstrate immunohistochemical features of a myopathy. Immunoblotting is helpful in evaluating the dystrophinopathies.

DIFFERENTIAL DIAGNOSIS

- Consider other causes of discolored urine such as hematuria and beet ingestion.
- Consider other causes of muscle pain and/or weakness: viral illnesses, Lyme disease, suppurative myositis, Guillain-Barré syndrome,

collagen vascular diseases.

TREATMENT

INITIAL STABILIZATION

Aggressive repletion of fluids should be initiated promptly. If an underlying cause is identified, it should be corrected or removed.

General Measures

- Early fluid resuscitation is essential to prevent worsening kidney function. Vigorous hydration with crystalloid IV fluids should be followed by adequate maintenance fluids (e.g., 2–3 times maintenance) to provide brisk urine flow (e.g., >2 mL/kg/h or >200 mL/h).
- Alkalinization of the urine is not clearly superior to fluids alone, although risks of alkalinization are minimal.
- Use of diuretics, including furosemide (a loop diuretic), are controversial and use should be limited to fluid-replete patients. Use of mannitol is not clearly beneficial and may actually worsen AKI.

MEDICATION

- Administration of sodium bicarbonate (along with fluids) to correct or prevent acidosis is reasonable. Correction of acidosis is also beneficial in the management of hyperkalemia (potassium is shifted intracellularly).
- With alkalinization, monitor closely for worsening hypocalcemia.
- Use of diuretics is controversial; consider use in fluid-replete patients with AKI to maintain urine output and avoid volume overload (e.g., furosemide 1–2 mg/kg/dose IV). Furosemide will also maximize potassium elimination by the kidney.
- Additional treatment for severe hyperkalemia may be necessary and includes IV calcium gluconate, sodium bicarbonate, insulin and glucose, beta-2-agonist drugs, and Kayexalate.
- Correct hypocalcemia only if symptoms are present or in the setting of severe hyperkalemia in order to prevent the complication of calcium-phosphate deposition and late hypercalcemia.
- Conventional hemodialysis does not remove myoglobin effectively;

continuous venovenous hemofiltration may be more effective.

Indications for dialysis include acute renal failure with the following:

- Severe hyperkalemia refractory to medical management or rapidly rising potassium
- Severe metabolic acidosis resistant to medical management
- Volume overload/respiratory distress secondary to pulmonary edema

ONGOING CARE

Close monitoring of labs with serial measurements of CK levels, creatinine, and electrolytes is essential. The patient's fluid status should be monitored closely, and volume repletion should be continued until urine is clear and negative for blood. The patient should also be watched closely for signs of ongoing muscle injury, compartment syndrome, or DIC.

PROGNOSIS

- Prognosis is generally good, with acute kidney injury being the major life-threatening complication.
- Prompt cessation of rhabdomyolysis may be expected when the inciting cause is corrected or resolved.
- Although most children recover promptly, severe muscle injury may cause prolonged muscle weakness and warrant follow-up by physical and occupational therapy.
- With resolution of myoglobinuria, acute kidney injury is expected to be reversible.

COMPLICATIONS

- Electrolyte release from muscle can lead to severe hyperkalemia, hyperphosphatemia, and secondary hypocalcemia.
- Electrolyte derangement may result in cardiac arrhythmias.
- AKI occurs in 13–50% of patients. Risk factors for AKI include higher CK level ($>3,000$), concurrent administration of nephrotoxic agents, and volume depletion.
- Compartment syndrome may result from muscle swelling.
- Use of bicarbonate may precipitate symptomatic hypocalcemia.

- Use of calcium therapy for severe hyperkalemia or symptomatic hypocalcemia may result in calcium-phosphate deposition or exacerbate late hypercalcemia.
- Failure to discontinue IV fluids if oligoanuric renal failure develops could produce iatrogenic fluid overload.

- M62.82 Rhabdomyolysis
- T79.5XXA Traumatic anuria, initial encounter

RHABDOMYOSARCOMA

Amit J. Sabnis • Steven G. DuBois

BASICS

DESCRIPTION

- A soft tissue cancer with features of skeletal muscle differentiation. Prognostic classification of rhabdomyosarcoma (RMS) currently depends on the following:
 - Anatomic site of disease (stage)
 - Extent of resection and spread (group)
 - Underlying histology (alveolar vs. embryonal or other variants, e.g., botryoid)

EPIDEMIOLOGY

- The most common pediatric soft tissue sarcomas (tumors of mesenchymal origin)
- Accounts for ~5% of childhood cancer
- Boys at slightly increased risk compared to girls (incidence by gender of 1.5:1)
- Peaks in children <7 years of age, with another smaller peak in late adolescence
- Median age at diagnosis is 5 years.

Incidence

- 4.5 cases per 1 million children per year
- U.S. annual incidence of about 350 cases per year

RISK FACTORS

- Radiation exposure, including a possible connection to in utero exposure
- High birth weight associated with embryonal rhabdomyosarcoma in one study.

Genetics

- About 90% of cases are sporadic.

- Several predisposing conditions:
 - Li-Fraumeni (autosomal dominant)
 - TP53 mutation leads to cancer predisposition through loss of DNA damage signaling.
 - Increased risk for soft tissue sarcomas, osteosarcoma, adrenocortical carcinoma, choroid plexus carcinoma, leukemias, breast cancer, and other cancers
 - Beckwith-Wiedemann syndrome (sporadic)
 - Improper epigenetic regulation of 11p15 leads to an overgrowth syndrome.
 - Increased risk of a range of embryonal cancers early in life, including Wilms tumor, hepatoblastoma, and RMS
 - Neurofibromatosis type I and Costello syndrome (autosomal dominant)
 - Mutational activation of HRAS (Costello) or loss of the RAS-negative regulator NF1 (neurofibromatosis) leads to unchecked RAS signaling and increased risk for RMS.

GENERAL PREVENTION

- No standard approach because most cases are sporadic
- Avoidance of radiation in patients with known predisposing syndromes (e.g., Li-Fraumeni syndrome)

PATHOPHYSIOLOGY

- Alveolar rhabdomyosarcomas (ARMS; about 20% of cases) carry translocations t(2;13) or t(1;13) resulting in the fusion transcription factors PAX3-FOXO1 or PAX7-FOXO1.
 - Alveolar histology and presence of PAX3-FOXO1 is a poor prognostic factor.
 - Animal models combining expression of PAX3-FOXO1 and loss of either TP53 or CDKN2A recapitulate ARMS.
- Embryonal rhabdomyosarcomas (ERMS; about 60% of cases) commonly carry mutations in the RAS pathway as well as loss of heterozygosity at 11p15.
 - Animal models of ERMS target activating Ras mutations to myogenic progenitor cells.

- The botryoid subtype of ERMS includes submucosal tumors with a favorable prognosis.
- The remainder of cases include pleomorphic or anaplastic histologies and also harbor a poor prognosis.

COMMONLY ASSOCIATED CONDITIONS

- Syndromes listed in “Genetics” have the highest association.
- CNS and genitourinary (GU) anomalies (Chiari malformations, horseshoe kidneys, etc.) in one autopsy-based report

DIAGNOSIS

HISTORY

- Often presents as a firm mass that may be painless
- Additional symptoms relate to location of primary mass:
 - Orbital (10%): unilateral proptosis, ophthalmoplegia, visual changes
 - Head and neck—parameningeal (16%): sinus pressure, nasal congestion, hypophonation, discharge from the nose or ear, unilateral hearing loss, ophthalmoplegia
 - ▢ Parameningeal tumors with intracranial extension can present with headache, vomiting, and cranial nerve palsies.
 - Head and neck—nonparameningeal (10%; includes scalp, buccal mucosa, face): asymmetric facies, palpable mass
 - Extremities (20%): palpable mass, often tender or inflamed
 - Genitourinary (25%): bloody or mucous vaginal discharge, prolapse of tissue through vagina or urethra, hematuria, urinary retention, constipation, firm testicular mass

PHYSICAL EXAM

- Exam findings correlate with sites, as described earlier under “History.”
 - Orbital: proptosis; tumor may be visible beneath everted palpebrum
 - Head and neck: visibly asymmetric facies. Tumors arising in the sinuses or pharynx may be visible in the oral or nasal cavity.
 - Extremities: palpable mass, often tender or inflamed. Lymph nodes commonly involved.

- Genitourinary: Prolapsed tissue may be visible through urethra (bladder primary) or vagina (vaginal primary); firm scrotal mass (paratesticular primary)
- Abnormal neurologic exam raises suspicion for intracranial extension.
- Evidence of cytopenias (petechiae, pallor) raises suspicion for bone marrow metastases.
- Enlarged lymph nodes suggest regional nodal spread, common in extremity RMS.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - To provide an estimate of marrow involvement
 - To help rule out a hematopoietic malignancy
- Electrolytes including calcium and magnesium, liver function tests, and blood urea nitrogen (BUN)/creatinine prior to initiating therapy
- Tumor lysis labs (uric acid, lactate dehydrogenase [LDH] and phosphate in addition to chemistries above) may be helpful if other malignancies are diagnostic considerations.

Imaging

- MRI (preferred) or CT scan of primary site
- Chest CT to rule out pulmonary metastases (most common site of metastatic disease)
- Abdominal and pelvic CT to evaluate for nodal metastases in paratesticular tumors
- ^{99m}Tc bone scan and/or PET scan to evaluate for bone metastasis

Diagnostic Procedures/Other

- Surgical biopsy, performed by an experienced surgeon with a high index of suspicion for malignancy and with appropriate precautions to prevent tumor spill

ALERT

Testicular masses should not be biopsied but rather resected along with the spermatic cord through an inguinal approach. It is vital that the performing surgeon is aware of the potential diagnosis of RMS.

- Bilateral bone marrow biopsies to evaluate for metastatic disease in the bone marrow
- Lumbar puncture for CSF cytology if intracranial extension is a possibility (parameningeal tumors)
- Echocardiogram to ensure normal cardiac function before administering anthracyclines

Pathologic Findings

- Small round blue cells are characteristic, although may see spindle cell elements.
- All RMS are considered high-grade tumors.
- Immunohistochemical stains include positivity for desmin and myogenin, negativity for CD45, CD99, and synaptophysin.
- Diffuse myogenin staining suggests ARMS.
- Fluorescence in situ hybridization (FISH) probes for FOXO1 translocations may help identify ARMS.

DIFFERENTIAL DIAGNOSIS

- Other small round blue cell tumors
 - Ewing sarcoma (CD99+)
 - Neuroblastoma (synaptophysin+)
 - Non-Hodgkin lymphoma (CD45+)
- Other cancers
 - Non-RMS soft tissue sarcomas
 - Germ cell tumors (especially GU masses)
 - Rhabdoid tumor
- Nonmalignant masses
 - Trauma
 - Benign growths (lipoma, rhabdomyoma)
 - Abscess or other infectious process

TREATMENT

MEDICATION

- The backbone of RMS chemotherapy in North America is cycles of vincristine and actinomycin D, with or without cyclophosphamide

(also known as “VA” or “VAC”).

- VA can be given as outpatient therapy.
- Cyclophosphamide is omitted for low-risk patients.
- Additional agents under investigation for high risk or relapsed patients include doxorubicin, ifosfamide, etoposide, and camptothecins (e.g., irinotecan).
- Experimental protocols include insulin-like growth factor 1 receptor (IGF-1R) monoclonal antibodies.
- Supportive care regimens include *Pneumocystis carinii* pneumonia (PCP) prophylaxis, myeloid growth factors (e.g., granulocyte colony-stimulating factor [G-CSF]) to shorten neutropenia, antiemetics, and laxatives.

ADDITIONAL TREATMENT

General Measures

- Therapy usually lasts approximately 1 year.
- Patients require surgery and/or radiation therapy for local control.
- Cytotoxic chemotherapy has significant short- and long-term toxicities (see “[Complications](#)”).
- The majority of children are treated at pediatric oncology centers to provide
 - Access to the most recent cooperative group clinical trials
 - A multidisciplinary team of pediatric oncologists, surgeons, radiation oncologists, pathologists, pharmacists, nutritionists, and social work support

ADDITIONAL THERAPIES

- In North America, radiation therapy is used for local control in all cases, except completely resected ERMS.
- Any nonresected sites of metastatic disease are also typically treated with radiation.

ISSUES FOR REFERRAL

- Referral to an experienced pediatric oncology center is strongly encouraged.
- A pediatric oncologist should be consulted whenever the diagnosis of RMS is suspected, prior to any invasive procedures.

- Pediatric oncology consultation should also be encouraged for young adults with RMS.

SURGERY/OTHER PROCEDURES

- Surgeons assist in pretreatment staging and in determining a patient's clinical group based on extent of initial surgery.
- Given radiosensitivity of RMS, avoid surgical procedures that will result in significant loss of function.
- If deemed resectable without significant loss of function, the goal should be complete excision with negative margins.

INPATIENT CONSIDERATIONS

- Admit patients with severe cytopenias, threat to vision or airway due to mass effect, or for expedited workup if unable to access care.
- Diagnostic workup can often be performed on an expedited outpatient schedule.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients seen regularly by pediatric oncology
- After completion of therapy, follow-up with pediatric oncology is every 3 months for the 1st year, then the interval between visits can be gradually increased.
- Patients should continue to receive annual preventive health visits with their primary medical doctor (PMD).
- Vaccinations are deferred during cytotoxic therapy due to limited efficacy, although annual influenza vaccines are recommended.

PATIENT EDUCATION

- Patients' families are reminded that fevers are medical emergencies in children receiving chemotherapy.
- Patients' families are advised of signs/symptoms that might suggest recurrent disease.

PROGNOSIS

- Overall survival is approximately 70%, with significant differences

based on risk group.

- Current risk stratification in North America includes the following:
 - Stage (based on anatomic site of disease, size, and regional node involvement)
 - Orbital, nonparameningeal head and neck, vaginal, and biliary tract are favorable.
 - Extremity and parameningeal sites are unfavorable.
 - Clinical group (extent of residual disease remaining after initial surgery)
 - Gross residual disease is unfavorable (except in orbital disease).
 - Metastatic disease is very unfavorable.
 - Histology
 - ARMS is never classified as low risk.
- 5-year event-free survival is estimated to be
 - >90% for low-risk disease
 - 70–80% for intermediate-risk disease
 - <30% for high-risk disease

COMPLICATIONS

- RMS therapy is intensive and has numerous secondary effects.
- Acute toxicities:
 - Marrow suppression, requiring blood and platelet transfusions and raising the risk of life-threatening sepsis
 - Severe nausea and vomiting
 - Mucosal injury with pain and poor PO intake
 - Neuropathic pain, extremity weakness, and constipation due to vincristine
 - Risk of hemorrhagic cystitis (rare) with cyclophosphamide
 - Hepatic sinusoidal obstructive syndrome
- Late effects (see “[Cancer Therapy Late Effects](#)” chapter):
 - Infertility (related to cyclophosphamide or ifosfamide)
 - Cardiomyopathy (related to doxorubicin)
 - Secondary malignancies (e.g., leukemia from chemotherapy or sarcomas in radiation field)
 - Radiation vasculopathy (increased risk of stroke in patients with CNS radiation, hypertension in those with renal radiation)

- Long-term monitoring in a Cancer Survivorship program is recommended.

CODES

ICD10

- C49.9 Malignant neoplasm of connective and soft tissue, unsp
- C49.0 Malignant neoplasm of connective and soft tissue of head, face and neck
- C49.5 Malignant neoplasm of connective and soft tissue of pelvis

FAQ

- Q: Are other children in the family at risk for developing rhabdomyosarcoma?
- A: Familial risk for developing RMS is rare, outside of syndromes addressed in “Genetics.”
- Q: Does a patient’s age influence outcome?
- A: Patients <1 and >10 years of age have poorer outcomes than the majority of RMS patients, who are diagnosed between those ages.

RHEUMATIC FEVER

David Hehir

BASICS

DESCRIPTION

- A postinfectious inflammatory disease caused by rheumatogenic strains of group A β -hemolytic Streptococcus (GABHS)
- Acute rheumatic fever (ARF) results in a wide range of disease, from mild joint involvement to chronic carditis.
- The most significant socioeconomic impact is caused by its most severe form, rheumatic heart disease (RHD). Although rarely fatal in the acute phase, RHD may result in significant disability and shortened lifespan. Therefore, the elimination of RHD is a main goal of the World Health Federation.

EPIDEMIOLOGY

- Occurs following pharyngitis with rheumatogenic GABHS strains
- GABHS strains causing skin infections have been associated with ARF in tropical and underdeveloped areas of the world.
- Initial episode seen primarily in patients 5–15 years of age
- No racial or ethnic predilections

Incidence

- Historically, untreated GABHS infection results in ARF in 0.1–0.3% of cases, with attack rates as high as 3% in endemic areas.
- Decrease in incidence due to increased use of antibiotics, improved environmental factors such as overcrowding, and changing virulence patterns of GABHS strains

Prevalence

- 12 million people are affected by ARF worldwide, with 400,000 cases of RHD.
- RHD accounts for 25–40% of all cardiac disease worldwide.

RISK FACTORS

Genetics

No specific genetic risk factor identified, although numerous studies have demonstrated an association of ARF with specific human leukocyte antigen (HLA) alleles.

PATHOPHYSIOLOGY

- GABHS triggers a complex inflammatory host response, affecting the heart, joints, brain, blood vessels, and subcutaneous tissue.
- Classic example of molecular mimicry, in which the host produces antibodies to certain GABHS M proteins, which are similar in structure to host proteins such as myosin, resulting in autoimmune tissue damage
- Aschoff nodules are proliferative lesions noted in the myocardium that may persist for months to years after initiation of disease.

ETIOLOGY

Immune-mediated inflammatory reaction to specific rheumatogenic strains of GABHS

DIAGNOSIS

HISTORY

Diagnosis is based on the modified Jones criteria (updated 1992):

- Evidence of recent GABHS infection **PLUS** 2 major **OR** 1 major and 2 minor criteria
- Major criteria (% affected)
 - Polyarthritis (70%): migratory arthritis of major joints; more common in adults
 - Carditis (50%): 85% of those with carditis have mitral regurgitation, and 54% have aortic valve involvement. Symptoms range from asymptomatic murmur to fulminant heart failure; carditis is more common and more severe in children.
 - Sydenham chorea (15%): abnormal behavior and/or involuntary, purposeless movements
 - Erythema marginatum (10%): evanescent, pink rash with serpiginous borders

- Subcutaneous nodules (2–10%): painless nodules over extensor surfaces of large joints, the occiput, and/or vertebral processes
- Minor criteria
 - Fever
 - Arthralgia (mild pain without objective findings): can only be considered without finding of arthritis
 - Elevated acute-phase reactants: ESR, C-reactive protein
 - Prolongation of the PR interval on ECG
- Exceptions to the Jones criteria include the following:
 - Sydenham chorea alone
 - Subclinical carditis (echocardiogram evidence of RHD) in the absence of other criteria should be treated as ARF.
 - Jones criteria not useful with recurrence; World Health Organization (WHO) recommends treating recurrence in a patient with RHD history and presence of any new major or minor criterion.

PHYSICAL EXAM

- Cardiac
 - Murmur of valvulitis: holosystolic mitral regurgitant murmur, Carey-Coombs apical mid-diastolic murmur, or a basal diastolic murmur of aortic insufficiency (major criterion)
 - Pericardial friction rub: pericardial effusion
- Musculoskeletal
 - Pain, limited motion, erythema, warmth of 2 or more large joints: arthritis (major criterion)
- Neurologic
 - Choreiform movements (must be differentiated from tics, athetosis, and hyperkinesia)
 - Sydenham chorea (major criterion)
- Dermatologic
 - Evanescent, pink rash with pale centers and serpiginous borders on the trunk and proximal extremities: erythema marginatum (major criterion)
 - Firm, painless nodules over the extensor surface of large joints, occiput, and/or spinous processes: subcutaneous nodules (major criterion)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Specific tests: No specific diagnostic test is available.
- Nonspecific tests
 - Throat culture: neither sensitive nor specific; false negative in up to 2/3 of affected patients or false positive in patients who are colonized
 - Elevated or rising streptococcal antibody titers, antistreptolysin O, anti-DNase B, and antihyaluronidase may be helpful.
 - ESR and C-reactive protein elevation

Imaging

- ECG: prolonged PR interval (minor criterion), junctional rhythm, transient arrhythmias, ST-T wave changes
- Chest radiograph: Cardiomegaly may indicate carditis or pericardial effusion. Pulmonary edema may reflect left heart failure due to valvulitis.
- Echocardiogram: Assess valve involvement, ventricular dilatation, function, and pericardial effusion.

DIFFERENTIAL DIAGNOSIS

- Carditis
 - Viral
 - Bacterial
 - Rickettsial
 - Parasitic
 - Mycoplasma mycoides
 - Kawasaki disease
- Arthritis
 - Poststreptococcal reactive arthritis (PSRA)
 - Serum sickness
 - Septic arthritis (e.g., gonococcal)
 - Lyme disease
- Collagen vascular disease
 - Juvenile rheumatoid arthritis (small joints, not migratory, and not relieved promptly with aspirin)

- Systemic lupus erythematosus
- Bacterial endocarditis
- Chorea
 - Congenital choreoathetosis
 - Brain tumors
 - Huntington chorea
 - Wilson disease
 - Pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS)
- Hematologic disorders with joint involvement
 - Sickle cell anemia
 - Leukemia
- Congenital heart defects: previously undiagnosed valvular heart disease
- Mitral valve prolapse with regurgitation

TREATMENT

MEDICATION

First Line

- Anti-inflammatory
 - Aspirin 60–100 mg/kg/24 h PO divided q6–8h; may be reduced when fever and acute-phase reactants have normalized for 6–8 weeks
- Antibiotics in ARF
 - Penicillin V potassium
 - Children: 250 mg 2–3 times/day for 10 days
 - Adolescents, adults: 500 mg 2–3 times/day for 10 days
- Secondary prophylaxis
 - Penicillin G benzathine IM (600,000 U for weight <27 kg or 1,200,000 U for weight >27 kg) every 3–4 weeks

Second Line

- Anti-inflammatory
 - Prednisone 2 mg/kg/24 h for 2 weeks, then taper
- Antibiotics in ARF

- Erythromycin, amoxicillin, 1st-generation cephalosporin
- Secondary prophylaxis
 - Penicillin V potassium 250 mg b.i.d.
 - Erythromycin, sulfadiazine

ADDITIONAL TREATMENT

General Measures

- Primary prevention: appropriate and early treatment of GABHS pharyngitis
- Interventions to address poverty, crowding, and housing challenges
- Treatment of ARF
 - Antibiotics: full course of penicillin or equivalent to eradicate active infection; does not alter course of carditis
 - Anti-inflammatory: High-dose aspirin is standard; steroids may help for severe carditis but remain controversial.
 - Cardiac support: aggressive support of cardiac function and use of systemic afterload reduction for severe disease
 - Surgical valvuloplasty or valve replacement may be necessary in severe cases.
 - Bed rest: controversial; recommended at times for severe cases
- Secondary prevention of recurrence
 - Ideally administered as penicillin G benzathine as a monthly IM injection, but oral daily penicillin or erythromycin is acceptable in areas of low prevalence.
 - Duration is based on clinical presentation and degree of cardiac involvement:
 - ▢ ARF without cardiac involvement: 5 years or until age 18 years, whichever is longer
 - ▢ ARF with mild or resolved carditis: 10 years or until age 25 years, whichever is longer
 - ▢ ARF with severe carditis or cardiac surgery: lifelong
- Treatment of chorea
 - Usually supportive
 - Phenobarbital and haloperidol are most commonly used; chlorpromazine, diazepam, or valproic acid also used

ISSUES FOR REFERRAL

Patients with new murmurs or clinical evidence of heart failure should be referred to a cardiologist.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Full treatment of streptococcal pharyngitis infection and cardiac support if heart failure present
- Treatment phases include primary prevention, management of ARF, and secondary prevention of recurrence.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients without carditis
 - Close follow-up is needed for 2–3 weeks to assess patient's condition for development of acute carditis.
 - Long-term pediatric follow-up is needed to diagnose patients with indolent carditis.
 - Long-term follow-up is needed to evaluate patients who develop chorea.
 - Prophylaxis should be stressed even in patients without carditis.
- Patients with carditis
 - Cardiology follow-up is needed to assess development or evolution of RHD.
 - Symptoms of worsening heart failure suggest progression of valvular or myocardial disease, recurrent ARF, or endocarditis.
 - Secondary prophylaxis and bacterial endocarditis prophylaxis should be stressed.

PROGNOSIS

- ARF recurrence rate as high as 36% without prophylaxis
- Chorea may last weeks to months and has a similarly high recurrence rate.
- Carditis may resolve spontaneously (70–80%) or progress. Severity of the initial carditis is a major determinant of progression.

COMPLICATIONS

Long-term complications related to evolution of RHD

- Mitral stenosis
- Mitral regurgitation
- Aortic stenosis
- Aortic regurgitation
- Chronic heart failure

- I09.9 Rheumatic heart disease, unspecified
- M06.9 Rheumatoid arthritis, unspecified

FAQ

- Q: Does a negative throat culture rule out ARF?
- A: No. Throat cultures may be negative in 2/3 of patients.

- Q: Is there a vaccine available that is effective in preventing ARF?
- A: Not at present. Given that >90 antigenic strains of group A Streptococcus have been identified; vaccines development is focused on strains with the greatest virulence.
- Q: What genetic factors predispose to ARF?
- A: Patients with certain HLA-DR antigens are predisposed to ARF. The specific antigen/allele varies with the ethnic group.
- Q: Can ECG evidence of carditis alone be used to diagnose rheumatic fever?
- A: An ECG finding of carditis in the absence of a murmur does not fulfill the Jones criteria. However, many experts would agree to treat subclinical carditis as ARF, especially in areas of high prevalence.

RHINITIS, ALLERGIC

Esther K. Chung • Karen P. Zimmer

BASICS

DESCRIPTION

- Inflammation of the nasal and sinus mucosae, associated with sneezing, swelling, increased mucus production, and nasal obstruction; may be classified as seasonal, perennial, or a combination
 - Seasonal: periodic symptoms, involving the same season for at least 2 consecutive years; most often due to pollens (e.g., trees, grass, weeds) and outdoor spores
 - Perennial: occurring at least 9 months of the year; may be more difficult to detect because of overlap with other infections; may be due to multiple seasonal allergies or continual exposure to allergens (e.g., dust mites, cockroaches, molds, and animal dander)
 - Perennial, with seasonal exacerbations
- The Allergic Rhinitis and Its Impact on Asthma (ARIA) World Health Organization expert panel prefer the classification for allergic rhinitis of intermittent or persistent, with subclassifications of mild, moderate, or severe.

EPIDEMIOLOGY

Prevalence

Most common allergic disease; affecting approximately 40 million Americans; affects 40% of children and 15%–30% of adolescents

RISK FACTORS

Genetics

Increased incidence in families with atopic disease. If 1 parent has allergies, each child has approximately a 30% chance of having an allergy; if both parents have allergies, each child has a 70% chance of having an allergy.

GENERAL PREVENTION

- Minimize exposure to dust mites: Consider removing carpets, upholstered furniture, and curtains; washing bedding in hot water frequently, at least every 1–2 weeks; use pillow and mattress covers.
- Minimize exposure to animal dander.
- Minimize exposure to all animals; consider using solutions containing tannic acid, which will denature animal allergens; shampoo pets frequently if pets cannot be removed from the household; use air vent filters.
- Minimize exposure to pollens: Keep windows closed, use air-conditioning and avoid leaf raking or lawn mowing.
- Minimize exposure to molds: Keep houseplants out of the bedroom; avoid spending time in the basement, keep humidity at 35–50%.
- Early introduction of complementary foods—particularly cereals, fish, eggs—prior to a year of age was inversely associated with allergic rhinitis.

ETIOLOGY

- Indoor allergens: house dust mite, cockroaches, animal dander, cigarette smoke, hair spray, paint, molds
- Pollens: tree pollens in early spring, grass in late spring and early summer, ragweed in late summer and autumn
- Multiple environmental factors
- Changes in air temperature

COMMONLY ASSOCIATED CONDITIONS

- Asthma
- Allergic conjunctivitis
- Atopic dermatitis (eczema)
- Urticaria
- Otitis media with effusion
- Sleep, taste, and/or smell disturbance
- Nasal polyps
- Mouth breathing
- Snoring
- Adenoidal hypertrophy and sleep apnea
- Decreased appetite

- Delayed speech

DIAGNOSIS

HISTORY

- Typical symptoms: Patient often reports bilateral stuffy nose, sneezing, itching, runny nose, noisy breathing, snoring, cough, halitosis, and repeated throat clearing. Sensation of plugged ears and wheezing may occur.
- Red and itchy eyes
- Symptom occurrence: seasonal, perennial, or episodic
- Exacerbating factors including pollen, animals, cigarette smoke, dust, molds
- Family history of atopic disease such as asthma or atopic dermatitis
- Any related illnesses: Asthma, urticaria, eczema, ear infections, and delayed speech are commonly associated conditions.

PHYSICAL EXAM

- Allergic shiners
 - Dark discoloration beneath the eyes due to obstruction of lymphatic and venous drainage, chronic nasal obstruction, and suborbital edema
- Dennie-Morgan lines
 - Creases in the lower eyelid radiating outward from the inner canthus; caused by spasm in the muscles of Müller around eye due to chronic congestion and stasis of blood
- Allergic salute
 - A gesture characterized by rubbing the nose with the palm of the hand upward to decrease itching and temporarily open the nasal passages
- Allergic crease
 - Transverse crease near the tip of the nose, secondary to rubbing
- Nasal mucosa may appear pale and/or edematous; mucoid or watery material may be seen in the nasal cavity; check for nasal polyps and septal deviation.

DIAGNOSTIC TESTS & INTERPRETATION

- Audiometry and tympanometry when indicated
- Sweat test if cystic fibrosis is suspected or if nasal polyps are present

Lab

- Nasal cytology
- Specimen of nasal discharge to check for the presence of eosinophils. Have the patient blow his or her nose into a piece of nonporous paper or collect discharge with a cotton swab and transfer the discharge to a glass slide. >10% eosinophils are considered positive for nasal eosinophilia. Note: Use of intranasal steroids may reduce the number of eosinophils found in nasal discharge.
- Radioallergosorbent tests (RAST)
 - In vitro test to measure allergen-specific IgE; expensive; useful in patients who have diffuse atopic dermatitis. The ImmunoCAP system (Pharmacia Diagnostics) is the preferred method for specific IgE testing; uses a single blood sample to identify levels of specific IgE to a number of common respiratory allergens (available as a profile specific to the region of the country where the patient resides), food antigens (food allergy profile), or both (childhood allergy profile)
- Total IgE: elevated in allergic rhinitis; not routinely indicated but may come as part of specific IgE testing; >100 kU/L is considered elevated.
- CBC: may show eosinophilia; not routinely indicated
- Skin testing
 - Skin prick test: percutaneous, qualitative test in which antigen concentrate is placed on the skin of the volar surface of the arm or upper back, and a needle is inserted; high negative predictive value; the skin reaction is graded subjectively from 0 to 4.
 - Intradermal test: qualitative test in which antigen is introduced intradermally (0.02 mL with a 26–30-gauge needle); more sensitive than the prick test and often used if prick test is negative or equivocal; the degree of swelling and erythema is graded from 0 to 4.
 - Caution: Skin tests may be difficult to interpret in patients with diffuse eczema and dermatographism.

- Although positive allergen-specific IgE testing or skin prick testing denote sensitization to an allergen, these positive tests must be interpreted in the context of the clinical presentation.

Diagnostic Procedures/Other

Rhinoscopy to assess the nasal turbinates and to look for nasal polyps

DIFFERENTIAL DIAGNOSIS

- Infection
 - Viral upper respiratory tract infection
 - Bacterial sinusitis
- Environmental
 - Foreign body
 - Temperature
 - Odors
- Tumors
 - Nasal polyps
 - Dermoid cyst
 - Nasal glioma
- Congenital
 - Cystic fibrosis
 - Choanal atresia
 - Ciliary motility disorder (e.g., immotile cilia syndrome)
 - Septal deviation
 - Primary atrophic rhinitis
- Immunologic
 - Sarcoidosis
 - Granulomatosis with polyangiitis (Wegener granulomatosis)
 - Systemic lupus erythematosus
 - Sjögren syndrome
- Allergic
 - Nonallergic perennial rhinitis
 - Idiopathic (vasomotor) rhinitis
 - Drug-induced rhinitis
 - Food-induced rhinitis
- Miscellaneous

- Rhinitis medicamentosa
- Rhinitis associated with pregnancy/other hormonal rhinitis
- Hypothyroidism
- Idiopathic neonatal rhinitis

TREATMENT

MEDICATION

- Improve mucociliary flow.
 - Steam inhalation
 - Normal saline drops
 - Bicarbonate spray
 - N-acetylcysteine (orally or inhaled)
 - Oral guaifenesin
- Antihistamines: competitively blocking histamine (H₁) receptors; suppress itching, ocular symptoms, sneezing, and rhinorrhea; not very effective against nasal congestion
- Intranasal 2nd-generation antihistamine
 - Azelastine: age ≥ 5 years; 137 mcg per spray; 1 spray per nostril twice a day. Safety and effectiveness of this dose have been established for children older than 5 years, but the efficacy has not yet been established in the pediatric population and is extrapolated from adult data.
- 2nd-generation antihistamines: tend not to cross the blood–brain barrier and therefore do not have CNS side effects such as drowsiness
 - Loratadine (Claritin): FDA-approved for children as young as 2 years of age. Dose: ages 2–5 years, 5 mg/day PO; ages 6 years or older, 10 mg/day PO
 - Desloratadine (Clarinex): FDA-approved for children ≥ 6 months of age. Dose: 6–12 months, 1 mg/day PO; 12 months–5 years, 1.25 mg/day PO; 6–12 years, 2.5 mg/day PO; >12 years, 5 mg/day PO
 - Cetirizine HCl (Zyrtec): FDA-approved for children as young as 6 months of age. Dose: age 6 months–5 years, 2.5 mg = 1/2 tsp/day (1 mg/mL banana–grape-flavored syrup) PO with maximum dose of 5 mg/day (must be divided into 2.5 mg b.i.d. for children <2 years of

- age). Age ≥ 6 years, 5–10 mg/day
- Levocetirizine (Xyzal): dose: age 6 months–5 years: 1.25 mg/day (1/2 tsp = 2.5 mL); ages 6–11 years: 2.5 mg/day (half tab or 1 tsp = 5 mL) PO; age ≥ 12 years: 5 mg/day (1 tab or 2 tsp = 10 mL) PO
 - Fexofenadine HCl (Allegra): ages 2–11 years: 1 tsp = 5 mL (30 mg/5 mL) or 30-mg tab b.i.d.; age ≥ 12 years, 60 mg b.i.d. or 180 mg/24 h PO
 - 1st-generation antihistamine side effects include drowsiness, performance impairment, and paradoxical excitement; anticholinergic (e.g., dry mouth, tachycardia, urinary retention, and constipation): diphenhydramine (Benadryl) 5 mg/kg/day PO divided q.i.d.
 - Intranasal steroids: blunt early-phase reactions and block late-phase reactions; may not be fully effective until several days to 2 weeks after initiation of therapy; must be used regularly and best when administered lying down with the head back
 - Beclomethasone (Vancenase, Beconase): for use in children ≥ 6 years of age
 - Flunisolide (Aerobid): for use in children ≥ 6 years of age
 - Fluticasone propionate (Flonase 0.05%): for use in children ≥ 4 years of age
 - Budesonide (Rhinocort): for use in children ≥ 6 years of age
 - Triamcinolone acetonide (Nasacort): for use in children ≥ 2 years of age
 - Mometasone furoate monohydrate (Nasonex): for children ≥ 2 years of age
 - Intranasal antihistamines: azelastine hydrochloride (Astelin; approved for children ≥ 5 years; 5–11 years: 1 spray each nostril b.i.d.; ≥ 12 years: 2 sprays each nostril b.i.d.) and olopatadine (Patanase; approved for children ≥ 6 years; 6–11 years: 1 spray per nostril b.i.d.; 12 years and older: 2 sprays per nostril b.i.d.) are FDA-approved for use in seasonal allergic rhinitis.
 - Topical cromolyn (Nasalcrom): mast cell stabilizer; minimal side effects; does not provide immediate relief (may take 2–4 weeks to see clinical effect): for use in children ≥ 2 years of age
 - Oral decongestants: Alpha-1 and -2 agonists (e.g., ephedrine,

pseudoephedrine, and phenylephrine) act to cause vasoconstriction, decreased blood supply to the nasal mucosa, and decreased mucosal edema. Cardiovascular and CNS side effects include tremors, agitation, hypertension, insomnia, and headaches.

- Topical decongestants: Sympathomimetics such as short-acting phenylephrine (Neo-Synephrine) and long-acting oxymetazoline (Afrin) may be useful for a few days to open nasal passages to allow for delivery of topical steroids; side effects include drying of the mucosa and burning. Use for more than a few (3–5) days may result in rebound vasodilatation and congestion (rhinitis medicamentosa).
- Combined oral decongestants and antihistamines: numerous preparations on the market
- Leukotriene receptor antagonist (montelukast [Singulair]): for use in children ≥ 6 months of age. Dose for 6 months to 23 months, one packet 4-mg granules; 2–5 years, 1 granule packet (4 mg) or 4-mg chewable tab daily; 6–14 years, 5-mg chewable tab daily; age ≥ 15 years, 10-mg tab daily
- Immunotherapy: also referred to as hyposensitization or desensitization; consists of a series of injections with specific allergens, with increasing concentrations of allergens, once or twice weekly; recommended for patients who have not responded to pharmacologic therapy
 - Effective and long lasting. After several months to years of treatment, total serum IgE levels decrease, and the intensity of the early-phase response is reduced.
 - Side effects include urticaria, bronchospasm, hypotension, and anaphylaxis.

ADDITIONAL TREATMENT

General Measures

Avoidance therapy: Identify and eliminate known/suspected allergens.

SURGERY/OTHER PROCEDURES

- Removal of allergic polyps
- Inferior turbinate surgery to reduce the size of the turbinate and relieve obstruction

- Endoscopic sinus surgery to relieve obstruction

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Fever, prolonged or severe headache, dizziness, pain, or purulent discharge should suggest a diagnosis other than allergic rhinitis alone

PROGNOSIS

Generally good: Complete recovery occurs in 5–10% of patients.

COMPLICATIONS

- Chronic sinusitis
- Recurrent otitis media
- Hoarseness
- Loss of smell
- Loss of hearing
- High-arched palate and dental malocclusion from chronic mouth breathing

CODES

ICD10

- J30.9 Allergic rhinitis, unspecified
- J30.1 Allergic rhinitis due to pollen
- J30.89 Other allergic rhinitis

FAQ

- Q: How does one minimize exposure to dust mites?
- A: Keep household temperature low; maintain humidity at ~40–50%; wash linens weekly at hot temperatures; use a microfilter when vacuuming; place mattress and box spring in tightly woven casing; use air-conditioning; use high-efficiency particulate air filter units.
- Q: How often are nasal polyps associated with cystic fibrosis?
- A: In up to 40% of children, nasal polyps are associated with cystic fibrosis. <0.5% of children with asthma and rhinitis have nasal polyps.
- Q: When used on a daily basis, are intranasal steroids safe?
- A: Yes. It is generally accepted that inhaled steroids are safe. Growth suppression has been reported in children using certain intranasal steroids; however, this effect does not appear to be an effect of all intranasal steroids. Importantly, one should use the lowest effective dose of intranasal steroids when treating allergic rhinitis.

RICKETS/OSTEOMALACIA

Alison M. Boyce • Laura L. Tosi

BASICS

DESCRIPTION

- Osteomalacia refers to impaired bone mineralization, caused primarily by deficiencies in vitamin D and/or calcium.
- In children, osteomalacia leads to growth plate abnormalities, termed rickets.

EPIDEMIOLOGY

- The prevalence of rickets and osteomalacia is very high in many parts of the world.
- Reported with increasing frequency in the United States since the 1980s

GENERAL PREVENTION

- Vitamin D supplements should be given to breastfed infants and high-risk individuals.
- In the United States and Canada, cow's milk, infant formula, and cereals are fortified with vitamin D.

PATHOPHYSIOLOGY

Rickets arises due to decreased availability of phosphorus and calcium to mineralize the skeletal matrix, leading to growth plate disorganization and accumulation of undermineralized osteoid. This results in growth plate expansion, bone weakening, and skeletal deformities.

ETIOLOGY

Primary causes include the following:

- Nutritional
 - Insufficient vitamin D and/or calcium intakes (common)
 - Insufficient phosphorus intake (rare)
- Deficient sunlight exposure
- Malabsorption

- Celiac disease
- Cystic fibrosis
- Liver disease
- Renal tubular defects
 - Cystinosis
 - Fanconi syndrome
 - Renal tubular acidosis
- Abnormalities in vitamin D metabolism
 - Anticonvulsant use
 - Liver disease
- Genetic forms (see “Table 1.”)

Table 1. Biochemical features of rickets/osteomalacia

	Ca	Phos	Alk phos	iPTH	25-(OH)D	1,25-(OH) ₂ D	Urine Ca/Cr	TRP
Nutritional/insufficient sunlight	N or ↓	↓	↑	↑	↓	↑	↓	↑
Malabsorption	N or ↓	↓	↑	↑	↓	↑	↓	↑
Renal tubular defects	N or ↓	↓	↑	↑	N	↑	↑	N or ↓
Altered vitamin D metabolism	N or ↓	↓	↑	↑	↓	↑	↓	↑
Genetic forms of rickets								
X-linked, AD, and AR hypophosphatemic rickets	N	↓	↑	N or ↑	N	N or ↑	N or ↓	↓
1α-hydroxylase deficiency	↓	↓	↑	↑	N	↓	↓	↑
Vitamin D receptor mutations (Vitamin D resistance)	↓	↓	↑	↑	N	↓	↓	↑
Hereditary hypophosphatemic rickets with hypercalciuria	N or ↓	↓	↑	↑	N	↑	↑	↓
Hypophosphatasia	N or ↑	N or ↑	↓	N or ↓	N	N or ↓	N or ↑	N

Ca, calcium; Phos, phosphorus; Alk phos, alkaline phosphatase; iPTH, intact parathyroid hormone; 25-(OH)D, 25-vitamin D; 1,25-(OH)₂D, 1,25-dihydroxyvitamin D; Ca/Cr, calcium/creatinine ratio; TRP, tubular reabsorption of phosphorus [$1 - (U \text{ Phos} \times P \text{ Cr}) / (U \text{ Cr} \times S \text{ Phos}) \times 100$]; normal 85–95%; N, normal; AD, autosomal dominant; AR, autosomal recessive.

RISK FACTORS

- Infants born to vitamin D–deficient mothers
- Low birth weight and/or prematurity
- Breastfeeding without vitamin D supplementation
- Poor nutrition
- Increased skin pigmentation
- Higher latitudes and winter months
- Use of sunscreens
- Malabsorption
- Renal tubulopathies

DIAGNOSIS

HISTORY

- Inadequate nutrition
 - Prolonged breastfeeding without vitamin D supplementation

- Low dietary calcium intake
- Strict vegan diet without adequate calcium
- Premature infants taking unfortified formula
- Parenteral hyperalimentation
- Low levels of sunlight exposure
- Symptoms of malabsorption:
 - Steatorrhea, abdominal pain, weight loss
- Symptoms of renal tubular dysfunction:
 - Nephrolithiasis, polyuria
- Bone pain
- Delayed gross motor development
- Generalized muscular weakness
- Irritability
- Fractures following minimal trauma
- Dental abscesses
- Anticonvulsant use
- Family history of rickets

PHYSICAL EXAM

- Growth deceleration
- Widening at the wrists, knees, and/or ankles
- Bowing of the extremities (varus or valgus deformities)
- Skull abnormalities
 - Anterior fontanelle widening and/or delayed closure
 - Frontal bossing
 - Craniotabes (softening of the skull)
- Chest deformities
 - Prominent costochondral junctions (“rachitic rosary”)
 - Pectus carinatum
 - Horizontal groove along the lower ribs (“Harrison groove”)
- Scoliosis
- Hypotonia
- Waddling gait

DIAGNOSTIC TESTS & INTERPRETATION

Initial Labs

- 25-vitamin D
 - Major circulating form, and most sensitive indicator of vitamin D stores
 - Sometimes reported as D₂ (plant derived) and D₃ (animal derived) forms
 - D₂ + D₃ = total available 25-vitamin D
- Serum calcium, phosphorous (make sure age-appropriate norms for phosphorus are used by lab), and alkaline phosphatase
- Intact parathyroid hormone
- Urine calcium, creatinine, and urinalysis
- If rarer forms of rickets being considered: 1,25-vitamin D, urine phosphorus

Imaging

- Radiographic findings:
 - Widening, cupping, and/or fraying of the growth plates
 - Expansion of anterior ribs at the costochondral junctions
 - Bowing of the long bones
 - Osteopenia
- Knee or wrist films may be used diagnostically, and to monitor treatment response

DIFFERENTIAL DIAGNOSIS

- See [Table 1](#) for ways to differentiate forms of rickets.
- Metaphyseal chondrodysplasia
- Blount disease
- Chronic recurrent multifocal osteomyelitis
- Neurofibromatosis type 1
- Renal osteodystrophy (combines features of rickets, osteomalacia, secondary hyperparathyroidism, and osteoporosis)

TREATMENT

GENERAL MEASURES

Treatment depends on the underlying etiology.

ADDITIONAL THERAPIES

- Treatment of vitamin D deficiency: high dose repletion with cholecalciferol (D₃) or ergocalciferol (D₂) over 8–12 weeks (goal total of ~200,000–400,000 IU)
 - Infants and children <5 years of age: 2,000 IU daily
 - Children 5 years of age–adult: 4,000–5,000 IU daily, or 14,000 to 50,000 IU weekly
- Following repletion, transition to daily maintenance dose (see “Table 2”).

Table 2. Dietary reference intake for calcium and vitamin D

Age	Calcium			Vitamin D		
	Estimated Average Requirement (mg/day)	Recommended Dietary Allowance (mg/day)	Upper Level Intake (mg/day)	Estimated Average Requirement (IU/day)	Recommended Dietary Allowance (IU/day)	Upper Level Intake (IU/day)
0–6 months	200	200	1,000	400	400	1,000
6–12 months	260	260	1,500	400	400	1,500
1–3 years	500	700	2,500	400	600	2,500
4–8 years	800	1,000	2,500	400	600	3,000
9–18 years	1,100	1,300	3,000	400	600	4,000
19–30 years	800	1,000	2,500	400	600	4,000

Adapted from Ross C, Abrams S, Aloia J, et al. Dietary Reference Intakes for Calcium and Vitamin D. Washington, DC: The National Academies Press; 2011.

- Supplement with 30–75 mg/kg elemental calcium divided t.i.d. to prevent hungry bone syndrome (hypocalcemia and hypophosphatemia during healing).
- Higher doses of vitamin D often required in patients with malabsorption, altered vitamin D metabolism, and/or obesity
- Optimal serum 25-vitamin D concentrations are controversial, however concentrations >20 ng/mL (50 nmol/L) sufficient to prevent rickets in otherwise healthy children.

ISSUES FOR REFERRAL

- Consider endocrinology referral for infants, children with hypocalcemia, severe disease, suspected genetic forms of rickets, and/or lack of radiographic evidence of healing by 3 months.
- Nephrology referral for management of tubular dysfunction
- Orthopedic referral for patients with severe bowing

INPATIENT CONSIDERATIONS

Admission Criteria

- Rickets can generally be managed in the outpatient setting, however inpatient admission may be considered if:

- Severe hypocalcemia with tetany or seizures
- Lack of response to therapy (suspected non-adherence)

Discharge Criteria

- Stable laboratory values
- Normalization in mental status and neurology exam improvement

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Monitor serum calcium, phosphorus, alkaline phosphatase, PTH, and spot urinary calcium/creatinine ratio every 2–4 weeks. Note: Alkaline phosphatase may rise initially with treatment and then decrease gradually.
- Consider follow-up imaging after completion of high-dose vitamin D repletion.
- Patients who continue high-dose vitamin D for longer than prescribed may be at risk for hypercalcemia.

PATIENT EDUCATION

Ensure appropriate vitamin D and calcium intake to prevent recurrence (see “[Table 2](#)”).

PROGNOSIS

- Rickets generally resolves with appropriate treatment.
- If radiographs and/or biochemical parameters not improving, consider the possibility of poor adherence, other forms of rickets, or alternative diagnoses.

COMPLICATIONS

- Failure to thrive, poor motor development
- Bowing and skeletal deformity
- Fractures
- Hypocalcemic tetany and seizures

- E55.9 Vitamin D deficiency, unspecified
- E58 Dietary calcium deficiency

FAQ

- Q: What is the best way to diagnose rickets?
- A: Laboratory evaluation and x-rays are the best ways to make the diagnosis. Radiographic findings are best seen at the distal radius and ulna, and/or the distal femur and proximal tibia.
- Q: What are the recommendations for vitamin D supplementation in infants and children?
- A: The American Academy of Pediatrics recommends the following:
 - All breastfed infants should receive 400 IU daily.
 - Nonbreastfed infants ingesting <500 mL/day of vitamin D–fortified formula or milk should receive 400 IU daily.
 - Children who do not get regular sunlight exposure or do not

consume at least 500 mL/day of vitamin D–fortified milk should receive 600 IU daily.

- Q: How is rickets/osteomalacia different from osteoporosis?
- A: Osteoporosis in children is defined by a combination of decreased bone mass coupled with fracture. Although bone density is reduced, bone matrix is generally normally mineralized. In rickets/osteomalacia, the primary defect is impaired mineralization of the underlying bone matrix. Osteoporosis and rickets/osteomalacia both result in an increased fracture risk; however, osteoporosis does not generally lead to growth plate and long bone deformities.

RICKETTSIAL DISEASE

Gordon E. Schutze

BASICS

DESCRIPTION

- Disorders caused by the Rickettsiae family of organisms including those which cause Rocky Mountain spotted fever and other similar tick-borne illnesses, the typhus group, and the organisms that cause ehrlichiosis and anaplasmosis
- All organisms are obligate intracellular gram-negative bacteria and therefore are difficult to grow in culture.
- The diseases caused by each group of organisms are similar, encompassing a syndrome including fever, rash, headache, and capillary leak; all are transmitted via an insect vector.

GENERAL PREVENTION

- Fleas, ticks, and mites should be controlled in endemic areas with the appropriate insecticides.
- Clothing to cover the entire body should be worn in tick-infested areas. In the case of a recognized bite, ticks should be removed from human skin properly, with care not to expel the contents of the tick's stomach into the site of the bite.
- In areas where louse-borne typhus is epidemic, periodic delousing and dusting of insecticide into clothes are recommended.
- Paradoxical effect of rodenticides:
 - Fleas and mites seek alternate hosts (i.e., humans) when mice or rats are not present.
 - Therefore, rodenticides should not be the only preventive measure taken in endemic areas.
- Except for scrub typhus, all rickettsial diseases produce long-term immunity to the etiologic organisms within the same group.

PATHOPHYSIOLOGY

Spotted fever, typhus, ehrlichiosis, and anaplasmosis groups cause

vasculitis as a result of organisms invading the endothelial cells of small blood vessels or white blood cells. This manifests as rash in cutaneous tissues and systemic illness due to capillary leak throughout other organs.

ETIOLOGY

- Spotted fever group rickettsia and the agents of ehrlichiosis and anaplasmosis (*Ehrlichia* and *Anaplasma* species) are transmitted to humans by ticks.
- Rickettsialpox and scrub typhus are transmitted by mites associated with mice.
- Epidemic typhus is a louse-borne illness, and endemic typhus, also known as murine typhus, is transmitted by fleas.
- The rickettsial diseases that occur in the United States are Rocky Mountain spotted fever, murine typhus, rickettsialpox, epidemic typhus, ehrlichiosis, and anaplasmosis.

DIAGNOSIS

HISTORY

- In general, rickettsial disease should be considered as a diagnosis in a patient with fever, headache, and rash. Progression of rash can be particularly helpful in considering the diagnosis.
- Signs and symptoms:
 - Spotted fever group
 - Illness often begins with fever, myalgia, and headache.
 - Rash occurs 3–5 days following onset of symptoms and is typically described as centripetal, beginning on hands and feet and moving toward the trunk. Rash is variable and may not always follow this pattern.
 - Other symptoms include headache, neurologic changes, hypotension, hyponatremia, and consumptive coagulopathy.
 - Fulminant RMSF may cause cardiovascular collapse.
 - Rickettsialpox
 - Similar to spotted fever group, although less severe and with fewer systemic symptoms; rash often includes an inoculation

eschar.

- Typhus group
 - Epidemic typhus is transmitted by the human body louse and causes fever, headache, and rash that can progress to pulmonary symptoms, neurologic disease, and death.
 - Endemic typhus is transmitted by fleas associated with rodents and causes symptoms similar to epidemic typhus, although with a less prevalent rash.
 - Scrub typhus is also similar but causes marked neurologic symptoms including mental status changes.
- Ehrlichiosis/anaplasmosis
 - Spectrum of illnesses including human monocytotropic ehrlichiosis and human granulocytotropic anaplasmosis that cause fever, headache, and myalgias similar to the spotted fever group.
 - Rash is less common as compared to spotted fever and occurs in <50% of patients in ehrlichiosis and very few in anaplasmosis.

PHYSICAL EXAM

- All rickettsial diseases cause fever and the majority cause rash.
- These 3 findings suggest illness caused by the spotted fever group:
 - Hypotension, cardiovascular instability
 - Hepatosplenomegaly
 - Tache noire (French for black spot): The earliest finding in the spotted fever group, this lesion originates at the site of the infecting bite and may form eschar with regional lymphadenopathy related to the eschar. The lesion is usually found on the head in children and on the legs in adults; present in 30–90% of cases.
- These 3 findings suggest illness caused by the typhus group:
 - Impaired level of consciousness
 - Pulmonary and renal involvement
 - Brill-Zinsser disease is actually a recrudescence of a previous infection with epidemic (louse-borne) typhus caused by *Rickettsia prowazekii*; can occur years after the initial infection and is usually less severe than the initial episode of louse-borne typhus.
- These findings suggest ehrlichiosis:

- Acute febrile illness characterized by headache and myalgia
- Rash in ~50%; spares palms, soles, and face
- Thrombocytopenia, leukopenia (lymphopenia), hyponatremia, and elevated liver function tests
- These findings suggest anaplasmosis:
 - Acute febrile illness characterized by headache and myalgia
 - Thrombocytopenia, leukopenia (neutropenia), hyponatremia, and elevated liver function tests

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serologic testing is the standard for laboratory diagnosis of rickettsial disease because the organisms are obligate intracellular bacteria and do not grow in culture.
- Serologic tests are available for all rickettsial organisms. There is some cross-reactivity among similar organisms.
- Serologic testing is often negative at the onset of illness and requires a convalescent (paired) sample done 2–3 weeks later for comparison. If the convalescent titer is 4-fold or greater than the acute, it is considered positive.
- Polymerase chain reaction (PCR) tests are rarely done in clinical labs and have significant inaccuracy given the similarities in genomes of these organisms.
- The Weil-Felix agglutination test has poor sensitivity and specificity and is not used in the United States.

DIFFERENTIAL DIAGNOSIS

- Before rash appears, constitutional symptoms associated with the spotted fevers result in a broad differential diagnosis. After rash appears, the diagnoses are more limited.
- Infectious:
 - Measles
 - Meningococcemia
 - Secondary syphilis
 - Coxsackievirus (e.g., hand-foot-and-mouth disease)
 - Infectious mononucleosis

- Enteroviral infection
- Environmental (poisons)
- Drug hypersensitivity reaction (i.e., toxicodermatosis)
- Tumors: leukemia with thrombocytopenia
- Immunologic: idiopathic thrombocytopenia purpura
- Miscellaneous:
 - Leukocytoclastic angiitis
 - Erythema multiforme/Stevens-Johnson syndrome

TREATMENT

MEDICATION

- The 1st-line antibiotic treatment for all rickettsial diseases is doxycycline. Therapy is most effective if instituted within the 1st week of illness.
- Antibiotics should be given for 7–14 days.
 - Studies have shown that there is little risk of tooth staining in children <8 years old who receive doxycycline.
 - In the case of rickettsial disease, the benefit of giving doxycycline far outweighs the risk of adverse effects.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Fluid resuscitation and respiratory support as indicated
- Antimicrobial therapy should be instituted as soon as the diagnosis is suspected and should not be delayed while awaiting serologic confirmation.
- Patients may require blood product transfusion in the case of consumptive coagulopathy or severe thrombocytopenia.

ONGOING CARE

PROGNOSIS

Improvement in the patient's clinical status usually takes place within 1–2 weeks after therapy starts, depending on the severity of illness. This

improvement may also be delayed if treatment is begun after the 1st week of illness.

COMPLICATIONS

- Venous thrombosis
- Disseminated intravascular coagulation
- Cardiac injury including endocarditis
- Severe disease is more common in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, cardiac insufficiency, or immunodeficiency.

CODES

ICD10

- A79.9 Rickettsiosis, unspecified
- A77.0 Spotted fever due to *Rickettsia rickettsii*
- A75.9 Typhus fever, unspecified

FAQ

- Q: Should my child receive antibiotics if he is bitten by a tick in an area endemic to rickettsial disease?

- A: There is no role for prophylaxis against rickettsial diseases for patients who have suffered tick bites.
- Q: Are there differences between typhoid and typhus?
- A: Typhoid, or typhoid fever, is a separate entity from typhus. Typhoid is an enteric infection caused by *Salmonella typhi* and is unrelated to the rickettsial diseases.
- Q: If I contract a rickettsial illness, can I get that illness or a similar illness again?
- A: With the exception of scrub typhus, infection with a rickettsial organism confers immunity to other rickettsia within the same group.

ROCKY MOUNTAIN SPOTTED FEVER

Carolyn A. Paris • George Anthony Woodward

BASICS

DESCRIPTION

- Life-threatening, small vessel vasculitis
- Caused by infection with *Rickettsia rickettsii*, an obligate intracellular gram-negative coccobacillus, transmitted by three species of ticks in the United States
- Member of spotted fever subgroup of rickettsial diseases
- Seasonal endemic disease but may occur in other areas and throughout the year
- Classic symptoms of fever, headache, and rash following tick exposure are often not present.

EPIDEMIOLOGY

- Most common rickettsial disease in the United States
- Seasonal: April–September accounts for 90% of cases.
- Geographic
 - Restricted to countries of western hemisphere
 - Cases reported from all states except Alaska, Hawaii, and Maine
 - Occurs most often in southern Atlantic and south central regions: 1994–2003, >50% of cases in North Carolina, South Carolina, Tennessee, Oklahoma, Arkansas
 - Less often seen in Rocky Mountain states
 - Also occurs in southern Canada, Mexico, and Central and South America
- Single isolated cases most common in United States; clusters are reported infrequently in United States (4.4% familial) but are more typical in certain endemic areas (e.g., Brazil).
- Up to 2/3 of patients are <15 years old.

Incidence

- Annual incidence: 7 cases per million people (2002–2007); the highest

recorded level in >80 years of national surveillance

- Cyclic fluctuations in incidence; 250–1,200 cases reported per year
- More often reported in American Indians, whites, males, and children; incidence highest in 5–9-year-olds
- Fatal outcome reported in 23% of untreated, and 5% of treated, cases
- Geographic variations in case fatality occur, likely due to different levels of pathogenicity, host factors, and delayed recognition in less endemic regions.
- 15% reported deaths in children <10 years of age

Prevalence

4–22% of children show significant antibody titers in endemic areas, likely representative of subclinical disease.

RISK FACTORS

R. rickettsii–infected tick exposure or rural environment or occupation increasing forest exposure in endemic region

GENERAL PREVENTION

- Avoid tick-infested areas; limit skin exposure with long, light-colored clothing, tucked-in socks, or boots; inspect frequently.
- Use tick repellants or impregnated clothing.
 - DEET most effective
 - Essential oils that offer natural alternatives considered safe (soybean, lemon eucalyptus, citronella, and clove)
- Remove ticks promptly.
 - Do not crush; may increase transmission
 - Avoid direct contact; remove with tweezers or gloved fingers close to skin.
 - Apply steady upward traction until tick's grip is released.
 - Clean wound.
 - Matches, petroleum jelly, nail polish, and rubbing alcohol are not effective for removal.
- Vaccine not available in the United States; may not prevent disease but does prevent deaths

PATHOPHYSIOLOGY

- Transmission usually occurs from tick bite (reservoir):
 - Usually >4 hours of attachment needed to transmit disease (often 24 hours)
 - Can occur by transfusion or aerosol route
- Incubation period 2–14 days, average 7 days
- *R. rickettsii* spreads through the lymphatic system, causing a small vessel vasculitis that affects all organs, especially skin and adrenals; increased vascular permeability and focal areas of endothelial proliferation
- Causes hyponatremia, hypoalbuminemia, edema, and hypotension
- Immunity is conferred following disease.

ETIOLOGY

Wood tick (*Dermacentor andersoni*) in Rocky Mountain states and southwest Canada; dog tick (*Dermacentor variabilis*) in east central region and areas of Pacific coast; *Rhipicephalus sanguineus* in Arizona and northern Mexico; *Amblyomma cajennense* and *Amblyomma aureolatum* in Central and South America

COMMONLY ASSOCIATED CONDITIONS

- Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency account for a disproportionate number of deaths.
- Serious biologic weapon threat due to virulence causing severe disease; difficulty establishing diagnosis; low levels of immunity; agent available in nature; high infectivity; and feasibility of propagation, stabilization, and dispersal; thus development of a cross-protective vaccine against all *Rickettsia* is desirable for biodefense as well as for travel medicine.

DIAGNOSIS

HISTORY

- History: classic triad of fever, headache, and rash seen in ~50% of cases
- Abdominal pain common mainly in children
- Symptoms usually appear 2–8 days after tick bite.

- Gradual fever onset to $>40^{\circ}\text{C}$ (104°F), often unresponsive to antipyretics
- Headache: intense, retrobulbar or frontal, persistent and difficult to treat; young children may not describe
- Cough, dyspnea
- Nausea, vomiting, abdominal pain, diarrhea
- Tick bite is reported in only 50–60% of cases.

PHYSICAL EXAM

- Fever and rash present in 85% of patients.
- Skin
 - Rash: usually appears by illness days 2–3, may be >6 th day; 10–15% never develop rash so absence should not delay therapy.
 - Usually small, irregular, erythematous blanching macules, become maculopapular then petechial and confluent hemorrhagic
 - Usually on wrists and ankles first, spreads within hours to trunk, neck, and face; may involve palms, soles, and scrotum
 - May appear first on trunk or diffusely; can progress to necrosis of ears, nose, scrotum, fingers, or toes
 - Difficult to detect in people with dark skin
- CNS: meningismus, restlessness, irritability, apprehension, confusion, delirium, lethargy, stupor, coma, ataxia, opisthotonos, aphasia, papilledema, seizures, cortical blindness, central deafness, spastic paralysis, cranial nerve palsy
- Cardiac: CHF, myocarditis, arrhythmias, hypovolemic vascular collapse
- Pulmonary: pneumonitis, dyspnea, pulmonary edema, hypoxemia, pleural effusions, alveolar infiltrates
- GI: diarrhea, hepatomegaly, splenomegaly, anorexia, jaundice, mild pancreatitis
- Ocular: conjunctivitis, venous engorgement, papilledema, cotton wool spots, retinal hemorrhages, retinal artery occlusion, uveitis
- Other: edema, myalgias (especially calf or thigh), parotitis, orchitis, pharyngitis

DIAGNOSTIC TESTS & INTERPRETATION

Presumptive diagnosis based on signs, symptoms, exposure history, and epidemiologic considerations rather than laboratory aids

Lab

- Nonspecific
 - CBC: anemia (30%), thrombocytopenia (from consumptive coagulopathy); normal or low leukocytes days 4–5, subsequent leukocytosis associated with secondary bacterial disease; bandemia common
 - Electrolytes: hyponatremia
 - Elevated BUN, creatinine, liver function tests, bilirubin, creatine kinase
 - Screen for disseminated intravascular coagulation (rare), prolonged prothrombin time, decreased fibrinogen (consumption).
 - Arterial blood gases: acidosis
 - Hypoalbuminemia
 - CSF: usually clear (leukocyte count <10), may see pleocytosis in 1/3 and increased protein in 1/2 of patients
- Specific serologic tests
 - No early specific laboratory tests; serologic data reliable by days 10–12 of illness; negative results do not exclude diagnosis.
 - All test results normalize with early intervention.
 - Indirect immunofluorescence assay (IFA)
 - Best and most widely available method
 - 2 serum samples obtained weeks apart showing 4-fold increase in IgG and IgM anti-*R. rickettsii* antibody titers
 - Positive 6–10 days after onset of disease, sensitivity increases to 94% with convalescence serum sample from days 14 to 21 days; specificity 100%
 - PCR, immunohistochemical staining, and culture are best done on biopsy specimen (of rash site or at autopsy) due to low circulating organism levels.
 - Routine hospital blood cultures will not detect; available only at specialty labs
 - Weil-Felix test: oldest specific test but nonspecific and insensitive; no longer recommended

Imaging

Chest radiograph, ECG, and echocardiogram are recommended.

Distinctive features on MR images (brain and spinal cord) may lead to early diagnosis; CT findings are less often present.

DIFFERENTIAL DIAGNOSIS

Measles, meningococcemia, ehrlichiosis, typhoid fever, leptospirosis, rubella, scarlet fever, disseminated gonococcal disease, infectious mononucleosis, secondary syphilis, rheumatic fever, enteroviral infection, immune thrombocytic purpura, thrombotic thrombocytopenic purpura, immune complex vasculitis, drug hypersensitivity reaction, murine typhus, rickettsialpox, and recrudescent typhus

ALERT

Do not exclude diagnosis even if there is no history of tick bite, no rash present, and/or results of serologic tests are negative. Treatment should be started presumptively and postponement of therapy while awaiting laboratory confirmation or presence of rash.

TREATMENT

MEDICATION

Treatment should be initiated based on clinical and epidemiologic information, as laboratory confirmation may not be available during acute illness. All agents are rickettsiostatic (hinder replication), not rickettsicidal, so host can eradicate disease. Treat until there is evidence of clinical improvement and at least 3 days without fever; standard duration is 5–10 days.

First Line

- Doxycycline (usual tetracycline antibiotic) is the drug of choice at any age:
 - Adults: 100 mg q12h PO/IV
 - Children under 45 kg (100 lb): 4.4 mg/kg/24 h PO/IV divided b.i.d.
 - Also treats ehrlichiosis (similar presentation)
 - Side effects: less likely to stain teeth than tetracycline;

contraindicated for pregnancy, although can be considered even in pregnancy if the mother's life is in danger and the theoretical concerns on the fetus is discussed

- Chloramphenicol (alternative during pregnancy)
 - Adult: 50–100 mg/kg/24 h IV divided q6h (max 4 g/24 h)
 - Child >1 month of age: 50–100 mg/kg/24 h IV divided q6h (max 4 g/24 h)
 - Side effects: peripheral neuropathy, aplastic anemia, “gray baby syndrome” with high dosage, possible association with leukemia, hemolytic anemia with G6PD
 - Not as effective as tetracyclines, or against ehrlichiosis; higher mortality rate in those treated with chloramphenicol than tetracyclines; consider only rarely such as during pregnancy.

Second Line

- Quinolones (ciprofloxacin, pefloxacin), macrolide (clarithromycin) with in vitro effect, no clinical evidence of efficacy
- Corticosteroids
 - May be helpful in severe cases, although no controlled studies published
 - Not advised for mild or moderately ill patients

ADDITIONAL TREATMENT

General Measures

- Treat empirically if clinical suspicion.
- Platelets as indicated for thrombocytopenia
- Vitamin K (IM) for prolonged clotting time
- Manage hyponatremia with fluid restriction; avoid sodium supplements.
- Albumin if indicated
- Report to state health department.

INPATIENT CONSIDERATIONS

Initial Stabilization

Volume, electrolyte support as indicated

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Expect improvement in 24–36 hours and defervescence in 2–3 days with treatment, especially if initiated <5 days after onset of symptoms.

PROGNOSIS

- Related to early recognition of disease and initiation of appropriate therapy
- Case fatality 2–4% if treated <6 days from onset of symptoms
- Case fatality 15–22.9% if treated >6 days from onset of symptoms
 - Higher mortality if <4 years, G6PD deficiency, CNS involvement, renal failure, jaundice, cardiovascular collapse, hepatomegaly, thrombocytopenia, DIC, GI symptoms, inappropriate antibiotics, late rash, absence of headache, or male gender
 - Death usually between 8th and 15th days (fulminant cases with death in 5–6 days)

COMPLICATIONS

- Uncommon with early, appropriate treatment
- Neurologic sequelae
 - Behavioral disturbances, learning disabilities (more common), emotional lability, hyperactivity, memory loss, seizures
- Dermatologic sequelae
 - Gangrene of extremities, end organs, skin necrosis
 - Skin rash usually heals without sequelae.
- Hematologic sequelae: DIC
- GI sequelae
 - Hepatic dysfunction
 - Hypoalbuminemia from hepatic dysfunction, protein loss from damaged vessels
- Cardiac sequelae: can have persistent cardiac findings, CHF, cardiovascular collapse
- Metabolic sequelae: hyponatremia from water shift to intracellular spaces, sodium loss in urine
- Renal sequelae: acute tubular necrosis

CODES

ICD10

A77.0 Spotted fever due to *Rickettsia rickettsii*

FAQ

- Q: In which patients should Rocky Mountain spotted fever be considered in the differential diagnosis?
- A: Anyone with a fever during the spring and summer who has been in an endemic area, regardless of presence of rash or history of tick bite. Nonspecific symptoms (e.g., GI, respiratory, rashes) may lead to misdiagnosis and thus delay therapy.

- Q: Should a child with a tick bite receive antibiotic prophylaxis when a tick is discovered?
- A: There is no evidence that prophylaxis is necessary or efficacious in preventing disease. To contract disease, one must be bitten by a tick that carries the disease (low risk), the tick must transmit the Rickettsia (low risk, usually requires >6 hours of attachment), and the Rickettsia must be pathogenic if inoculated (low risk).

ROSEOLA

Ross Newman • Jason Newland

BASICS

DESCRIPTION

Roseola infantum is a common illness in preschool-aged children characterized by fever lasting 3–7 days followed by rapid defervescence and the appearance of a blanching maculopapular rash (usually on the 4th day of illness) lasting only 1–2 days.

EPIDEMIOLOGY

- Roseola affects children from 3 months to 4 years of age. The peak age is 7–13 months.
- 90% of cases occur in the first 2 years of life.
- No gender predilection
- Roseola can occur throughout the year; outbreaks have occurred in all seasons.

GENERAL PREVENTION

- The virus that causes roseola infantum is usually transmitted via respiratory secretions or fecal–oral spread. Good hand hygiene is recommended.
- Outbreaks in hospitals have been reported, and standard infection control precautions are recommended.

PATHOPHYSIOLOGY

- Incubation period is 5–15 days.
- The typical pattern of rash that appears as the fever disappears may represent virus neutralization in the skin.

ETIOLOGY

- A major cause of roseola is human herpesvirus 6 and 7 (HHV-6 and HHV-7).
 - HHV-6 was first associated with roseola infantum in 1988.
 - HHV-6 and HHV-7 account for 20–40% of unexplained febrile

illness in emergency department visits by febrile infants 6 months to 2 years of age.

- Almost all children will acquire a primary infection and be seropositive for HHV-6 by the age of 4 years.
- ~30% of children infected with HHV-6 will present with the classic manifestations of roseola.
- Roseola-like illnesses have been associated with a number of different viruses, including enterovirus (coxsackievirus A and B, echoviruses), adenoviruses (types 1, 2, 3), parainfluenza virus, and measles vaccine virus.

DIAGNOSIS

HISTORY

- Diagnosis is clinical, based on classic features.
- Affected children generally do not look sick.
- Fever, typically $>39.5^{\circ}\text{C}$, lasting 3–7 days
- Mild cough and acute rhinitis may be present.

PHYSICAL EXAMINATION

- Rash
 - Erythematous, blanching, maculopapular
 - First appears on trunk, spreads to face and extremities
 - Appears for 1–2 days after fever resolves
- Other findings:
 - Lymphadenopathy
 - Eyelid edema
 - Bulging fontanelle can occur occasionally.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Not helpful in diagnosis
 - Polymerase chain reaction (PCR) tests are available for detecting HHV-6 and HHV-7 but generally not needed.
- CBC
 - Occasionally, leukopenia with lymphocytosis is noted.

- Thrombocytopenia is likely secondary to viral bone marrow suppression.

DIFFERENTIAL DIAGNOSIS

- Roseola has a distinctive presentation but does resemble other viral exanthems.
- Antibiotic-associated rash in a child taking oral antibiotics when rash develops after defervescence
- Rubella and enteroviral infections
- Viral exanthems in preschool-aged children are sometimes called roseola even when fever is concomitant with rash.

ONGOING CARE

PROGNOSIS

Most children with roseola infantum recover without sequelae.

COMPLICATIONS

- Seizures
 - Most common complication of roseola
 - Between 10 and 15% of children have a generalized tonic-clonic seizure associated with fever.
- Aseptic meningitis with <200 cells, primarily mononuclear cells, have been reported.
- Encephalitis
- Thrombocytopenic purpura

CODES

ICD10

- B08.20 Exanthema subitum [sixth disease], unspecified
- B08.21 Exanthema subitum [sixth disease] due to human herpesvirus 6
- B08.22 Exanthema subitum [sixth disease] due to human herpesvirus 7

FAQ

- Q: When can a child with roseola return to day care?
- A: As soon as fever subsides; there is no infectious risk of spread afterward. The child may return to day care even with the rash visible.
- Q: Will there be long-term sequelae in the child who has a seizure associated with roseola?
- A: In general, these seizures are typical febrile seizures that hold only a slightly higher risk than the general population for long-term neurologic sequelae (e.g., epilepsy).

ROTAVIRUS

John Bower

BASICS

DESCRIPTION

Rotavirus is a leading cause of gastroenteritis in the United States and worldwide. Characterized by frequent watery stools, illness ranges from mild diarrhea to disease complicated by severe dehydration, especially in young children.

EPIDEMIOLOGY

- Rotavirus is a major cause of diarrheal disease and accounts for 5% of all deaths in children <5 years of age worldwide.
- The peak age for infection is between 6 and 24 months of age. Nearly all children acquire the virus by 5 years of age.
- In temperate climates, rotavirus activity peaks during the cold weather months but can appear year round in warmer climates.
- Transmission occurs primarily by the fecal–oral route.
- Rotavirus is highly contagious. This is due to several factors.
 - The virus has a very low inoculum of infection, requiring as few as 10 infectious particles to cause disease.
 - A high density of virus is shed into the stool during acute illness and for 1–3 days before and after diarrhea.
 - There is prolonged survival of the virus on a variety of environmental surfaces.
- The incubation period is 1–3 days.
- Prior to the rotavirus vaccine, U.S. children <5 years of age with diarrhea had a hospitalization rate of 52/10,000 person-years and an ED visit rate of 185/10,000 person-years.
- After the rotavirus vaccine was introduced in 2006, the hospitalization rate for all children <5 years with diarrhea fell by nearly 50% and ED visits by 25%.

RISK FACTORS

- Young infants, especially preterm infants, are at higher risk for severe dehydration and gastrointestinal complications.
- Immunocompromised patients, particularly with primary immunodeficiencies and hematopoietic stem cell transplantation are at higher risk for complications and prolonged shedding.

GENERAL PREVENTION

- Proper hand hygiene and cleaning of contaminated surfaces is essential to reducing person-to-person transmission.
- Contact precautions for hospitalized patients
- Two live oral vaccines are licensed in the US:
 - Live human/bovine reassortant pentavalent rotavirus (RV5). Given as a 3-dose series.
 - Live human attenuated monovalent rotavirus (RV1). Given as a 2-dose series.

PATHOPHYSIOLOGY

- Rotavirus infects and replicates within the enterocytes of the small bowel. Several factors appear to contribute to secretory diarrhea.
 - The nonstructural protein (NSP4) acts as an enterotoxin that triggers secretory diarrhea by increasing Cl^- secretion and decreasing Na^+ absorption.
 - Malabsorption develops due to disruption of microvilli and decreased surface transport of digestive enzymes.
 - NSP4 appears to activate the enteric nervous system, which activates a secretory state that further contributes to intestinal fluid loss.

ETIOLOGY

- Rotavirus is an 11-segment double-stranded RNA virus with 7 different antigenic groups (A–G).
- Types A, B, and C are responsible for most human infections, with group A being the most common.
- Group A rotavirus is further divided into multiple serotypes based on 2 outer capsid viral proteins: VP7 (G) and VP4 (P).

DIAGNOSIS

HISTORY

- Stools are watery and often foul-smelling.
- Gross blood or mucus is usually absent—their presence more often suggests a bacterial pathogen.
- Diarrhea usually lasts 3–8 days.
- Stool frequency can range from several to 20 episodes per day.
- Vomiting accompanies diarrhea 85% of the time. Vomiting often precedes diarrhea and resolves in 1–2 days.
- Fever can exceed 102°F in 1/3 of patients.
- Two thirds of patients present with diarrhea, vomiting, and fever.
- Family members often have a history of current or recent diarrhea.

PHYSICAL EXAM

Relevant physical findings are targeted to assess for potential dehydration.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum electrolytes, BUN, and creatinine are important in evaluating for dehydration and electrolyte abnormalities secondary to diarrhea.
- Rapid tests for rotavirus
 - By EIA or latex agglutination
 - Have an overall sensitivity of 80% and specificity of 99%
 - Sensitivity is highest in the first 4 days of illness.
- Rapid PCR testing is becoming increasingly available for rotavirus, including multiplex assays that incorporate other common agents of viral gastroenteritis.
- Fecal leukocyte and stool guaiac testing is not helpful.
- Two thirds of hospitalized children have mild elevations in their transaminases.

DIFFERENTIAL DIAGNOSIS

- Viral pathogens occur in 80–90% of patients with secretory diarrhea. Besides rotavirus, common gastrointestinal viruses include the following:

- Norovirus
- Sapovirus
- Astrovirus
- Enteric adenovirus
- Bacterial infections may present with secretory diarrhea.
 - Salmonella
 - Shigella
 - Campylobacter
 - Aeromonas
 - Clostridium difficile
 - Yersinia
- Parasitic infections:
 - Giardia
 - Cryptosporidium
 - Cyclospora
 - Isospora

TREATMENT

MEDICATION

- Antimotility agents are generally avoided for all forms of infectious diarrhea in children.
- Several studies suggest that supplementation with a specific probiotic strain, *Lactobacillus rhamnosus* GG, during acute rotavirus gastroenteritis might decrease the duration of diarrhea (mean duration decrease: approximately 1 day).

INPATIENT CONSIDERATIONS

Initial Stabilization

- Provide appropriate intravenous, nasogastric, or oral fluids for volume replacement and correction of electrolyte abnormalities due to diarrhea.
- Monitor fluid balance and serum electrolytes.
- Place patients in contact precautions.

ONGOING CARE

COMPLICATIONS

- Hyponatremia and metabolic acidosis occur more often with rotavirus gastroenteritis than other forms of viral gastroenteritis and may become severe enough to require intensive care management.
- Gram-negative sepsis can occur secondary to mucosal injury.
- Rotavirus gastroenteritis has been associated with necrotizing enterocolitis in preterm infants.
- Diarrhea may be more severe and protracted in immunocompromised hosts.

CODES

ICD10

A08.0 Rotaviral enteritis

FAQ

- Q: How long are children contagious following rotavirus infections?
- A: In most children, rotavirus shedding ceases within 7 days of the diarrhea resolving. However, asymptomatic shedding can persist in some children for up to several weeks—and in some cases longer. Young infants with severe diarrhea and immunocompromised patients are more likely to have persistent asymptomatic rotavirus shedding and may pose a risk for spread in the day care and hospital setting.
- Q: Is there a risk for intussusception with rotavirus vaccine?
- A: Postlicensure data for the RV5 and RV1 vaccines do point to a slightly higher risk for intussusception following administration of the first two doses of rotavirus vaccine. This infrequent complication; however, is far outweighed by the vaccine's substantial benefits in reducing hospitalization and death, and its worldwide use is strongly recommended.

SALICYLATE POISONING (ASPIRIN)

Kevin C. Osterhoudt

BASICS

DESCRIPTION

- May occur with acute or chronic overdosage of the following:
 - Acetylsalicylic acid (aspirin)
 - Methyl salicylate (oil of wintergreen)
 - Bismuth subsalicylate (Pepto Bismol)
 - Salicylic acid (a keratolytic)
 - Other salicylate-containing drugs
- The potentially toxic acute oral dose of acetylsalicylic acid is >150 mg/kg.

EPIDEMIOLOGY

- Analgesics are the most common drugs implicated in human exposures reported to U.S. poison control centers.
- Salicylate preparations constitute $\sim 9\%$ of all analgesic poisoning exposures reported to poison control centers.

PATHOPHYSIOLOGY

- Ingested drug is absorbed in stomach and proximal intestine.
- With therapeutic aspirin dosing, serum levels peak in 1–2 hours (standard preparations) or 4–6 hours (enteric coated).
- After oral overdose, absorption may be prolonged and erratic.
- Acetylsalicylate ingestion may produce gastritis and may trigger centrally mediated vomiting.
- After overdose, the elimination half-life of salicylate becomes prolonged.
- As blood pH falls, the proportion of nonionized salicylate rises, and more salicylate shifts into tissues, including brain.
- Toxic salicylate exposures uncouple mitochondrial oxidative phosphorylation and increase oxygen consumption.
- Direct stimulation of the medullary respiratory center leads to

hyperventilation and respiratory alkalosis.

- Multiple metabolic derangements produce a wide anion gap metabolic acidosis.
- Dehydration and electrolyte shifts are common.
- Low cerebral glucose concentrations may exist despite normal serum glucose concentrations.
- Pulmonary and/or cerebral edema may occur.

COMMONLY ASSOCIATED CONDITIONS

- Aspirin is often marketed in combination with other pharmaceuticals, which may complicate drug overdose situations.
- Adolescents frequently overdose on more than 1 drug preparation.
- Therapeutic use of acetylsalicylic acid among children with influenza has been associated with the occurrence of Reye syndrome.

DIAGNOSIS

HISTORY

- Aspirin poisoning mimics many illnesses, and chronic overdosage often results in delayed diagnosis.
- Enteric coating may lead to significantly delayed drug absorption.
- Timing of ingestion allows for proper consideration of the risks versus benefits of gastrointestinal decontamination.
- Tinnitus frequently associated with serum salicylate levels >25 mg/dL

PHYSICAL EXAM

- Hyperpnea indicates primary central hyperventilation and/or compensation for metabolic acidosis.
- Hyperpyrexia: Presence of “fever” may confuse salicylism with infection.
- Hypoxia: Pulmonary edema complicates therapy of aspirin overdose.
- Hypotension indicates severe dehydration, likely complicated by metabolic acidosis and salicylate-mediated myocardial inefficiency.
- Encephalopathy: CNS depression or seizures represent grave toxicity.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum electrolytes: A wide anion gap metabolic acidosis is common, and hypoglycemia or hyperglycemia may occur.
- Arterial blood gas: may show mixed respiratory alkalosis/metabolic acidosis
- Salicylate level: Serum salicylate levels >60–100 mg/dL (acute) or 30–40 mg/dL (chronic) portend serious toxicity.
- Urine pH: allows monitoring of adequacy of urinary alkalization
- Acetaminophen level: Acetaminophen may be a coingestant.
- Ferric chloride test: A few drops of 10% ferric chloride will turn brown or purple in 1 mL of urine that contains salicylate.

ALERT

- Respiratory acidosis suggests central nervous system depression and is an ominous sign.
- Salicylate levels after chronic or acute-on-chronic overdose correlate poorly to clinical condition.
- Serial salicylate levels may be necessary to rule out ongoing drug absorption.

DIFFERENTIAL DIAGNOSIS

- Gastroenteritis
- Pneumonia
- Metabolic disease
- Ketoacidosis
- Sepsis
- Meningitis/encephalitis

TREATMENT

GENERAL MEASURES

- Fluids/alkalinization
 - Intravascular volume should be repleted with intermittent boluses of 10–20 mL/kg of isotonic crystalloid.
 - Altered mentation may imply CNS hypoglycemia and should be treated with dextrose.

- Acidemia should be treated with sodium bicarbonate to limit salicylate distribution to the brain. Serum pH of 7.5 is reasonable goal.
- With significant poisoning, an IV infusion of 5% dextrose with 100–150 mEq/L of sodium bicarbonate and 20–40 mEq/L of potassium chloride should be initiated at 1.5–2 times maintenance requirements. Titrate fluid volume to produce urine output of 2–3 mL/kg/h. Titrate alkalinization to produce urine pH between 7.5 and 8, which greatly increases the urinary elimination of salicylate via “ion-trapping” effect.
- Hemodialysis indications
 - Acute serum salicylate level >100 mg/dL
 - Chronic serum salicylate level >60 mg/dL
 - Severe acidosis or severe electrolyte disturbance
 - Renal failure
 - Pulmonary edema
 - Persistent neurologic dysfunction
 - Progressive clinical deterioration

ALERT

- Hypokalemia may interfere with the ability to achieve urinary alkalinization.
- Sedating a salicylate-poisoned patient may lead to respiratory depression and clinical deterioration.
- Endotracheal intubation is dangerous and, if performed, must be accompanied by sodium bicarbonate IV bolus and hyperventilation to prevent worsening acidemia and salicylate distribution to the brain.
- Hemodialysis equipment must be carefully primed to prevent worsening hypovolemia and cardiovascular collapse.
- If hemodialysis is performed, adjust dialysate to maintain alkalemia.
- Pulmonary edema and/or cerebral edema may complicate fluid management.

INPATIENT CONSIDERATIONS

Initial Stabilization

GI decontamination

- Activated charcoal 1 g/kg (maximum 75 g) may be administered if aspirin is judged to be present in the stomach or proximal intestine.
- Many authorities suggest a 2nd charcoal dose 2–4 hours after the 1st or if salicylate levels continue to rise.
- Whole-bowel irrigation may reduce drug absorption after large overdoses.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Drug administration education should be offered to victims of chronic overdose.
- Mental health services should be provided to victims of intentional overdose.

PROGNOSIS

- Chronic therapeutic misuse often leads to delayed diagnosis and has the most serious prognosis.
- Single acute ingestion of >300 mg/kg acetylsalicylic acid should be considered life threatening.

COMPLICATIONS

- Nausea and vomiting
- Dehydration
- Metabolic acidosis
- Electrolyte abnormalities
- Disorientation, coma, seizures
- Noncardiogenic pulmonary edema
- Renal failure
- Cerebral edema and death

FAQ

- Q: What amount of the candy-scented oil of wintergreen is toxic to a toddler?
- A: Oil of wintergreen may contain as much as 98% methyl salicylate. 1 mL of methyl salicylate is the equivalent of 1,400 mg of aspirin. Therefore, 1 teaspoon of oil of wintergreen represents a very serious “aspirin” overdose.
- Q: Is there a prognostic nomogram for aspirin poisoning similar to that used for acetaminophen overdose?
- A: The Done nomogram is applicable only to ingestion of non–enteric-coated aspirin by children with normal mentation and normal blood pH, and the validity of its prognostication is suspect. Its use is not widely recommended.

SALMONELLA INFECTIONS

John Bower

BASICS

DESCRIPTION

Salmonella isolates are broadly divided into the following: 1) nontyphoidal serotypes, with illness ranging from uncomplicated gastroenteritis to meningitis; and 2) typhoidal serotypes, responsible for typhoid and paratyphoid fever (collectively called enteric fever).

EPIDEMIOLOGY

- Salmonella is a leading cause of foodborne infection in the United States and worldwide.
- Reservoirs
 - Nontyphoidal Salmonella serotypes are commonly found in agricultural products, particularly cattle, poultry, and eggs. Less common sources include produce, dairy products, and processed foods. Humans may asymptotically shed the bacteria for weeks, even months. Reptiles are another well-recognized reservoir for infection.
 - Typhoidal serotypes are found only in humans with acute or chronic infection.
- Transmission
 - Spread occurs via the fecal–oral route. Food and water contamination is the most common mechanism of exposure, followed by direct contact with contaminated surfaces and live animals.
 - Salmonella generally requires a high-bacterial inoculum to cause infection.
- Age/season: Salmonella infections are most common in children younger than 4 years of age and during the summer months.

RISK FACTORS

- Young infants (especially those <3 months of age), children with sickle

cell disease (SCD), human immunodeficiency virus (HIV), malignancy, and other immunocompromised conditions are at high risk for extraintestinal complications from nontyphoidal *Salmonella* gastroenteritis.

- Travel to underdeveloped countries

GENERAL PREVENTION

- Proper cleaning of food preparation surfaces and careful hand hygiene, particularly when handling foods at risk for *Salmonella* contamination
- Foods that frequently harbor *Salmonella*, such as meat, poultry, and eggs, require thorough cooking.
- Children <5 years old, and all those with high-risk conditions, should avoid contact with reptiles (e.g., lizards, snakes, turtles).
- Vaccines for typhoid fever have an efficacy of 50–80% and are recommended for the following: 1) travel to endemic areas and 2) close contacts of carriers. Available vaccines include the following:
 - Ty21a, live vaccine for children ≥ 6 years of age; given PO every other day for 4 doses
 - ViCPS, inactivated vaccine for children ≥ 2 years of age; given as a single IM dose

ETIOLOGY

Salmonella is classified into 2 species: *Salmonella enterica* and *Salmonella bongori*. Species are further divided into 1 of over 2,500 serotypes.

- Common nontyphoidal serotypes include the following: *Salmonella enterica* ser Enteritidis, *Salmonella enterica* ser Typhimurium, *Salmonella enterica* ser Newport, and *Salmonella enterica* ser Heidelberg.
- Typhoidal serotypes include the following: *Salmonella enterica* ser Typhi and *Salmonella enterica* ser Paratyphi.

COMMONLY ASSOCIATED CONDITIONS

Following infection of the intestinal epithelium, *Salmonella* strains present with a variety of clinical manifestations.

- Acute gastroenteritis is the most common illness involving nontyphoidal serotypes:
 - Diarrhea is often watery but can be inflammatory with varying

amounts of mucus and/or blood.

- The incubation period is 12–48 hours, and illness usually resolves within 3–5 days. Asymptomatic shedding is common with a mean duration of 5 weeks—longer in infants.
- Transient bacteremia (nontyphoidal)
 - Bacteremia occurs in up to 5% of infected immunocompetent children and in 10% or more of high-risk patients. Young infants are generally at higher risk for bacteremia.
 - The most common serotypes associated with bacteremia include *Salmonella* Enteritidis, *Salmonella* Heidelberg, and *Salmonella* Typhimurium.
 - Bacteremia can result in localized extraintestinal infection.
- Localized extraintestinal infection (nontyphoidal)
 - Local infections occur in 3–5% of otherwise healthy bacteremic children and in up to 30% of high-risk bacteremic patients.
 - Infections include meningitis, septic arthritis, osteomyelitis, and pneumonia.
 - Infants <3 months of age are at higher risk for meningitis.
- Enteric fever (typhoid and paratyphoid fever)
 - The most important serotypes are *Salmonella* Typhi, followed by the less frequent and milder Paratyphi strain.
 - Incubation is usually 7–10 days but can be 3–60 days.
 - The clinical course is often insidious with progression of disease over 3–4 weeks. Week 1–2: Fever, headache, myalgia, abdominal pain, and listlessness are common. Diarrhea occurs in less than half of patients, and constipation is common. Week 2–3: Fever increases, and rose spots (maculopapular rash) may appear. Splenomegaly and respiratory symptoms may develop. Week 3–4: Fever gradually improves, however, serious complications, such as intestinal perforation, may develop at this time.

DIAGNOSIS

HISTORY

- Exposure history: nontyphoidal

- Recent contact with farm animals (e.g., fairs and petting zoos) or reptiles. Reptiles may pose a risk even without direct contact.
- Recent travel to underdeveloped regions of the world
- Close contacts with recent gastroenteritis
- Consumption of raw milk or undercooked eggs
- Exposure history: typhoidal
 - Travel to underdeveloped countries or close contact to persons recently living in, or visiting, endemic regions.
- Clinical history: nontyphoidal
 - Vomiting appears in half of infected children.
 - Fever (up to 39°C) and abdominal pain are common complaints.
 - Stools with mucus and/or blood should raise suspicion for *Salmonella* as well as other common bacterial intestinal pathogens. Blood in the stool appears in less than 1/3 of patients with *Salmonella*.
 - Signs or symptoms indicative of sepsis, meningitis, osteomyelitis, or septic arthritis—especially in young infants and other high-risk patients—should raise suspicion for *Salmonella*.
 - A positive blood culture with a gram-negative rod may precede the diagnosis of *Salmonella* gastroenteritis.
- Clinical history: typhoidal
 - Half of infected patients present with constipation. Only 1/3 of children have diarrhea.
 - Fever ranges from 39° to 40°C and worsens through the first and second week of illness.
 - Rash and mental status changes may be present.
 - In children <5 years, enteric fever may appear as a nonspecific viral illness.

PHYSICAL EXAM

- Nontyphoidal infections
 - Examine for signs of dehydration.
 - Children with uncomplicated bacteremia may be clinically indistinguishable from nonbacteremic patients.
 - Fever can be absent in children with bacteremia, especially young infants.

- Examine for localized signs of infection in bone and joints.
- Very young infants with Salmonella may present with a normal exam, including those with meningitis.
- When possible, directly inspect stool for gross blood and mucus.
- Enteric fever
 - Patients with high fever may exhibit a relative bradycardia.
 - A coated tongue may be noted.
 - Hepatomegaly and splenomegaly are common.
 - 2–4 mm maculopapular lesions (rose spots) appear in up to 25% of patients.
 - Rales and rhonchi can be present.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Testing involves the following:
 - Basic blood chemistries may reveal dehydration and electrolyte imbalances.
 - WBC counts vary widely and are generally not helpful in diagnosis.
 - Bilirubin and serum transaminases may be elevated with enteric fever.
 - Stool culture is the most sensitive test for nontyphoidal gastrointestinal infection. Preliminary culture results reveal nonlactose fermenting, H₂S-producing colonies.
 - Fecal leukocyte and stool guaiac tests have limited sensitivity and specificity for diagnosing bacterial gastroenteritis.
 - Blood cultures are positive in up to 5% of nontyphoidal infections and 60–80% of patients with enteric fever.
 - Bone marrow aspirations are positive in 80–95% of patients with typhoid fever.
 - Routine bacterial culture of urine, CSF, or bone or joint aspirates should be obtained when clinically indicated.

DIFFERENTIAL DIAGNOSIS

- Illnesses that appear similar to nontyphoidal Salmonella infection
 - Acute gastroenteritis caused by Shigella, Escherichia coli, Campylobacter, and Yersinia is indistinguishable from Salmonella.

- Clostridium difficile causes watery and inflammatory diarrhea, especially in children >2 years of age.
- Norovirus, rotavirus, Cryptosporidium, and Giardia are common causes of watery diarrhea.
- Allergic colitis
- Inflammatory bowel disease
- Bone and joint infection due to Staphylococcus aureus, group A strep, pneumococcus, and Kingella
- Enteric fever from Salmonella may appear similar to the following:
 - Appendicitis
 - Brucellosis
 - Dengue fever
 - Malaria
 - Nonspecific viral illness

TREATMENT

MEDICATION

- Antimicrobials are not indicated for uncomplicated nontyphoidal gastroenteritis, and their use has been associated with prolonged carriage.
- Antimicrobial therapy is indicated for the following:
 - High-risk patients with nontyphoidal gastroenteritis pending blood culture results. These include the following: 1) infants <3 months of age; 2) children with HIV, SCD, and 3) those with malignancy and/or receiving immunosuppressive therapy.
 - Patients with known or suspected nontyphoidal bacteremia or localized infection
 - Patients with known or suspected enteric fever
- Antimicrobial choice
 - Ceftriaxone or cefotaxime is the preferred drug for empirical therapy of nontyphoidal and typhoidal infections while awaiting blood culture and sensitivity results.
 - If shown to be susceptible, amoxicillin or trimethoprim/sulfamethoxazole (TMP/SMX) may be used in high-

risk patients with uncomplicated nontyphoidal gastroenteritis and negative blood cultures.

- Antimicrobial selection should be based on culture results when available. High rates of resistance occur with ampicillin and TMP/SMX.
- Quinolones are generally active but not approved for patients <18 years of age.
- Corticosteroids may provide benefit to critically ill patients with enteric fever.

INPATIENT CONSIDERATIONS

Initial Management

- Patients with dehydration and electrolyte abnormalities require appropriate volume replacement.
- Antimotility agents are generally avoided for all forms of infectious diarrhea in children.
- Consult orthopedics for management of suspected bone and joint infections.
- Administer antimicrobials only for specific clinical indications.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Acute nontyphoidal gastroenteritis
 - Encourage appropriate oral rehydrating fluids and monitor for signs and symptoms of dehydration.
 - Monitor for invasive complications, especially among high-risk patients.
 - Apprise patients and/or families of the risk for prolonged asymptomatic shedding.
 - Instruct patients and families in proper hand hygiene.
- Enteric fever
 - Fever can persist up to 7 days after starting appropriate antimicrobial therapy.
 - Monitor for serious complications such as intestinal bleeding, even

after the patient appears to be improving.

- Monitor for evidence of relapse.
- Instruct patients and families in proper hand hygiene.

ALERT

- Serious complications of enteric fever can present as the patient appears to be improving.
- Even with appropriate therapy, patients with enteric fever may relapse 2–3 weeks after the initial fever resolves.

PROGNOSIS

- Noninvasive nontyphoidal gastroenteritis is typically a self-limiting infection.
- Individuals often shed the organism for weeks, and a small number of patients may continue to shed for >1 year.
- Relapse of typhoid fever occurs in 4–20% of patients up to 3 weeks after the fever resolves.

COMPLICATIONS

- Dehydration is the most common complication caused by acute gastroenteritis.
- Nontyphoidal *Salmonella* gastroenteritis may be complicated by the following:
 - Bacteremia, especially in high-risk patients
 - Osteomyelitis and septic arthritis. Patients with sickle cell disease are particularly susceptible.
 - Meningitis. The course is frequently severe and may be associated with abscess formation and relapse.
 - Other infectious complications include pneumonia, pyelonephritis, and pericarditis.
- Enteric fever complications include intestinal perforation and hemorrhage, cholecystitis, hepatitis encephalopathy, pneumonia, myocarditis, shock, and disseminated intravascular coagulation.

CODES

ICD10

- A02.9 Salmonella infection, unspecified
- A02.0 Salmonella enteritis
- A01.00 Typhoid fever, unspecified

FAQ

- Q: When can children infected with Salmonella return to day care or school?
- A: In general, infants and children with nontyphoidal Salmonella infection may return to day care or school 24 hours after their diarrhea has resolved. Repeat stool cultures are not recommended because asymptomatic shedding is common, and the risk of spread is low. Health officials may recommend documenting a negative stool culture if there are obvious concerns regarding a child's hygiene. Children with S. Typhi infection who are ≥ 5 years of age and asymptomatic for over 24 hours, may attend school without repeating stool cultures. For children < 5 years of age with S. Typhi, it is generally required that the

child be asymptomatic and have 3 negative stool cultures before returning to day care. Most health departments adopt this approach.

SARCOIDOSIS

Peter Weiser • Randy Q. Cron

BASICS

DESCRIPTION

A multisystem chronic granulomatous disease that has two distinct variants often differentiated by age of onset

EPIDEMIOLOGY

- More common in the southeastern part of the United States
- Early-onset sarcoidosis/Blau syndrome
 - Disease occurs before age 4 years as arthritis, uveitis, and dermatitis.
- Adult-type disease
 - Diagnosed in adolescence as Löfgren syndrome with erythema nodosum, polyarthritis, and hilar adenopathy
 - However, marked pulmonary involvement may also occur in older adolescents.
 - CNS involvement (rare): seizures, cranial neuropathy, hypothalamic dysfunction

RISK FACTORS

Genetics

- Blacks are more commonly affected than whites; specific genetic tendencies not identified.
- Early childhood cases of arthritis, uveitis, and dermatitis may result from mutation of the CARD15/NOD2 gene—either spontaneous or hereditary (AD)—familial form, the latter also known as Blau syndrome. Some of the mutation-negative patients have systemic/visceral involvement.

ETIOLOGY

- Unknown (possibly infectious)
- Resembles pulmonary borreliosis

- Possible association with substantial dust inhalation (e.g., collapse of World Trade Center towers in New York)

PATHOPHYSIOLOGY

T-cell-mediated disease resulting in noncaseating epithelioid giant cell granulomas in affected organs

DIAGNOSIS

HISTORY

Prolonged malaise, fever, weight loss, rash, painful arthritis, swollen lymph nodes, chronic cough, and hematuria (can be microscopic) may be initial complaints.

PHYSICAL EXAM

- Peripheral lymphadenopathy is most common manifestation.
- Conjunctival injection
- Bilateral parotid gland enlargement and hepatosplenomegaly may be present.
- The arthritis, usually in the ankles, is extremely tender and boggy.
- Rash is diffuse, erythematous, and macular or plaque-like. It can also be erythema nodosum.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Mild anemia, leukopenia, lymphopenia
- Erythrocyte sedimentation rate (ESR) elevated
- Angiotensin converting enzyme (ACE) level
 - Can be elevated
 - Produced in many granulomatous diseases but is useful in cases in which index of suspicion is high
 - Not a perfect screening test; however, can follow levels in response to treatment
 - False positives: may be elevated in
 - Miliary tuberculosis

- Biliary cirrhosis
- Lysozyme level elevation
 - May be more sensitive than ACE level for detecting sarcoidosis
 - May be useful to follow disease activity in proven cases, if ACE levels cannot be used
 - False positives: may be elevated in
 - Lymphoma
- Serum calcium and creatinine levels
 - Important in baseline evaluation
- Urine test for blood
 - Seen in patients with hypercalciuria
- Synovial effusion is typically mildly inflammatory.
- Biopsy of affected organ, such as peripheral lymph node, parotid gland, skin, conjunctivae, minor salivary gland, or synovium (demonstrating noncaseating granuloma), is helpful and many times diagnostic.

Imaging

- Chest radiography
 - May demonstrate hilar adenopathy
- Gallium scan
 - Demonstrates uptake diffusely in lungs (extremely sensitive test)

ALERT

Uveitis may be occult; slit-lamp ophthalmologic evaluation is important.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Tuberculosis
 - Bacterial sepsis
 - Mumps
 - HIV
 - Gonorrhea
 - Lyme disease
 - Pulmonary mycoses
- Tumors
 - Leukemia
 - Neuroblastoma

- Lymphoma
- Immunologic
 - Oligoarticular juvenile idiopathic arthritis (for early-onset type)
 - Systemic juvenile idiopathic arthritis
 - Systemic lupus erythematosus
 - Sjögren disease
 - Dermatomyositis
 - Behçet disease
 - Crohn disease
- Immunodeficiency
 - Common variable immunodeficiency
- Skin
 - Granuloma annulare
 - Erythema nodosum due to Streptococcus, hepatitis B, or inflammatory bowel disease (IBD)

ALERT

- Pitfalls in diagnosis include not considering IBD arthritis with erythema nodosum.
- Granulomatous skin lesions can occur in both.
- Gene mutations in CARD15/NOD occur in both IBD and Blau syndrome, albeit at different regions of the same chromosome.

TREATMENT

Medications are used to treat active disease with clinical symptoms.

- Pitfalls include overtreating asymptomatic lymphadenopathy and not detecting hypercalciuria.

MEDICATION

- Corticosteroids may provide rapid improvement; NSAIDs/analgesics for symptom relief.
- In cases of chronic disease, immunosuppressive medications such as methotrexate can be used in addition to corticosteroids.
- The tumor necrosis factor inhibitors, specifically antibodies like infliximab and adalimumab show promising preliminary results and

should be considered especially in uveitis.

- In cases of hypercalciuria/hypercalcemia, consider hydration and furosemide.
- Cyclophosphamide for neurosarcoidosis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Referral to rheumatologist indicated, also regular ophthalmologic assessment
- Signs to watch for:
 - Climbing creatinine
 - Shortness of breath
 - Persistent uveal tract inflammation
 - Neurologic deficit

PROGNOSIS

- Variable in early onset. Severe organ involvement and joint and eye damage can occur—needs close follow-up.
- Löfgren syndrome can resolve after a couple of years.
- More than 40% of older children with adult-type disease have persistent pulmonary changes, but only a few will have pulmonary symptoms.

COMPLICATIONS

- In children, usually related to uveitis or from hypercalciuria resulting in renal injury. Lung, CNS, and ocular involvement can bring long-term defects.
- In older adolescents, pulmonary problems, such as restrictive lung disease, as well as severe growth delay, may occur.

ADDITIONAL READING

CODES

ICD10

- D86.9 Sarcoidosis, unspecified
- D86.0 Sarcoidosis of lung
- D86.86 Sarcoid arthropathy

FAQ

- Q: Why is therapy in childhood sarcoidosis more aggressive compared with adults?
- A: These may be 2 distinct granulomatous diseases. Early-onset sarcoidosis is a very aggressive and destructive disease requiring chronic therapy rather than a relatively short course of steroids.

SCABIES

Jessica Nash

BASICS

DESCRIPTION

- Scabies is a parasitic infection caused by the mite *Sarcoptes scabiei*, which infects the stratum corneum of the skin and results in an intense pruritic rash.
- Crusted scabies is a subtype categorized by a more intense pruritus and rash with a heavier burden of mites.
 - Previously called “Norwegian scabies”
 - More common in immunocompromised (i.e., HIV, long-term steroid use) and debilitated patients with sensory neuropathies and paralysis
- Nodular scabies is a rare clinical subtype presenting with red to brown nodules secondary to hypersensitivity reaction to mites and their by-products.

EPIDEMIOLOGY

- Results from close personal and prolonged contact with another human infected with mites
- Occurs worldwide and is endemic in many countries
- Scabies affects all people from different ethnicities, social economic levels, and gender.

Incidence

Varies worldwide, with cyclical fluctuations for new cases; estimates are 1–15 new cases per 1,000 people per year.

Prevalence

Estimated 300 million cases worldwide

GENERAL PREVENTION

- Avoid direct skin-to-skin contact with a person who has scabies and with the clothing/bedding used by a person who has scabies.

- Ensure that any close contacts that have been exposed are treated even if asymptomatic because symptoms can take up to 30 days to develop.
- Everyone in the household should be treated at the same time.
- All bedding and clothing used in the prior 3 days by a person with scabies needs to be washed with hot water and dried in a hot dryer for at least 10 minutes or should be dry-cleaned.
- Furniture and carpets in the household of an infected person should be vacuumed.
- Anything that cannot be washed should be isolated from humans for at least 2 days or, more conservatively, for up to 3 weeks.

PATHOPHYSIOLOGY

- The mite of scabies is a parasite that burrows into the skin and lays eggs. They travel anywhere between 0.5 and 5.0 mm a day. The larvae hatch from the eggs in 2–3 days and become adults and then the cycle repeats.
- Papules are not due to the mite itself but due to a hypersensitivity reaction to the mites' saliva, eggs, and feces.
- If the individual has never been exposed, there is an incubation period which can be between 4 and 6 weeks before symptoms manifest.
- Those with prior exposure and thus sensitized can have milder symptoms that occur within 1–4 days.
- Crusted scabies subtype has thousands to millions more mites, making infectivity easier even at less contact. The mite is the same as with classic scabies.

ETIOLOGY

S. scabiei var *hominis* adult female mite is about 0.3-mm long with eight legs and barely visible with the naked eye.

DIAGNOSIS

HISTORY

- Patients usually present with a history of rash that is intensely pruritic and worse at night because mite activity increases at night based on temperature of the human body.

- Rash present on hands and wrist and may also be in genital area.
- Children younger than 2 years of age may present with a vesicular rash on face and other regions of body not typical in older children and adults.
- Other family members or household contacts with a similar rash given contact with infected person is needed for transmission.

PHYSICAL EXAM

- Usually presents with a papular erythematous rash
- One pathognomonic sign is the burrow line, a linear, wavy, S-shaped mark which occurs as the mite burrows into the skin; can be difficult to see because scratching can obliterate the burrow, but it helps with diagnosis if visualized
- To better identify burrows, can use a washable marker on the skin, then remove markings with water or alcohol. The ink will remain within the burrow, making it easier to see.
- Common sites of rash are interdigital web spaces of hands and feet. Papules can be present in flexor region of wrist, extensor region of elbows, axillary folds, genital region, and periareolar regions of breast.
- Presentation differs in young children versus older children and adults.
 - Children younger than 2 years of age usually have a more widespread distribution that also includes face, neck, palms, and soles.
 - Rash in young children also can be more vesicular.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Direct visualization
 - Potassium hydroxide preparation of a skin scraping
 - Use a blade to scrape skin, isolate the mite from scrapings, and view scrapings under microscopy.
 - Look for mites and mite fecal matter.
- Visualization of the burrows can be made easier using the “burrow ink test.”
 - Use ink to mark areas where scabies are suspected, then wipe away the surface ink with alcohol pad.

- If ink tracks into the mite burrow, making a grossly visible zigzagged line, the test is positive.
- In atypical cases, skin biopsy can be formed.
- Other more specialized tests are under development such as antigen detection, PCR of skin scrapings, or intradermal tests.

DIFFERENTIAL DIAGNOSIS

- Contact dermatitis
- Atopic dermatitis
- Insect bites
- Drug rash
- Infantile acropustulosis
- Impetigo
- Papular urticaria
- Viral exanthem

TREATMENT

MEDICATION

- Permethrin 5% cream
 - Drug of choice for children and infants >2 months of age
 - Is neurotoxic to the mite
 - The cream is applied from neck to toe, paying special attention to interdigital regions; skinfolds of wrist, elbow, and inguinal creases; and under nails.
 - In young children, include the entire head and neck as well because these aren't spared in this age group.
 - Rinse cream off the body 8–14 hours after application.
 - Often, one retreatment 1 week after initial treatment is needed. Some recommend retreating once 4 days later (instead of waiting 7 days).
- Crotamiton 10% cream
 - Not commonly used
 - Not approved in children
 - Apply from chin to toe and reapply 24 hours later. Then remove by

a cleansing bath 48 hours after the last application.

- Sulfur 5–10% cream
 - Can be used for infants younger than 2 months and pregnant lactating woman
 - Must be reapplied daily for 3 days
- Ivermectin
 - Oral antiparasitic agent
 - Not recommend for women who are pregnant or lactating
 - Safety profile for children is unknown.
 - Not FDA approved for treatment of scabies
- Mild to moderate topical steroids
 - Note, topical steroids have no efficacy in treating the mite infection but can be helpful for the intense pruritus during and just after the scabies infection.
- Lindane 1%
 - Not commonly used due to concern for systemic toxicity
 - American Academy of Pediatrics (AAP) Redbook (2012) states that “because of safety concerns and availability of other treatments, lindane should not be used for treatment of scabies.”
 - Side effects can include seizures, headache, and vertigo.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Treatment failure occurs but is usually due to incomplete treatment of all contacts at the same time.
- Recommend follow-up 2 weeks after treatment to ensure no new burrows, new papules, or new vesicles have developed, which would most likely indicate inadequate application of treatment.

PROGNOSIS

Prognosis is great with early identification and treatment.

COMPLICATIONS

- Secondary bacterial skin infection

- Post scabies pruritus: Pruritus that occurs for weeks after treatment should not be confused with treatment failure.

FAQ

- Q: What do I do with the clothes or cloth items that cannot be washed at this time?
- A: Store them in a plastic bag and put them away for 3 days because the mite cannot live more than 3 days without a human host. Couches and carpet should be vacuumed.
- Q: When will my child no longer be contagious?

- A: If treated properly, children are no longer contagious after one treatment. Although your child may still have pruritus, he or she is no longer considered contagious and can return to school.
- Q: When will the rash resolve?
- A: The rash may take 3–4 weeks to resolve after treatment and should not be considered a treatment failure unless a new rash develops.

SCARLET FEVER

Emily C. Borman-Shoap • John S. Andrews

BASICS

DESCRIPTION

- Scarlet fever or “scarlatina” is a manifestation of infection with *Streptococcus pyogenes* (group A β -hemolytic *Streptococcus*) that is characterized by an erythematous “sandpaper” rash. It results from infection with a strain of *S. pyogenes* that elaborates streptococcal pyrogenic exotoxin (SPE).
- Typically occurs in the setting of streptococcal pharyngitis but may occur with group A streptococcal skin or wound infections
- Associated SPE A, B, C, and F. SPE A is associated with more virulent disease.
- Similar syndrome may also be seen in infection with certain enterotoxin-producing strains of *Staphylococcus aureus*, known as staphylococcal scarlet fever.

GENERAL PREVENTION

- Prompt treatment leads to fewer secondary cases of streptococcal disease.
- Some experts recommend chemoprophylaxis with penicillin in children with repeated documented episodes occurring at short intervals.
- Control measures, including hygiene advice and exclusion of infected students for 24 hours while initiating penicillin treatment, were ineffective in a school outbreak.

EPIDEMIOLOGY

- Equal prevalence in boys and girls
- Most common between ages 3 and 15 years, possibly related to the requirement for prior sensitization and toxin-specific immunity
- Little seasonal variation, although some increased prevalence in winter and spring
- Incubation period is 2–5 days for strep pharyngitis and may be up to 10

days for strep skin infections.

Incidence

Peak incidence during the first few school years

Prevalence

By age 10 years, 80% of children have developed toxin-specific antibodies.

PATHOPHYSIOLOGY

- Susceptible individuals are thought to lack toxin-specific immunity. This is supported by results of the Dick test, in which a small amount of toxin introduced intradermally produces local erythema in susceptible individuals but no reaction in those with toxin-specific immunity.
- Rash and other toxic manifestations of scarlet fever have been attributed to the development of hypersensitivity to the toxin, which requires prior exposure to the toxin.
- Toxin production depends on lysogeny of the infecting *Streptococcus* by a temperate bacteriophage.
- Histologic examination of affected skin shows dilated blood and lymphatic vessels and engorged capillaries, most prominently around hair follicles.
- Acute, edematous polymorphonuclear inflammatory reaction is seen microscopically within affected tissues.
- Epidermal inflammatory reaction is usually followed by hyperkeratosis, which accounts for scaling during defervescence.

DIAGNOSIS

HISTORY

- Sudden onset of fever up to 40.5°C, sore throat, headache, nausea, vomiting, and toxicity are classic symptoms for group A streptococcal disease.
- Texture of rash (e.g., feels like sandpaper) is more important than appearance.
- Characteristic rash typically occurs 12–48 hours after onset of fever.

- Patient may complain of abdominal pain or muscle aches before onset of rash as well as aching in extremities or back.
- There may be close contacts with streptococcal infection.

PHYSICAL EXAM

- Fine maculopapular (sandpaper texture) rash on erythematous background: usually begins on the trunk and spreads to involve almost the entire body within hours to days. Although the rash seen with scarlet fever is generally fine and sandpaper-like, larger papules and petechiae may be seen.
- Rash may be more easily detected by palpation than visual inspection
- Pastia line: accentuation of erythema in flexor creases (antecubital, axillary, inguinal)
- Circumoral pallor: Area around mouth appears pale in comparison to flushed cheeks.
- Rash blanches with pressure and ultimately desquamates: Desquamation occurs within 7–21 days from onset of illness.
- Systemic toxicity: may indicate incorrect diagnosis
- Dorsum of tongue: has white coat early in illness with edematous red papillae. White covering desquamates and reveals swollen, red, and mottled strawberry tongue.
- Other findings:
 - Pharynx and tonsils are beefy red and may contain exudate.
 - Hemorrhagic spots on interior pillar of tonsils and soft palate
 - Large, tender anterior cervical nodes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Rapid streptococcal antigen tests: effective as screening tests; 70–90% sensitivity and >95% specificity. Positive rapid tests do not require culture confirmation.
- Throat culture: the gold standard with best sensitivity (>90%) for group A β -hemolytic streptococci. A culture should be performed when rapid test is negative.
- White blood cell count: usually elevated, although may be elevated in viral pharyngitis as well. Low count would be rare with streptococcal

infection.

- Eosinophilia (up to 30%): common in the recovery phase
- Dick test: of historic interest; no longer used clinically
- Pitfalls
 - A positive throat culture may be evidence only of carriage in some cases of acute pharyngitis that are actually viral (e.g., Epstein-Barr virus).
 - Milder disease is becoming more common and is easier to miss. Rash may involve only the bridge of the nose, face, shoulders, and upper chest. Circumoral pallor and severe exudative pharyngitis are being seen less frequently.

DIFFERENTIAL DIAGNOSIS

- Viral exanthems (measles, rubella, erythema infectiosum)
- Drug eruptions
- Staphylococcal scalded skin syndrome
- Toxic epidermal necrolysis
- Toxic shock syndrome (streptococcal or staphylococcal)
- Kawasaki disease
- Uncommon entities:
 - Infection with *Arcanobacterium hemolyticum*
 - Mercury poisoning (acrodynia)
 - Atropine intoxication
 - Boric acid poisoning
 - Rifampin overdose

TREATMENT

GENERAL MEASURES

- Identical to therapy for streptococcal pharyngitis
- Therapy started as late as 9 days after illness onset should be effective in preventing acute rheumatic fever.
- May withhold treatment until throat culture result is available
- Immediate therapy probably shortens symptomatic period.

MEDICATION

Penicillin or amoxicillin remain the drugs of choice to treat streptococcal pharyngitis. Resistance to penicillin has never been documented in the United States.

- Oral penicillin V potassium (10 days)
 - Children: 250 mg twice or 3 times daily
 - Adolescents: 250 mg 4 times daily or 500 mg twice daily
- Oral amoxicillin (10 days)
 - 50/mg/kg once daily (max 1,000 mg/dose)
 - Alternate 25 mg/kg/dose (max 500 mg/dose) twice daily
- Intramuscular penicillin G benzathine
 - Equally effective as oral penicillin
 - Dose: 600,000 U for children <14 kg (<30 lb); 900,000–1,200,000 U for children 14–27 kg; and 1,200,000 U for children >27 kg and adults
 - Ensures compliance (only one dose needed)
 - Benzathine/procaine penicillin combinations are less painful.

The following medications are options for penicillin-allergic patients:

- Oral cephalexin (10 days)
 - 20 mg/kg/dose twice daily (max 500 mg/dose)
- Oral cefadroxil (10 days)
 - 30 mg/kg/dose once daily (max 2 g/dose)
- Oral azithromycin (5 days)
 - 12 mg/kg/dose once daily (max 500 mg/dose)
- Oral clarithromycin (10 days)
 - 7.5 mg/kg/dose twice daily (max 500 mg/dose)

Tetracyclines and sulfonamides should not be used because of resistance of group A streptococci.

ONGOING CARE

- Fever and symptoms usually resolve within 24–48 hours of antibiotic treatment.
- Nonsuppurative complications occur after the acute streptococcal infection has resolved.
 - Acute rheumatic fever occurs an average of 18 days after untreated

infection. Treatment must be initiated within 9 days of onset to prevent this complication

- Acute postinfectious glomerulonephritis occurs an average of 10 days after infection. The risk of glomerulonephritis is not reduced by treatment with antibiotics.

PROGNOSIS

Overall prognosis is excellent.

- Few patients suffer suppurative complications.
- Risk of developing acute rheumatic fever in untreated streptococcal infections is about 3% under epidemic conditions (0.3% in endemic situations).
- Acute postinfectious glomerulonephritis is uncommon. Risk may be as high as 10–15% following infections with certain nephritogenic strains.

COMPLICATIONS

- Patients with scarlet fever may experience hyperkeratosis. Peeling of the affected skin may also occur 2 weeks after the acute infection.
- Other complications worth noting may occur following any primary manifestation of group A streptococcal infection and are not specific to scarlet fever.
 - Streptococcal toxic shock syndrome is a toxin-mediated complication of streptococcal infection that may be life threatening.
 - Suppurative complications of streptococcal pharyngitis include the following:
 - Cervical adenitis
 - Peritonsillar abscess
 - Retropharyngeal abscess
 - Sinusitis
 - Otitis media
 - Mastoiditis
 - Meningitis
 - Brain abscess
 - Thrombosis of intracranial venous sinuses
 - Nonsuppurative complications include acute rheumatic fever and

postinfectious glomerulonephritis

- A38.9 Scarlet fever, uncomplicated
- J02.0 Streptococcal pharyngitis

FAQ

- Q: Should household contacts have throat cultures performed?
- A: Obtain cultures only from symptomatic household contacts.
- Q: Is there any indication for throat culture in asymptomatic individuals (e.g., household contact of infected individual or test of cure in treated individual)?
- A: No. Throat culture of close contacts of highly vulnerable individuals (e.g., those with recurrent rheumatic fever) may be indicated.
- Q: Is culture confirmation of strep infection necessary to make the diagnosis of scarlet fever?

- A: No. Although laboratory evidence of strep infection is supportive, scarlet fever is a clinical diagnosis.
- Q: Should posttreatment throat cultures be performed?
- A: Only in symptomatic individuals and patients at risk for acute rheumatic fever.
- Q: Can scarlet fever occur in the absence of pharyngitis?
- A: Yes. Scarlet fever has been reported after group A streptococcal skin infections
- Q: Can scarlet fever recur?
- A: Yes. There have been documented reports of recurrent scarlet fever.
- Q: Have there been documented child care outbreaks of scarlet fever?
- A: Yes. Outbreaks have been traced to single strains in this setting.
- Q: How soon can children return to school or child care?
- A: When they are afebrile and after at least 24 hours of antibiotic therapy

SCLERODERMA

Peter Weiser • Randy Q. Cron

BASICS

DESCRIPTION

- Scleroderma means “hard skin.” It can be systemic or localized.
- Systemic sclerosis (SSc) or progressive systemic sclerosis (PSS)
 - Diffuse cutaneous SSc: affects skin and internal organs (lungs, GI tract)
 - Limited cutaneous SSc, also known as CREST: a variant form of SSc characterized by calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, telangiectases
- Localized
 - Morphea
 - Linear scleroderma
 - En Coup de Sabre/Parry-Romberg syndrome

EPIDEMIOLOGY

- Systemic
 - Age of onset: 30–50 years; very rare in children
 - Sex ratio
 - <7 years, male = female
 - >7 years, female > male (3:1)
 - 15–44 years, female > male (15:1)
- CREST
 - Earlier age of onset than SSc
 - Almost nonexistent in children
 - Female > male

Incidence

- Systemic: 0.27 per million annually
- CREST: affects ~1/2 of patients with systemic disease
- Localized: approximately 10× more common than SSc in childhood

PATHOPHYSIOLOGY

- Systemic involvement
 - Vasculopathy: based on high association with Raynaud phenomenon; vascular injury leading to fibrotic changes as a part of overcorrection
 - Serum factors: overexpression of endothelin, a potent vasoconstrictor with profibrotic activity
 - Immune dysfunction: autoimmunity directed against connective tissue antigen such as laminin or type IV collagen, platelet-derived growth factor receptors stimulating fibrosis
- Localized form
 - Alteration of normal glycosylation and hydroxylation of collagen
 - May represent distinct early and late processes
 - Early: increased hydrophilic glycosaminoglycan; increased T cells, macrophages, and plasma cells; mast cell hyperplasia
 - Late: increased collagen content; collagen is embryonic with narrow fibrils and immature cross-banding; atrophy of rete pegs, epithelial tissue projecting into underlying connective tissue

DIAGNOSIS

HISTORY

- Thickening of skin
- Tightness of joints
- Discoloration of skin
- Often insidious onset
- Morning stiffness
- Heartburn, dysphagia, reflux, cough with swallowing

Signs and symptoms:

- SSc
 - Diagnostic criteria (1 major criterion or 2 minor criteria required)
 - Major: sclerodermatous changes (tightness, thickening, induration) proximal to metacarpophalangeal or metatarsophalangeal joints
 - Minor: sclerodactyly-sclerodermatous changes limited to digits (unable to pinch skin over the digit), digital pitting, bibasilar pulmonary fibrosis not due to primary lung disease

- CREST
 - More severe calcinosis
 - Distal symptoms more severe
 - Associated with anti-centromere antibody
 - Occasional evolution into another connective tissue disease such as mixed connective tissue disease (MCTD) or systemic lupus erythematosus (SLE)
- Localized
 - Fibrosis limited to skin, subcutaneous (SC) tissue, and muscle
 - Systemic features including Raynaud phenomenon and visceral involvement are extremely rare except in Parry-Romberg.
 - Forms:
 - Morphea: ≥ 1 oval or round indurations that become hard and whitish early on, have active inflammatory border with violaceous color. Various forms: plaque or guttate (limited number of lesions); generalized (extensive); nodular (SC)
 - Linear: ≥ 1 linear areas affecting SC tissue, muscle, and bone; can cross joint lines and also affect limb growth
 - En Coup de Sabre: involves face or scalp; may be associated with seizures
 - Parry-Romberg syndrome: form of linear scleroderma; congenital dysplasia of SC tissue; neurologic changes such as transient ischemic attacks (TIAs) in brain matter under lesion, without its direct extension into the skull

PHYSICAL EXAM

- Findings in SSc:
 - Skin
 - Stage 1: Edema—tense, nonpitting; perhaps warm or tender but often asymptomatic
 - Stage 2: Sclerosis—waxy, hard texture; bound to SC structures, back of digits, face (loss of forehead wrinkles, reduced mouth orifice)
 - Stage 3: Atrophy—shiny appearance, hypopigmented or hyperpigmented, calcium deposits in SC tissue
 - Telangiectasias: macular dilatations that fill slowly, unlike spider

- telangiectasias
 - Loss of SC tissue pulp of the fingers and ulcerations on fingertips with prolonged healing in SSc
- Raynaud phenomenon
 - Primary phenomenon or Raynaud disease: not associated with underlying disease; milder; 75% are female.
 - Secondary Raynaud phenomenon: associated with underlying disease such as SSc, SLE, Sjögren syndrome, MCTD, dermatomyositis, and polymyositis; more serious. Present in ~90% of SSc patients.
 - Triple phase: blanching of digits with sharp border to normal-colored skin (arterial vasoconstriction) followed by cyanosis (venostasis) then erythema; tingling/numb sensation of the digits (reflex hyperemia to vasodilatation)
 - Usually fingers; also toes, nose, ears, and tongue; often spares thumb
- Calcinosis, especially over extensor joint surfaces in systemic form only
- Pitfalls
 - Failure to recognize limited mouth opening in SSc
 - Failure to evaluate periungual nailfold changes with Raynaud phenomenon: capillary dropout and dilated loops; occasional redundant cuticular growth and digital pitting
- Musculoskeletal
 - “Creaking” of thickened tendons
 - Contractures, especially proximal interphalangeal joints and elbows
 - Associated arthritis
 - Muscle inflammation in ~30% of cases
- GI
 - Mucosal telangiectasias of mouth
 - Decreased incisor distance/mouth opening secondary to skin tightness of the lips
 - Sicca syndrome with parotitis
 - Loosening of teeth secondary to periodontal membrane disease

- Esophageal disease: esophagitis, occasional ulceration or stricture
 - Large-bowel disease less common
- Cardiac
 - Primary cause of morbidity
 - Possibly due to Raynaud phenomenon of coronary arteries and pulmonary artery hypertension
 - Myocarditis possible
- Pulmonary
 - Interstitial fibrosis with gradual obliteration of vascular bed and resulting cor pulmonale
 - Parenchymal disease is almost universal; frequently asymmetric; may have hacking cough, dyspnea on exertion, pleural rub.
 - Combined pulmonary vascular and pulmonary parenchymal disease
 - Primary pulmonary vascular disease with right ventricular failure
- Renal: due to decreased renal plasma flow, proteinuria, hypertension, renal crisis
- CNS: cranial nerve involvement, especially sensory branch of trigeminal nerve
- Sicca syndrome
 - Xerostomia (dry mouth)
 - Keratoconjunctivitis sicca (dry eyes)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

There are no specific diagnostic tests.

- Nonspecific tests
 - Systemic form
 - Antinuclear antibody (ANA): often positive
 - Hemoglobin: 25% have anemia due to chronic disease or vitamin B₁₂ and folate deficiencies resulting from chronic malabsorption in sclerodermatous gut.
 - Eosinophilia: present in 50%
 - Sclero-70 (Scl-70 or topoisomerase 1) antibodies: present in 26% of adults; more common with diffuse disease than with peripheral vascular disease

- Anti-centromere antibody: present in 22%, almost exclusively with CREST
 - Muscle biopsy
- Localized forms
 - Eosinophilia: present in 25–50% during active disease
 - ANA: positive in 37–67%

Imaging

- Chest radiograph
 - Bibasilar pulmonary fibrosis
 - Rib notching
 - Calcifications (in CREST)
- High-resolution chest CT
 - Ground-glass attenuation
 - Honeycombing
- Bone radiograph
 - Acro-osteolysis: resorption of tufts of distal phalanges, especially with severe Raynaud phenomenon
 - Periarticular or SC calcification (15–25% patients)
 - Bony erosions

Diagnostic Procedures/Other

- For sicca syndrome
 - Schirmer test for dry eyes
 - Lip biopsy
 - Rose bengal staining of cornea
- ECG
 - 1st-degree block
 - Right and left bundle-branch block
 - Premature atrial contractions (PACs) and premature ventricular contractions (PVCs): nonspecific T-wave changes, ventricular hypertrophy
- Pulmonary function tests
 - Restrictive lung disease: present in 34% of patients with SSc
 - Earliest changes are decreased forced vital capacity (FVC) and small airway disease.
 - Decreased diffusing capacity of the lung for carbon monoxide

(DLCO): present in 18% of patients with SSc at the time of diagnosis

Pathologic Findings

- Histologic
 - Skin: loss of SC fat, increased amount of fibroblasts
 - Muscle: increased collagen and fat; negative immunofluorescence
 - Esophagus: Atrophic muscle replaced by fibrous tissue more commonly affects smooth muscle of lower 2/3 of esophagus.
- Esophageal manometry and pH probe: decreased or absent peristalsis of distal esophagus—distal dilatation, hiatal hernia, stricture
- Dilatation of second and third part of duodenum and proximal jejunum

DIFFERENTIAL DIAGNOSIS

- Graft-versus-host disease (GVHD)
- Phenylketonuria
- Borrelia infection: acrodermatitis chronica atrophicans
- Porphyria cutanea tarda
- Scleredema
- Stiff skin syndrome (mucin deposition in the dermis, hardening of the subcutaneous tissue with normal-looking epidermis)
- Eosinophilic fasciitis

TREATMENT

MEDICATION

Disease modification: Many agents have been tried; however, there are few controlled trials, and no proven treatment exists. Medications include the following:

- Localized
 - Imiquimod, calcitriol ointment, psoralen ultraviolet A light (PUVA) therapy, methotrexate, mycophenolate mofetil, cyclosporine
- Systemic
 - Colchicine: inhibits fibroproliferative process
 - Immunosuppressives
 - Steroids, chlorambucil, methotrexate, mycophenolate mofetil,

cyclosporine, cyclophosphamide, rituximab

- Pitfall: Avoid excessive use of immunosuppressive therapy late in disease when inflammatory component has resolved.

ADDITIONAL TREATMENT

General Measures

- Supportive care: Avoid trauma and excessive cold; keep extremities warm AND dry.
- Management of Raynaud phenomenon:
 - Avoid beta-blockers, caffeine, and stimulating ADHD medications.

ADDITIONAL THERAPIES

- Physical therapy
 - Helps retard development of contractures and muscle atrophy
 - Pitfall: insufficient physical therapy resulting in permanent joint contractures

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Localized forms
 - Physical exam for joint mobility, muscle bulk, and growth
 - Difficult to follow slow disease progression, thus photography of lesions every 3–6 months is recommended
- Systemic forms
 - Physical exam for digital ulcerations, joint mobility, muscle bulk, and growth
 - Yearly pulmonary function tests
 - Yearly barium swallow
 - ECHO

PROGNOSIS

- In localized forms, natural course includes several phases:
 - Initial: inflammation
 - Late: sclerosis

- Occasional regression over 3–5 years
- Contractures and limb size difference can persist with linear scleroderma.
- Systemic form is progressive and ultimate prognosis depends on severity of skin tightness, joint contracture, and visceral involvement.
- Mortality with SSc
 - Males > females
 - Non-whites > whites
- Most common cause of death in pediatric patients with SSc is secondary to cardiac, renal, and pulmonary complications.

COMPLICATIONS

- Localized
 - Skin thickening
 - Joint contractures
 - Leg length discrepancies
 - CNS bleed in Parry-Romberg

- M34.1 CR(E)ST syndrome
- L94.0 Localized scleroderma [morphea]

FAQ

- Q: Is a biopsy necessary?
- A: Biopsy is often useful to confirm diagnosis and assess degree of inflammation.
- Q: Is the sclero-70 antibody useful?
- A: Not for diagnosis; it is positive only in a subset of individuals with the systemic form and, therefore, useful for predicting more severe disease.

SCOLIOSIS (IDIOPATHIC)

Scott McKay • Jennifer A. Talarico • John P. Dormans

BASICS

DESCRIPTION

- Scoliosis: lateral curvature of spine exceeding 10 degrees on PA full-spine radiograph (with rotation of spine); curves <10 are termed spinal asymmetry; considered idiopathic only after other causes have been excluded
- Kyphosis: anteriorly concave curvature of vertebral column

EPIDEMIOLOGY

- Female-to-male ratios:
 - 1.4:1 for curves 11–20 degrees
 - 5.4:1 for curves >20 degrees

Prevalence

- Generally considered 1.5–3% for curves ≥ 10 degrees
- 0.3–0.5% for curves >20 degrees

RISK FACTORS

Genetics

Positive familial history for idiopathic scoliosis in 30% (not predictive of severity)

- Under active investigation: GWAS and whole exome sequencing studies
- Several candidate genes have been identified.

ETIOLOGY

By definition, unknown; listed are some theories, none proven in isolation:

- Genetic
 - Positive familial history for scoliosis in 30% (not predictive of severity)
- Connective tissue disorder
 - Associated with several connective tissue disorders (including

- Marfan syndrome, Ehlers-Danlos syndrome, etc.)
- Alterations in connective tissue of the spine, paraspinous muscles, and platelets
 - May be related to osteopenia (decreased bone mineral density) of vertebral bodies
 - Neurologic (equilibrium system)
 - Abnormalities noted in vestibular, ocular, proprioceptive, and vibratory functions
 - Hormonal
 - Lower levels of melatonin secreted from pineal body in those with adolescent idiopathic scoliosis
 - Growth hormone: more of an influential factor than an etiologic factor in studies
 - Vertebral growth abnormalities
 - Asymmetric growth rates between the right and left sides of the spine

COMMONLY ASSOCIATED CONDITIONS

- Connective tissue disorders, including Marfan syndrome and Ehlers-Danlos syndrome
- Neurofibromatosis
- Neuromuscular conditions, including cerebral palsy, spina bifida, spinal muscular atrophy, Friedreich ataxia, etc.
- If any of these conditions are present, the diagnosis is no longer idiopathic.

DIAGNOSIS

HISTORY

- Onset: Consider when first noted, by whom, rate of worsening, previous treatment, patient recent growth, the physical change of puberty, associated signs or symptoms, familial history, etc.
- Patients with idiopathic scoliosis usually should not have pain, although they might have a discomfort or mild pain.
- Back pain in scoliotic patients must be investigated thoroughly and

taken seriously.

- If night pain, consider tumor such as osteoid osteoma.

PHYSICAL EXAM

- General inspection to look for skin changes such as café au lait spots, pigmentation, or other signs of neurofibromatosis; also dysraphic signs (e.g., hairy patches, midline hemangioma, skin dimpling)
- Assess for skeletal maturity, hyperelasticity, contracture, congenital anomalies.
- Assess for deformity; asymmetry of spine, shoulders, waist, and trunk, including decompensation; abnormalities of thoracic kyphosis or cervical or lumbar lordosis; disfigurement of the torso; or rib rotation.
- Adams forward bend test used to look for rib or paraspinous elevations
- Assess for leg length discrepancy, congenital anomalies, and neurologic abnormalities (including abnormal abdominal reflex).
- Special finding:
 - Crankshaft phenomenon
 - Progression of curve size and rotation following posterior spinal fusion in a young child, result of continued anterior spinal growth
 - Patient is Risser 0, open triradiate cartilages, <10 years old, and prior to occurrence of peak height velocity (time of maximum spinal growth).
 - Consider anterior fusion in addition to posterior fusion.
- Physical exam tricks:
 - Measure angle of trunk rotation with scoliometer.
 - Abnormal abdominal reflex may suggest intraspinal pathology, including syrinx.
- Perform Adams forward bend test after the pelvis is leveled by inserting appropriately sized block underneath the short leg in patients with scoliosis and leg length discrepancy.

DIAGNOSTIC TESTS & INTERPRETATION

Pulmonary function testing is useful preoperatively for more severe curves.

Lab

Usually not helpful unless to rule out associated metabolic conditions

Imaging

- Plain standing posterior–anterior and lateral scoliosis films on long 3-foot radiograph cassette or 3-D low-dose radiation system
- One must look for soft tissue and congenital bony abnormalities (Wedge vertebrae, bars, hemivertebrae).
- Curve is measured using Cobb method.
- The status of the triradiate cartilage and Risser classification of iliac apophysis ossification are indicators of maturity.
- The triradiate cartilage usually closes before the iliac apophysis appears (Risser 0).
- Risser sign is defined by the amount of calcification present in the iliac apophysis and measures the progressive ossification from anterolaterally to posteromedially.
 - A Risser grade of 1 signifies up to 25% ossification of the iliac apophysis, proceeding to grade 4, which signifies 100% ossification.
 - A Risser grade of 5 means the iliac apophysis has fused to the iliac crest after 100% ossification.
 - Risser grade (0–5) gives an estimate of how much skeletal growth remains and is correlated with risk of curve progression.
- MRI is not routinely necessary for adult idiopathic scoliosis without back pain.
- 7% prevalence of intraspinal abnormalities are found in left thoracic curves, so MRI maybe indicated.
- Curve patterns are classified according to King or Lenke classifications.
- Renal ultrasound is used for evaluation of patient with congenital scoliosis (look for associated renal abnormalities).

DIFFERENTIAL DIAGNOSIS

- Adolescent idiopathic scoliosis (11–17 years)
- Juvenile idiopathic scoliosis (4–10 years)
- Infantile idiopathic scoliosis (0–3 years)
- Congenital scoliosis—due to bony abnormalities of the spine that are present at birth (failure of formation or segmentations of vertebrae)
- Scoliosis associated with neurofibromatosis
- Scoliosis associated with tumors (e.g., osteoid osteoma)

- Neuromuscular scoliosis (e.g., cerebral palsy, spina bifida, muscle disorders)
- Postural scoliosis (e.g., from leg length discrepancy)
 - No rib hump or rotation
 - Does not have fixed deformities
 - Disappears with forward bending
 - Long curve
 - No progression

TREATMENT

GENERAL MEASURES

- Treatment
 - Concepts for treatment are based on severity of deformity and on likelihood of progression.
- Observation
 - Curves <25 degrees
 - ▢ Immature patients (Risser 0, 1, 2) should be reevaluated in 4–6 months.
 - ▢ Skeletally mature patients (Risser 4 or 5) usually do not require ongoing follow-up unless special circumstances exist.
 - Curves 25–45 degrees in skeletally mature patients
 - ▢ Risser 4 or 5 patients are usually reevaluated in 6 months to 1 year.
 - ▢ Mature patients are usually reevaluated yearly.

ADDITIONAL THERAPIES

- Brace treatment
 - Curves 25–45 degrees (Risser 0, 1) and 30–45 degrees (Risser 2 or 3)
 - ▢ Brace on initial evaluation.
 - Curves ≥ 25 degrees (in Risser 0–3 patient) that have demonstrated >10 degrees progression during period of observation
 - ▢ Continue brace treatment until maturity (2 years postmenarchal and Risser 4 in females, Risser 5 in males).

- Brace types
 - Thoracolumbosacral orthosis (TLSO): success reported when used >16–18 hours daily; significantly improved outcome when compared with natural history
 - Cervicothoracolumbosacral orthosis (CTLSO): seldom needed except for higher thoracic or cervical curves
 - Nighttime bending brace

SURGERY/OTHER PROCEDURES

- Recommended when curves exceed 45–50 degrees
 - Exception: Balanced thoracic and lumbar curves <55 degrees may be observed for progression.
- Thoracic curves and double major curves
 - Posterior segmental fixation instrumentation remains current state of the art.
 - Anterior spinal instrumentation for selected curves
- Isolated thoracolumbar and lumbar curves
 - Anterior spinal fusion using solid rod segmental constructs

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Watch for back pain associated with idiopathic scoliosis (may indicate other diagnosis):
 - Present in 23% at time of initial evaluation (additional 9% during follow-up)
 - Of those with back pain, only 9% found to have identifiable cause such as spondylolysis, Scheuermann, syrinx, disc herniation, tumor, tether cord.

PROGNOSIS

- Overall, good for most patients
- Risk of curve progression related to patient's maturity (Risser sign, menarcheal status) and to size of curve
- Curves <20–25 degrees have low risk of progression, even if patient is

immature.

- Curves 25–45 degrees have higher risk of progression, particularly in skeletally immature patients.
- Curves >45–50 degrees have much higher risk of progression, regardless of maturity.

COMPLICATIONS

Natural history:

- Reduced pulmonary function for patients with thoracic curves >60 degrees
- Progression of lumbar curves >50 degrees in adult life with degenerative disc disease and pain in some
- Cosmetic and emotional issues
- Complications of brace use include skin irritation, discomfort, and noncompliance.
- Surgical complications are usually more severe, including infection, instrumentation loosening or breakage, neurologic damage, paralysis, or death.

- M40.56 Lordosis, unspecified, lumbar region

FAQ

- Q: How long do you observe a patient with spinal asymmetry before ordering a radiograph?
- A: It depends on the presence or absence of abnormalities on the physical exam. If any of the signs mentioned here are seen or significant back pain is present, a radiograph or referral is indicated. The scoliometer is also a useful tool in screening patients.
- Q: How long do you observe a patient with spinal asymmetry before referral to an orthopedic surgeon?
- A: Consider referral if
 - Cobb angle
 - ▣ >20 degrees
 - ▣ Progression of more than 5 degrees
- Q: If a child presents with scoliosis and back pain that occurs especially at night and is promptly relieved with nonsteroidal anti-inflammatory drugs, what diagnosis is suggested?
- A: Scoliosis associated with osteoid osteoma.

SEBORRHEIC DERMATITIS

Jennifer DiPace • Saskia Gex

BASICS

DESCRIPTION

- Seborrheic dermatitis (SD) is a multifactorial skin disease influenced by both host and environmental factors.
- Involves sebaceous areas of the body
 - Including the scalp, face, back, chest, and intertriginous areas
 - Characterized by greasy, yellow, scaly erythematous lesions
- Usually a self-limited condition in infants but can be a chronic, relapsing condition in adolescents and adults

EPIDEMIOLOGY

- Trimodal distribution: infants, adolescents, and adults >50 years of age
- Highest prevalence in first 3 months of life
- Affects approximately 10% of the general population and up to 70% of infants in the first 3 months of life
- No sex predilection in infants; however, in adolescents and adults, males are affected more commonly than females.
- Seasonal pattern: Prevalence of disease increases in winter months.
- Strong association between *Malassezia* species, a common commensal organism, and SD

RISK FACTORS

- There are no known genetic factors that contribute to disease.
- Hormonal effects: exposure to maternal estrogen in infancy and surge of androgens in puberty
- Immunocompromised status
 - Impaired cellular immunity may contribute to pathogenesis of disease.
 - Prevalence of SD in immunocompromised patients is significantly higher than in general population.

GENERAL PREVENTION

There are no known preventive measures.

PATHOPHYSIOLOGY

- Androgens stimulate sebaceous glands, causing production of more sebum.
- Malassezia
 - A lipophilic yeast that is normally found in sebum-rich areas of the skin
 - Can break down skin sebum lipids, producing potentially inflammatory fatty acids
- In response to the inflammatory fatty acids, keratinocytes produce proinflammatory cytokines.

ETIOLOGY

Not completely known, although it was thought that yeast, androgens, and the local host immune response play a role in SD development.

DIAGNOSIS

HISTORY

- Older children and adolescents: Ask about onset of puberty symptoms.
- Typically not pruritic
- Children and adolescents: Ask about symptoms and signs of immunocompromise such as frequent infections, failure to thrive, and chronic diarrhea.
- HIV and tuberculosis (TB) history

PHYSICAL EXAM

- Infants: “cradle cap”
 - Yellow, greasy adherent scales on the scalp
 - Lesions may also occur on the forehead, eyebrows, eyelids, postauricular area, and nasolabial folds.
 - No excoriations
 - No hepatosplenomegaly
- Adolescents and adults

- Mild: dry, flaking scalp or face in areas of facial hair; no surrounding inflammation
- More severe SD: patchy, orange/yellow, greasy plaques in scalp, nasolabial folds, postauricular area, intertriginous areas, or other regions of increased sebaceous gland activity
- Blepharitis with erythema and scaling of the eyelid margins may also occur.
- No excoriations
- No hepatosplenomegaly

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Primarily a clinical diagnosis; there are no specific tests for seborrhea.

Diagnostic Procedures/Surgery

Skin biopsy should be reserved for unusual or refractory cases of SD.

Pathologic Findings

- Skin biopsy findings
 - Predominance of neutrophils in the scale crust at the margins of follicular ostia
 - Yeast cells sometimes are visible within keratinocytes on special stains, but hyphae should not be present in SD.

DIFFERENTIAL DIAGNOSIS

- SD can be confused with infectious conditions of the skin, malignancy, or inflammatory disorders.
- Dermatophyte infections
 - Tinea capitis, tinea faciei, and tinea corporis are also scaling lesions. The lesions are scaly but not typically greasy or plaque-like.
 - Microscopic evaluation of lesion can differentiate it from SD by the presence of hyphae in dermatophyte infection.
- Malignancy/Langerhans cell histiocytosis (LCH)
 - LCH may present with a scaly erythematous lesions in the same distribution as SD.
 - Unlike SD, LCH may have the presence of small reddish-brown crusted papules or vesicles.

- In addition, there may be organ system involvement such as hepatosplenomegaly.
- LCH is refractory to typical treatment for SD.
- Immunologic
 - Atopic dermatitis
 - May present on the face of infants but typically spares the nasolabial folds
 - May also involve the extensor aspects of the extremities
 - Usually is pruritic
 - Psoriasis vulgaris
 - Typically presents as sharply defined plaques, bright red in color with thick silver scales
 - Unlike SD, children with psoriasis may have nail changes such as nail pitting and onycholysis.

TREATMENT

- Treatment depends on presentation and age of patient.
- For infants, SD usually has a benign and self-limited course. Medications may not be necessary for the treatment of infant SD.
- Physical measures such as the application of emollients followed by the removal of scalp scales with a comb may improve symptoms.
 - Examples of emollients include mineral oil, baby oil, or petroleum jelly.
 - There have been some studies to suggest that the use of organic oils such as olive oil or vegetable oil may provide an excellent media for *Malassezia* overgrowth, potentially worsening SD.
 - Frequent shampooing with a nonmedicated shampoo may also be beneficial.

MEDICATION

- For infants who do not respond to conservative therapy or for older children/adults, medications will likely be necessary.
- Classes of drugs that should be considered are keratolytic, antifungal, and anti-inflammatory medications. At the current time, there is no

- evidence to support the use of one class of drug versus another.
- Keratolytics: Massage into scalp 2–3 times per week, leave on 5 minutes, then rinse.
 - Salicylic acid
 - Shampoo or lotion
 - Coal tar
 - Shampoo
 - Decreases sebum production
 - Pyrithione zinc
 - Most commonly used as a shampoo
 - Also has antifungal properties
 - Antifungals
 - Selenium sulfide
 - Antifungal and keratolytic effect
 - Shampoo. Massage 5–10 mL of shampoo into wet scalp, leave on scalp 2–3 minutes, then rinse thoroughly.
 - Usually, 2 applications each week for 2 weeks will provide control.
 - Azoles: ketoconazole
 - 1% or 2% gel, lotion, or shampoo
 - Shampoo should be used twice per week (at least 3 days between doses) for up to 8 weeks. Caution: may cause eye irritation
 - Gel or lotion should be used twice daily for up to 2–4 weeks.
 - Ciclopirox: 1% shampoo
 - Can be used in children >16 years old
 - Massage into scalp, then rinse.
 - Use 2 times per week (at least 3 days between doses) for up to 4 weeks.
 - Anti-inflammatory therapies
 - Corticosteroids
 - Shampoo, foam, ointment, creams, or lotions
 - There are multiple options; treatment will depend on severity of inflammation and age of patient.
 - Ointments should be considered for more severe cases because skin absorption is improved.

- Foams can be used in hairy areas because of ease of application.
- Calcineurin inhibitors: tacrolimus ointment
 - Can be used in children >2 years of age
 - Fungicidal and anti-inflammatory properties
 - Apply thin layer of 0.03% ointment to affected area twice daily until symptoms resolve or up to 6 weeks.

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Tea tree oil 5% has been demonstrated to be effective in treating scalp seborrhea.
- Other alternative nutritional therapies that have been considered are probiotics and omega-3 essential fatty acids. However, there are no sufficient data on effectiveness or safety in children.

ONGOING CARE

PATIENT EDUCATION

- Response to treatment will likely occur in the first 2 weeks of therapy; however, long-term intermittent therapy may be required. Adolescents with SD may have a chronic course.
- The intermittent use of an antifungal shampoo can be used to prevent relapses.

PROGNOSIS

- The infantile form will typically self-resolve by the end of the 1st year of life.
- Older children and adolescents may have a more chronic, relapsing course.
- If SD doesn't respond to therapy within approximately 6 weeks, consider alternative diagnoses or underlying conditions such as immunodeficiency.

- L21.0 Seborrhea capitis
- L21.1 Seborrheic infantile dermatitis

FAQ

- Q: Is there a laboratory test to diagnose SD?
- A: There are no specific laboratory tests. It is a clinical diagnosis. If the diagnosis is unclear or refractory to treatment, consider a skin biopsy.
- Q: Are there seasonal changes in the course of SD?
- A: Some patients report worsening of symptoms in the winter months. Sunlight may improve patients' symptoms. UV therapy is a treatment option for extensive SD.
- Q: Does SD cause permanent hair loss?
- A: SD may cause some hair loss acutely. However, patients can be reassured that it does not cause permanent hair loss.

SEIZURES—FEBRILE

Rohini Coorg • Liu Lin Thio

BASICS

DESCRIPTION

Febrile seizure: seizure in ≤ 60 -month-old child accompanied by a fever ($\geq 100.4^{\circ}\text{F}$ or 38°C by any method) but without central nervous system infection or prior unprovoked seizure (American Academy of Pediatrics [AAP] guidelines use 6 months as the lower age limit, whereas International League Against Epilepsy uses 1 month)

2 types:

- Simple: febrile seizures that are generalized, last <15 minutes, AND do not recur in 24 hours
- Complex
 - Febrile seizures that are focal (including postictal weakness), last ≥ 15 minutes, OR occur >1 time in 24 hours
 - Febrile status epilepticus: 1 febrile seizure or series of febrile seizures without full recovery in between lasting ≥ 30 minutes

EPIDEMIOLOGY

- Age
 - Most febrile seizures occur between 6 months and 3 years of age.
 - Peak age is about 18 months.
- Type
 - 65–70% are simple febrile seizures.
 - 20–35% are complex febrile seizures.
 - ~5% are febrile status epilepticus.
- Timing of seizure
 - ~20% before or <1 hour of fever onset
 - ~60% 1–24 hours after fever onset
 - ~20% >24 hours after fever onset

Prevalence

- Most common childhood seizure

- Febrile seizures occur in 2–5% of children in the United States and Western Europe, 9–10% of children in Japan, and 14% of children in Guam.

RISK FACTORS

Positive family history of febrile seizures

Genetics

Usually multifactorial or polygenic inheritance

GENERAL PREVENTION

Antipyretics do not reduce the recurrence risk of simple febrile seizures.

PATHOPHYSIOLOGY

- Elevated temperatures in developing brain may increase neuronal excitability.
- Fever increases cytokines that may enhance neuronal excitability.
- Genetic factors
- Hyperventilation from fever causes a respiratory alkalosis that may promote seizures.

ETIOLOGY

- Any viral or bacterial infection
 - Human herpesvirus 6 and 7
 - Influenza A
- Vaccines
 - MMR(V) and DPT
 - Both increase the risk of febrile seizures but not epilepsy.
 - Benefits greatly outweigh any risk, and families should be encouraged to vaccinate.
- Shigellosis

COMMONLY ASSOCIATED CONDITIONS

- Generalized epilepsy with febrile seizures plus (GEFS+)
 - Febrile seizures beyond 6 years of age or afebrile seizures of varying types ranging from mild to severe
 - Multiple genes identified including SCN1A, SCN2A, SCN1B, GABRG2, GABRD, and PCDH19

- Febrile infection–related epilepsy syndrome (FIRES)
 - Catastrophic epileptic encephalopathy of unknown etiology that begins with a febrile illness and refractory status epilepticus
 - Has high morbidity and mortality

DIAGNOSIS

HISTORY

- Obtain detailed description of spell to determine if it was a seizure.
 - Circumstances in which spell occurred
 - Duration
 - Focal features suggest seizure
 - Postictal weakness suggests seizure
- Ask about prior seizures/spells.
 - Prior afebrile seizure suggests epilepsy.
 - Prior febrile seizures supports diagnosis.
 - Prior nonepileptic spells
- Determine cause of fever/illness
 - Duration
 - Height of fever
 - Symptoms: rhinorrhea, diarrhea
- Ask about new neurologic symptoms such as headache or change in gait that would require further evaluation.
- Ask about toxic ingestions.
- Identify seizure risk factors from past medical history.
 - Perinatal complications
 - Prior brain insult: trauma, meningitis
 - Developmental delay
- Medications including antibiotics
- Identify seizure risk factors from family history.
 - Febrile seizures
 - Epilepsy

PHYSICAL EXAM

- Identify fever source.

- Vital signs, including temperature
- Assess anterior fontanelle, sutures, and head circumference for increased intracranial pressure, which may occur with meningitis or space-occupying lesion.
- Assess for signs of meningitis such as nuchal rigidity.
- Examine ears and throat for infection.
- Examine skin for rashes and other signs of infection.
- Examine heart and lungs for infection.
- Assess for trauma.
- Detailed neurologic exam
 - Assess skin for neurocutaneous syndromes.
 - Assess mental status.
 - Assess for subtle signs of seizure such as myoclonus or nystagmus.
 - Examine cranial nerves. Include funduscopic exam for papilledema.
 - Examine gait, motor system, sensation, coordination, and deep tendon reflexes for abnormalities and asymmetries.

DIAGNOSTIC TESTS & INTERPRETATION

Simple Febrile Seizure

Recommendations from the 2011 AAP Guideline for neurologically healthy infants and children

Lab

- Serum electrolytes, calcium, phosphorus, magnesium, glucose, and complete blood count are not recommended solely for determining the cause of the seizure.
- Consider studies to determine fever source.
- Lumbar puncture
 - Perform when symptoms/signs of meningitis or intracranial infection are present
 - Consider lumbar puncture if
 - 6–12-month-old infant has deficient or unknown immunization status for *Haemophilus influenzae* type b or *Streptococcus pneumoniae*
 - Pretreated with antibiotics

Imaging

Not indicated

Electroencephalogram

- Not indicated
- Not predictive of febrile seizure recurrence or development of epilepsy

Complex Febrile Seizures

There is no AAP Guideline.

Lab

- Consider studies to identify fever source and as clinically indicated.
- Indications for lumbar puncture are similar to indications for lumbar puncture for simple febrile seizure but strongly consider for all, especially those with altered mental status.

Imaging

- Acute brain imaging usually unnecessary, especially if the only complex feature is multiple seizures. Recommend acute MRI (CT acceptable) if with persistently altered mental status, persistent focal neurologic findings, or symptoms/signs of increased intracranial pressure.
- Recommend routine brain MRI if not done acutely especially for focal seizure, focal exam findings, or focal EEG abnormality.

Electroencephalogram

- Recommend stat EEG if concerned about nonconvulsive status epilepticus.
- Recommend routine EEG, especially for abnormal neurologic development or exam. Epileptiform abnormalities or focal slowing may increase risk for developing epilepsy.

Febrile Status Epilepticus

No AAP Guideline. See “[Status Epilepticus](#)” chapter.

Lab

- Recommend studies to treat correctable causes of seizures (e.g., hypoglycemia, hyponatremia) and to identify fever source.
- Lumbar puncture
 - Perform for any suspicion of meningitis or intracranial infection but strongly consider for all especially if first episode or if mental status is altered.
 - It is important to note that febrile status epilepticus rarely causes a

CSF pleocytosis.

Imaging

- Recommend acute brain imaging (MRI preferred but CT acceptable), especially if first episode with abnormal mental status or focal neurologic findings.
- Recommend routine brain MRI if not done acutely; may show hippocampal injury that may increase risk for developing epilepsy

Electroencephalogram

- Recommend stat EEG if concerned about nonconvulsive status epilepticus.
- Recommend routine EEG; may show temporal slowing or attenuation that correlates with hippocampal abnormality on MRI

DIFFERENTIAL DIAGNOSIS

- Acute symptomatic seizure
 - Infection
 - Meningoencephalitis: primary diagnostic consideration; bacterial or viral; consider HSV.
 - Other infection such as gastroenteritis causing hyponatremic dehydration
 - Benign convulsions with mild gastroenteritis
 - Toxic/metabolic
 - Stroke
 - Trauma
- Epilepsy
- Nonepileptic spell
 - Febrile delirium
 - Chills
 - Breath-holding spells

TREATMENT

MEDICATION

- Abortive: consider rectal diazepam (0.5 mg/kg) for febrile seizures ≥ 5 minutes; may cause drowsiness and ataxia; rarely causes respiratory

depression

- Preventive
 - In certain clinical circumstances, for parental anxiety, may use oral diazepam (0.33 mg/kg every 8 hours) to the patient during a febrile illness until afebrile for 24 hours; may cause drowsiness and ataxia
 - Daily phenobarbital, valproate, or primidone prevents febrile seizures, but risks outweigh benefits.

ADDITIONAL TREATMENT

General Measures

- See “[Status Epilepticus](#)” chapter for treating febrile status epilepticus.
- Treat infection

ONGOING CARE

PROGNOSIS

- Febrile seizure recurrence
 - 50% of children <12 months of age at time of first simple febrile seizure have recurrent febrile seizures.
 - 30% of children >12 months of age at time of first febrile seizure have a second.
 - Of children with a second febrile seizure, 50% experience a third.
- Risk for developing epilepsy:
 - 6–7% for all febrile seizures
 - 2–7.5% for simple febrile seizures
 - 10–20% for complex febrile seizures
- Mortality
 - 0.85% for all febrile seizures
 - 0% for simple febrile seizures
 - <1.6% for complex febrile seizures with all deaths from febrile status epilepticus
- No evidence that simple febrile seizures increase risk of neurologic or cognitive deficits.

ADDITIONAL READING

CODES

ICD10

- R56.00 Simple febrile convulsions
- R56.01 Complex febrile convulsions

FAQ

- Q: What should parents be told?
- A: Good neurodevelopmental outcome for simple febrile seizures but relatively high risk for recurrence.
- Q: Can a child die from a febrile seizure?
- A: No reported mortality from simple febrile seizures or short complex febrile seizures. Small mortality with febrile status epilepticus.
- Q: Can a febrile seizure cause brain damage?
- A: Simple febrile seizures do not. Febrile status epilepticus may.
- Q: What should the parents do when the child has a seizure?
- A: Stay calm. Place child in safe place. Turn child on side to keep airway clear. Do not restrain. Do not put anything in mouth. Time seizure. If seizure lasts 5 minutes, call 911 and administer abortive

medication such as rectal diazepam if available.

- Q: What precautions should the parents take?
- A: Common sense steps such as no unsupervised baths or swimming and no climbing above head height. Always wear helmet when riding bike or doing other activity with wheels. No driving all-terrain vehicles.

SEIZURES, PARTIAL AND GENERALIZED

Kristen L. Park • Kelly G. Knupp

BASICS

DESCRIPTION

Seizures arise from abnormal electrical discharges in the cerebral cortex that lead to alterations of consciousness, behavior, motor activity, sensation, or autonomic function. Epilepsy is defined as 2 or more seizures without acute provocation. Seizures are classified as focal, generalized, and unknown.

- Focal seizure types
 - Without impairment of consciousness (either with observable motor or autonomic components or involving subjective sensory or psychic phenomena only)
 - With impairment of consciousness (dyscognitive)
 - Evolving to a bilateral, convulsive seizure
- Generalized seizure types
 - Tonic–clonic, absence, myoclonic, clonic, tonic, atonic
- Unknown seizure types: epileptic spasms

EPIDEMIOLOGY

Incidence

Epilepsy affects 0.5–1% of all children (birth through 16 years). 120,000 children seek care annually in the United States for a seizure. Between 20,000 and 45,000 children/year are diagnosed with epilepsy, highest risk is in the 1st year of life.

Prevalence

4–10 per 1,000 children in developed countries have epilepsy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Genetic
- Structural/metabolic
 - Brain tumor
 - Malformations of cortical development

- Neurocutaneous syndromes
- Prior cerebral insult
- Metabolic disorders
- Unknown cause

Genetics

- Epilepsy is both polygenic and multifactorial.
- The risk of epilepsy with an affected primary relative increases from the population risk (1–2%) to 2–5%.
- Single-gene epilepsy syndromes with defined genetic loci: autosomal dominant nocturnal frontal lobe epilepsy, benign familial neonatal convulsions, severe myoclonic epilepsy of infancy
- Other epilepsy syndromes (benign rolandic, childhood absence, juvenile myoclonic epilepsy) are heterogeneous.
- Epilepsy may also be a feature of other genetic and metabolic disorders such as trisomy 21, Angelman syndrome, and Menkes disease.

COMMONLY ASSOCIATED CONDITIONS

- The incidence of childhood-onset epilepsy associated with intellectual disability and cerebral palsy is 15–38%.
- Epilepsy occurs in 8–28% of children with autism.
- ADHD, depression, and anxiety are more common in children with epilepsy than in the general population.

DIAGNOSIS

HISTORY

- Age, family history of seizures, developmental status, birth history
- Health at seizure onset: febrile, ill, sleep deprivation, trauma, toxins, ingestion, head injury
- Current medications and change in antiepileptic medication
- Other neurologic signs: confusion; encephalopathy; weakness; sensory deficits; and change in vision, behavior, balance, or gait
- Detailed history of symptoms during seizure
 - Aura: subjective sensations
 - Behavior: preceding and during seizure

- Change in consciousness or responsiveness
- Vocal: cry, gasp, speech
- Motor: head or eye turning, jerking, posturing, stiffening, automatisms (purposeless repetitive movements such as picking at clothing, lip smacking)
- Respiration: cyanosis, change in breathing pattern, apnea
- Autonomic: pupillary dilation, drooling, incontinence, pallor, vomiting, tachycardia
- Symptoms after seizure: amnesia, confusion, sleepiness, transient focal weakness (Todd paresis), headache

PHYSICAL EXAM

- Vital signs: ABCs need to be checked immediately and recurrently, fever, tachycardia, bradycardia, or hypertension
- Signs of head trauma or child abuse: retinal hemorrhages, papilledema, presence of fractures, bruises of different ages
- Head circumference/abnormal head growth
- Signs of systemic infection: meningismus, purpura
- Skin examination: café au lait or ash leaf spots, facial hemangioma (suggesting neurocutaneous disorders)
- Neurologic examination: pupillary reactivity, mental status, focal motor weakness
- Seizures: If there is a question of continuing seizures, proceed with recommendations for “Status Epilepticus.”

ALERT

- Attention to adequate airway and breathing and need for oxygenation or ventilatory support is the primary focus.
- If the child continues to have a seizure or has recurrent seizures, an abortive benzodiazepine should be administered either rectally or IV.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Testing should be based on clinical history.
 - In general, a standard laboratory evaluation (electrolytes, CBC, liver enzymes, calcium, and magnesium) did not show unsuspected abnormalities or contribute to the diagnosis or management in

several clinical studies.

- An exception was hyponatremia (<125 mEq/L) found to be associated with seizures in 70% of infants younger than 6 months of age in one clinical study.
- Toxicology screening should be considered in any child in whom there is a question of drug exposure or substance abuse.
- Blood glucose (fingerstick can be obtained quickly)
- Antiepileptic drug (AED) levels if indicated; few of the newer AEDs have relevant or rapidly available serum levels but may be useful for documenting adherence to a medication regimen.

Imaging

- Neuroimaging: Evidence-based reviews showed low yields of acute CT or MRI in children presenting with seizures without focal signs or deficits. Current recommendations are as follows:
 - MRI is generally the preferred modality.
 - Emergent neuroimaging should be performed in any child with focal deficit not returning to baseline within several hours.
 - Nonurgent MRI is recommended based on clinical scenario and EEG findings.

Diagnostic Procedures/Other

- EEG
 - Indicated urgently if there is concern that child may be continuing to seize
 - Nonurgent EEGs are indicated for first afebrile seizure.
- Lumbar puncture
 - Not routinely recommended
 - Should be considered for meningeal signs, infants <6 months of age, or persistent alteration of consciousness
 - If intracranial hypertension, mass lesion, or hydrocephalus is suspected, defer lumbar puncture until after neuroimaging.

DIFFERENTIAL DIAGNOSIS

- Nonepileptic events
 - Syncope
 - Breath-holding spells

- Hyperventilation
- Nonepileptic events
 - Movements related to gastroesophageal reflux (Sandifer syndrome)
 - Sleep disorders: benign sleep myoclonus, night terrors, somnambulism, narcolepsy–cataplexy
 - Migraine/headache syndromes, especially complicated migraine
 - Nonepileptic movements: startle disease, shuddering spells, paroxysmal dyskinesias, tics, drug-induced dystonia
 - Behavioral: stereotypies, self-stimulatory behaviors, inattention/ADHD

TREATMENT

MEDICATION

- The choice of AED for long-term management of epilepsy depends on the specific seizure type and epilepsy syndrome. Monotherapy is always preferred.
- Many formulations (liquid, sprinkle caps, and extended-release) are available and should be individualized to the patient. For teenagers, extended-release forms may be recommended for compliance.
- Focal seizures (any type)
 - Oxcarbazepine 20–40 mg/kg/24 h
 - Levetiracetam 20–60 mg/kg/24 h
 - Lamotrigine: dosing varies with valproate
 - Topiramate 4–10 mg/kg/24 h
 - Valproate: 15–50 mg/kg/24 h
 - Zonisamide 2–10 mg/kg/24 h
- Genetic generalized epilepsies
 - Ethosuximide 15–40 mg/kg/24 h: initial AED for absence seizures
 - Levetiracetam
 - Topiramate
- Acute treatment of seizures
 - Benzodiazepines should be given for prolonged seizures (>5 minutes) or acute repetitive seizures.
 - Rectal diazepam (0.3–0.5 mg/kg/dose), intranasal/buccal

midazolam (0.2 mg/kg/dose), or oral/buccal lorazepam (Intensol, 0.05–0.1 mg/kg/dose, needs refrigeration) can be administered by parents/caregivers.

- Fosphenytoin 20 mEq/kg IM/IV
- Phenobarbital 10–20 mg/kg IV
- Levetiracetam 20 mg/kg IV
- Patients refractory to AED treatment: other options—ketogenic diet, vagus nerve stimulator, surgical resection

ALERT

- Hyponatremic seizures: serum sodium <120 mEq/dL in infants with gastroenteritis; slow sodium correction indicated
- Apnea and hypoventilation from excessive administration of benzodiazepines, phenobarbital for seizures. Monitor ventilation and oxygenation; avoid large doses.

ADDITIONAL TREATMENT

General Measures

- Chronic AED therapy is not indicated after acute symptomatic seizures or after a single unprovoked seizure in a child with normal neurologic examination and EEG.
- Chronic AED therapy may be considered after 1st seizure symptomatic of an acute, structural brain lesion (i.e., brain tumor).

ISSUES FOR REFERRAL

In general, patients who have not responded to 2 seizure medications should be evaluated by a neurologist who specializes in epilepsy.

ALERT

A 2-fold risk of increased suicidality has been associated with AED use, with an FDA black box warning on product labeling. Monitoring for suicidal ideation and mood changes is warranted in all patients taking AEDs.

ONGOING CARE

PATIENT EDUCATION

- Injuries: Rarely, serious injury occurs with brief seizures from loss of consciousness and resultant falls.
- Daily precautions: Few restrictions are needed with the exceptions of driving (see state laws) and dangerous sports.
- Supervision around water is strongly advised; showering is generally safer than bathing.
- Helmets should be worn with all wheeled toys; avoid top bunk beds or locked bedrooms and unprotected heights.
- Sudden unexplained death in epilepsy patients (SUDEP) should be mentioned to all patients at appropriate times.
- Families should be instructed in seizure first aid: roll patient on the side, place nothing in the mouth, ensure safe environment.

PROGNOSIS

- In a child who is neurologically normal with an unprovoked seizure, the risk of recurrence is 24% in 1 year and 45% in 14 years.
- If there is evidence of prior neurologic insult, the risk is 37% in 1 year.
- If the patient has 2 seizures separated by >24 hours, risk is 70% in 1 year.
- The EEG is the most significant predictor of recurrence: 15% risk in 1 year in a child with a normal EEG and 41% with an abnormal EEG.

COMPLICATIONS

- Brain damage
 - From brief seizures: no convincing evidence
 - From prolonged seizures (>30 minutes): Brain injury may occur secondary to hypoxia.
 - Untreated or poorly controlled epilepsy: increased risk of intractable epilepsy and SUDEP
- Status epilepticus
 - Incidence of 18–20/100,000/year in childhood
 - Mortality in children between 3 and 6%
 - Recurrence risk for status epilepticus is approximately 16% within the first year.
- Patient monitoring: depends on treatment and as mentioned earlier

FAQ

- Q: How do I know my child has epilepsy?
- A: The term “epilepsy” is applied to children with 2 or more seizures without an acute cause.
- Q: Will my child always have epilepsy?
- A: The likelihood of outgrowing epilepsy depends on the syndrome. In many cases, anticonvulsants can be discontinued if the child has been seizure free for 2 years.
- Q: Why does my child have epilepsy?

- A: There are many different reasons to have epilepsy, including genetic, trauma, and other abnormalities of the brain. About 40% of people with epilepsy never have an identified etiology.

SEPARATION ANXIETY DISORDER

Julie O'Brien • Renée Marquardt

BASICS

DESCRIPTION

Separation anxiety disorder (SAD) is defined as developmentally inappropriate fear and anxiety about being away from home and/or apart from the individuals to whom a child is most attached.

- This diagnosis should be distinguished from developmentally appropriate worries, fears, and responses to stressors.

EPIDEMIOLOGY

- Prevalence estimates range from 3.5 to 5.1%.
- Incidence is slightly higher in females than males.
- The mean age of onset is from 4.3 to 8.0 years, but the disorder can present at any age.

ETIOLOGY

Studies show that there are genetic and environmental precursors to the development of SAD:

- A temperament of behavioral inhibition in which a child tends to approach unfamiliar situations with distress, restraint, and avoidance has been shown to be associated with development of anxiety disorders.
- Early development of stranger anxiety
- Insecure attachment between parent and child
- Increased parental anxiety
- Parenting style of being excessively controlling and overprotective
- Exposure to negative life events or stressors
- Genetic predisposition with family history of anxiety or depression

COMMONLY ASSOCIATED CONDITIONS

Comorbid conditions are present in up to 80% of children with SAD, most commonly including the following:

- Depression
- Simple phobia
- Social phobia
- Generalized anxiety disorder
- Obsessive compulsive disorder
- Alcohol abuse in adolescence

DIAGNOSIS

- Anxiety with separation is a normative part of development, typically beginning around 6 or 7 months of age, peaking around 18 months and decreasing after 30 months.
 - Normal separation anxiety at 6–7 months manifests as shyness and anxiety with strangers.
 - At 12–18 months of age, children may have sleep disturbances, nightmares or nocturnal panic attacks, and oppositional behavior.
- SAD is distinguished by anxiety that becomes maladaptive, interfering with normal functioning or becomes overly frequent, severe, and persistent.
- DSM-IV criteria are as follows:
 - Developmentally inappropriate and excessive anxiety concerning separation from home or from those to whom the individual is attached as evidenced by 3 (or more) of the following:
 - Recurrent excessive distress when separation from home or major attachment figures occurs or is anticipated
 - Persistent and excessive worry about losing, or about possible harm befalling, major attachment figures
 - Persistent and excessive worry that an untoward event will lead to separation from a major attachment figure (e.g., getting lost or being kidnapped)
 - Persistent reluctance or refusal to go to school or elsewhere because of fear of separation
 - Persistently and excessively fearful or reluctant to be alone or without major attachment figures at home or without significant adults in other settings

- Persistent reluctance or refusal to go to sleep without being near a major attachment figure or to sleep away from home
- Repeated nightmares involving the theme of separation
- Repeated complaints of physical symptoms (such as headaches, stomachaches, nausea, or vomiting) when separation from major attachment figures occurs or is anticipated
- Duration of disturbance is at least 4 weeks.
- Onset is before age 18 years.
- Disturbance causes clinically significant distress or impairment in social, academic, or other important areas (occupational).

HISTORY

- Ask parents about the specific behaviors/complaints of the child at separation, including protests (tantrums/pleading negotiating), fearfulness, or somatic complaints.
 - Somatic complaints such as stomachaches and headaches are most typical.
- Ask caregivers what situations are impacted. Settings can include the following:
 - Separation for school or social/extracurricular activities
 - When the caregiver leaves the home
 - Being separated within the home (e.g., in another room from caregiver)
 - Bedtime
- Ask if sleep is impacted; specifically, ask about nightmares.
 - Children with SAD often have nightmares about separation, death, kidnapping, or serious accident.
- Ask if school attendance is impacted.
 - Avoidance behaviors such as procrastination during the morning routine before school or refusing to leave the side of a parent is common.
 - School refusal has been reported to occur in approximately 75% of children with SAD.
- Ask about duration.
 - Transient separation fears are common. In SAD, symptoms must last more than 4 weeks.

- Ask about possible stressors.
 - Symptoms may be precipitated by a stressor in some cases.
- Ask about impact.
 - Interferes with normative development in a number of ways such as difficulty attending school, participating in extracurricular activities, and attending sleepovers
 - Bedtime separation anxiety may result in sleep disruption to child and family.

PHYSICAL EXAM

There are no pertinent findings on physical exam.

DIAGNOSTIC TESTS & INTERPRETATION

- There are no pertinent findings on lab work.
- There is no standard tool for diagnosis.
- There are a variety of scales that can help in the diagnosis, including the Separation Anxiety Assessment Scale, which has both child and parent versions.

DIFFERENTIAL DIAGNOSIS

SAD should be distinguished from normal, developmentally appropriate separation anxiety. Additionally, one should consider possible life stressors or abuse. Alternate anxiety disorders include the following:

- Generalized anxiety disorder
 - Distinguished by anxiety that is generalized and often presents in later adolescence
 - In children, this tends to manifest as excessive concern over the quality of school or athletic performance at school, concern about punctuality, or overzealous in seeking of approval from authority figures.
- Social anxiety
 - Presents as fear or avoidance of social situations in general or specific situations (e.g., eating in public)
- Specific phobias
 - Occur when anxiety is due to a specific object or situation; unlike in adults, children may not recognize their anxiety/fear of the specific item as excessive

TREATMENT

Initial treatment should include psychoeducation for the caregiver (who will need to implement changes with the child) and cognitive behavioral techniques for the child.

- Psychoeducation for the caregiver includes explanations of the following:
 - The normative nature of anxiety
 - Caregiver response to child's protests and fears can inadvertently reinforce the child's separation behaviors.
- Specific advice to caregivers:
 - Do not prolong a good-bye:
 - Be brief.
 - Let the child know when you will return.
 - Reassure the child that you know that he/she will be ok.
 - Do not let the child see you are upset at the separation.
 - Do not overdo the reunion.
 - If a child is having extreme difficulties:
 - Start with smaller separations.
 - Use incentives and positive reinforcement for success (e.g., sticker charts or points).
 - Gradually build to larger separations.
- Anxiety workbooks can be used by the caregiver at home to provide activities for relaxation and reducing stress.
- Caregivers may need treatment for anxiety if their own anxiety seems to be contributing to the child's behavior.
- Cognitive behavioral therapy (CBT) with the child is aimed at helping the child evaluate the accuracy of his or her fears and learn helpful self-talk.

MEDICATION

Psychopharmacology should generally be used for separation anxiety only if nonmedication treatment is insufficient or if there are additional comorbid anxiety diagnoses that are significantly impairing and psychosocial treatments are simultaneously being pursued.

- Selective serotonin reuptake inhibitor (SSRIs) medications are the primary choice for anxiety disorders in children.
- Young children (<10 years of age) are at increased risk of side effects with SSRI medications.
 - As a result, slow dosing and frequent monitoring is needed.
 - Side effects include GI upset, headaches, dizziness, and agitation.
- SSRI medications have an FDA black box warning due to an increase in suicidal thinking and behavior in children and adolescents; monitoring recommendations need to be followed.

ISSUES FOR REFERRAL

If improvement is not seen within a month after providing education and guidance to caregiver, a referral to a mental health provider is indicated.

- A referral should be made to a mental health provider before medications would be considered for SAD.
- Treatment is usually brief for uncomplicated SAD. Therapy 1–2 times per week may last 6–12 weeks.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- If impairing symptoms continue for more than a month, a higher level of intervention may be indicated.
- If medications are started for anxiety in children, monitoring on a weekly basis is needed for at least 4 weeks after the medication is started or increased and monthly thereafter. (See FDA guidelines for specific medications.)

PROGNOSIS

Outcomes are good with intervention.

- Children with SAD are at higher lifetime risk for other mental health conditions, particularly panic disorders.
- SAD can continue through childhood and into adulthood; early identification and intervention is important to minimize morbidity.

CODES

ICD10

F93.0 Separation anxiety disorder of childhood

FAQ

- Q: How do I know if it is developmentally normal separation anxiety?
- A: When separation anxiety arises after the age of 6 years, it warrants intervention if it lasts for more than 4 weeks and/or is markedly impacting expected activities. Before the age of 6 years, separation fears are more common but warrant intervention if impairment in normal functioning is seen.
- Q: Can a teenager have SAD?
- A: Yes. SAD can affect a child of any age and can even persist into adulthood.
- Q: What type of mental health provider can treat SAD that does not respond to primary care intervention?
- A: Any master's or doctorate level mental health provider with experience in anxiety disorders in children and behavioral techniques such as CBT.

SEPSIS

Joanna E. Thomson • Craig H. Gosdin

BASICS

DESCRIPTION

- Systemic inflammatory response syndrome (SIRS): nonspecific inflammatory response, defined as at least 2 of the following 4 criteria (one of which must be either abnormal temperature OR leukocyte count):
 - Temperature >38.5 or $<36^{\circ}\text{C}$
 - Tachycardia (mean HR >2 SDs above normal for age)
 - Tachypnea (mean RR >2 SDs above normal for age)
 - Leukocytosis, leukopenia, or $>10\%$ bands
- Infection: suspected or proven infection or clinical syndrome associated with high probability of infection
- Sepsis: SIRS in the presence of infection
- Severe sepsis: sepsis accompanied by evidence of altered end organ perfusion (cardiovascular dysfunction OR acute respiratory distress syndrome [ARDS] OR 2 or more other organ dysfunctions)
- Septic shock: sepsis with cardiovascular dysfunction (hypotension, need for vasoactive drug to maintain normal BP, or any combination of unexplained metabolic acidosis, increased arterial lactate, oliguria, prolonged capillary refill, and core-to-peripheral temperature gap)

EPIDEMIOLOGY

Incidence

- Estimated overall annual incidence of 0.6 cases per 1,000 children but varies by age
 - Infants <1 year of age: 2.5 per 1,000 children
 - Age 1–4 years: 0.5 per 1,000 children
 - Age 5–14 years: 0.2 per 1,000 children
 - Age 15–19 years: 0.4 per 1,000 children

Prevalence

Sepsis is among the most common (10–25%) medical diagnoses on admission to PICUs.

RISK FACTORS

Sepsis may occur in previously healthy children, but it is a particular concern for children with chronic underlying conditions that render them immunosuppressed or vulnerable to invasive infections.

- Neutropenia (neutrophils $<1,000/\text{mm}^3$, especially $<500/\text{mm}^3$)
- Primary or acquired immunodeficiency (e.g., AIDS, severe combined immunodeficiency)
- Malignancy
- Organ transplant recipients
- Chronic use of high-dose systemic steroids
- Indwelling central venous catheters or other invasive devices (e.g., urinary catheter)
- Hyposplenism, either surgical or functional (e.g., sickle cell anemia)
- Neuromuscular disease (e.g., static encephalopathy)
- Extensive burns
- Multiple trauma injuries
- Prematurity
- Unimmunized/underimmunized children
- Severe malnutrition

GENERAL PREVENTION

- Routine vaccination for *Haemophilus influenzae* type b (Hib), *Streptococcus pneumoniae*, and *Neisseria meningitidis* particularly in high-risk patients (e.g., asplenia)
- Antibiotic prophylaxis for household or day care exposure to confirmed cases of Hib or *N. meningitidis*
- Prompt evaluation of fever in immunosuppressed patients
- Aseptic technique for insertion and care of vascular catheters, minimizing duration of use

ETIOLOGY

- Microbial invasion of the bloodstream or release of microbial products/toxins into the bloodstream; stimulates host defense, resulting in activation of proinflammatory mediators and systemic inflammation

- Pathogens vary with age, host immune status, and setting (community or hospital).
- Neonates
 - Group B Streptococcus
 - Escherichia coli
 - Staphylococcus aureus
 - Listeria monocytogenes
 - Enterococcus spp.
 - Herpes simplex virus
 - Enterovirus
- In neonates with a history of hospitalization, instrumentation, or mechanical ventilation, also consider
 - Coagulase-negative staphylococci
 - Gram-negative bacilli
 - Candida spp.
- Otherwise healthy older infants and children
 - Streptococcus pneumoniae
 - N. meningitidis
 - Staphylococcus aureus
 - Group A Streptococcus
 - Salmonella spp.
 - Rickettsiae
 - Influenza
- Patients with underlying immune defects are also susceptible to a broad range of additional organisms.

DIAGNOSIS

Requires high suspicion; fever and tachycardia are nonspecific and hypotension is generally a late sign.

HISTORY

- See “[Risk Factors](#)”
- Duration of illness before presentation
 - Abrupt onset of symptoms more typical of invasive bacterial

infection

- Change in behavior may be initial sign of systemic infection.
 - Irritability, lethargy, and poor feeding are especially important in infants and young children.
- Decreased urine output

PHYSICAL EXAM

All patients with suspected sepsis should have a full set of vital signs (e.g., temperature, pulse, respiratory rate, BP, pulse oximetry).

- Temperature
 - Fever is the hallmark of an infection but may be absent; infants may demonstrate hypothermia.
- General
 - Ill or toxic appearing
- HEENT and neck exam
 - Dehydration: sunken fontanelle, dry mucous membranes, sunken eyes
 - Meningismus or bulging fontanelle
 - Mucocutaneous bleeding
- Cardiovascular exam
 - Tachycardia or bradycardia
 - Hypotension
 - Cold shock: delayed capillary refill; diminished pulses; mottling; and cool, clammy extremities
 - Warm shock: flash capillary refill; bounding pulses; and warm, dry extremities
- Respiratory exam
 - Hypoxia and/or cyanosis
 - Apnea or tachypnea
 - Retractions, flaring or grunting
 - Poor air flow
- Abdominal exam
 - Distension
 - Hepatomegaly, splenomegaly
- Skin exam
 - Presence of petechiae and purpura (associated with

- meningococemia and disseminated intravascular coagulation)
- Pallor
- Neurologic
 - Abnormal mental status (somnolence, confusion, agitation, irritability)
 - Seizures
 - Abnormal reflexes or tone

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Patients with suspected sepsis should have

- Blood culture
 - Prior to starting antibiotics when possible
 - Culture yield is related to sample volume.
- CBC with differential
 - Leukocytosis with increased band count or leukopenia may be present.
- Electrolytes, glucose, ionized calcium
 - Metabolic acidosis
 - Hypoglycemia or hyperglycemia
 - Hypocalcemia
- BUN, creatinine:
 - May reflect dehydration
 - Evaluate for acute kidney injury
- Liver function tests
 - Evaluate for end organ injury
- Arterial blood gas (ABG) and lactate
 - Metabolic acidosis and/or hypoxemia
 - Elevated lactate due to inadequate tissue perfusion
- PT, PTT, fibrinogen, fibrin degradation products, platelets, peripheral smear
 - Screen for DIC: elevated PT, PTT, INR; decreased fibrinogen; increased fibrin degradation products
- Urinalysis and urine culture
 - Potential source of infection
- Lumbar puncture (when hemodynamically stable)

- Required for diagnosis of meningitis
- Inflammatory biomarkers (e.g., CRP, procalcitonin) may be helpful.
- Culture other potential sources of infection: abscess, wounds, indwelling devices, sputum, tracheal aspirate
- Diagnostic testing for other potential causative organisms (e.g., HSV, enterovirus, influenza)

Imaging

- Chest x-ray
- Head CT may be necessary if with altered mental status in presence of coagulopathy.

DIFFERENTIAL DIAGNOSIS

- Congenital heart disease
- Myocarditis, pericarditis, cardiomyopathy
- Cardiac dysrhythmia
- Myocardial infarction
- Pulmonary embolus
- Congenital adrenal hyperplasia
- Thyrotoxicosis, hypothyroidism
- Inborn errors of metabolism
- Hypoglycemia
- Diabetic ketoacidosis
- Severe anemia
- Methemoglobinemia
- Neoplasm
- Hemophagocytic lymphohistiocytosis
- Macrophage activation syndrome
- Dehydration
- Pyloric stenosis
- Necrotizing enterocolitis
- Malrotation/volvulus
- Intussusception
- Pancreatitis
- Infant botulism
- Toxic ingestion/poisoning

- Trauma (accidental or nonaccidental)

TREATMENT

GENERAL MEASURES

- Ensure a patent airway (consider endotracheal intubation).
- Provide supplemental oxygen and assist ventilation (e.g., bag-valve-mask device) as needed.
- Obtain large-bore peripheral intravenous access (consider central venous line or intraosseous line).
- Hemodynamic support
 - Early fluid resuscitation is imperative.
 - Volume resuscitation: bolus 20 mL/kg of normal saline, repeat as needed; consider blood after 60–80 mL/kg of crystalloid
 - Inotropic agents: If hemodynamic instability persists despite fluid resuscitation, start dopamine (begin at 5 mcg/kg/min, titrate up to 20 mcg/kg/min as needed). If fluid refractory/dopamine-resistant shock, start epinephrine for cold shock or norepinephrine for warm shock to normalize BP and restore perfusion.
- Broad-spectrum intravenous antibiotics to cover likely causative pathogens should be initiated promptly. Consider patient age, immune status, need for penetration into certain tissues (e.g., CNS), and whether the infection was community- or nosocomially acquired in empiric choice. In general, bactericidal drugs should be used.
 - Neonates ≤ 4 weeks: ampicillin and gentamicin or ampicillin and cefotaxime. Add acyclovir to either regimen if herpes simplex virus infection is suspected.
 - Infants and children ≥ 4 weeks: cefotaxime or ceftriaxone (no meningitis); vancomycin and cefotaxime or ceftriaxone (with meningitis)
 - Patients with immunosuppression and/or central venous catheters: vancomycin plus aminoglycoside plus advanced-generation cephalosporin (e.g., cefepime)
 - Patients with an intra-abdominal focus of infection: carbapenem; ticarcillin-clavulanate or piperacillin-tazobactam; ceftriaxone,

cefotaxime, or cefepime plus metronidazole; ampicillin plus gentamicin plus metronidazole or clindamycin

- Correct hypoglycemia and hypocalcemia.
- Corticosteroids: stress-dose hydrocortisone for catecholamine-resistant hypotension and in patients at risk for adrenal insufficiency
- Drainage or eradication of focus of infection

ALERT:

- Rapid recognition of sepsis is critical. Provide adequate initial volume resuscitation; early reversal of shock is associated with improved outcomes.
- Continuous monitoring and reassessment of the patient are essential.

INPATIENT CONSIDERATIONS

Admission Criteria

- Patients with sepsis should be admitted for close monitoring.
- Patients with severe sepsis or septic shock should be admitted to an ICU (e.g., requiring >60 mL/kg fluid resuscitation).

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Admit all patients with suspected sepsis to the hospital; consider ICU admission.
- Continuous BP monitoring for the development of refractory shock
- Serial vital signs and physical exams to monitor response to therapy
- Monitoring for complications of sepsis and the development of multiple organ dysfunction syndrome (MODS)
 - Chest radiograph and serial ABGs for evidence of acute lung injury/ARDS
 - Urine output, BUN, creatinine for acute kidney injury
 - Serial coagulation studies (PT/PTT) and platelets for development of DIC
 - Serial blood glucose levels for hypo- or hyperglycemia
 - Serial liver function tests for evidence of hepatic dysfunction

- Serial neurologic examinations for evidence of CNS dysfunction
- Upon pathogen identification, antibiotic therapy can be narrowed appropriately.

PROGNOSIS

- Case fatality rates have improved from nearly 50% to ~10%. With implementation of clinical practice guidelines focused on early reversal of shock, several studies have reduced in-hospital mortality rates to ~4–8% for patients with severe sepsis.
 - Mortality is higher in children with chronic illnesses than in previously healthy children.
 - Development of ARDS or MODS is associated with increased mortality.

COMPLICATIONS

- Sepsis is one of the leading causes of pediatric mortality and accounts for 7% of deaths.
- The most common complications are those resulting from hypoperfusion of vital organs or from organ injury incurred by the uncontrolled systemic inflammatory response:
 - Acute lung injury
 - Acute kidney injury
 - DIC
 - Hypoglycemia
 - ARDS
 - MODS

- R65.10 SIRS of non-infectious origin w/o acute organ dysfunction
- R65.20 Severe sepsis without septic shock

FAQ

- Q: What are the early clinical signs of sepsis?
- A: Vital sign changes such as tachycardia, tachypnea, along with respiratory distress/hypoxia and central nervous system alterations can be early signs of sepsis.

SEPTIC ARTHRITIS

Joanna E. Thomson • Erin E. Shaughnessy

BASICS

DESCRIPTION

Microbiologic infection and inflammation of the usually sterile joint space

EPIDEMIOLOGY

- Most common age: toddler and school age (2–6 years)
- Predominant sex: male (2:1 female)
- Most common location: lower extremities (hip, knee, and ankle) and large joints (hip, shoulder, elbow)

PATHOPHYSIOLOGY

- Entry of bacteria into joint space
 - Hematogenous spread (seeding during transient bacteremia) most common
 - Direct inoculation (penetrating trauma or during surgery)
 - Extension from bone infection (mainly in children <1 year old when vessels cross from metaphysis to epiphysis)
- In response to cytokines, influx of inflammatory cells, and release of proteolytic enzymes
- Leads to destruction of synovium and cartilaginous structures

ETIOLOGY

- Most common causes by age:
 - Neonates: group B Streptococcus, Staphylococcus aureus, Escherichia coli, and Candida albicans
 - Older children: Staphylococcus aureus, group A Streptococcus, Kingella kingae in toddlers, Haemophilus influenzae
- Also consider
 - Salmonella: in patients with sickle cell
 - Neisseria gonorrhoeae: in sexually active teens and neonates
 - Neisseria meningitidis

- Mycobacterium tuberculosis
- Rubella
- Parvovirus
- Hepatitis B or C
- Mumps
- Herpesviruses (Epstein-Barr virus, cytomegalovirus, herpes simplex virus, varicella-zoster virus)
- Fungal etiologies (e.g., coccidioidomycosis)

COMMONLY ASSOCIATED CONDITIONS

- Sick cell disease: Salmonella
- Immunocompromised patients: Mycoplasma, Ureaplasma, Klebsiella, or Aspergillus infection

DIAGNOSIS

HISTORY

- Systemic symptoms:
 - Fever (occurs within the first few days of illness in 75% of patients)
 - Malaise
 - Poor appetite
- Joint symptoms:
 - Pain: worsening, does not wax and wane
 - Limp
 - Inability to bear weight, refusal to move joint, positional preferences
 - Typically monoarticular
 - Consider hip involvement when the patient complains of knee or thigh pain.

PHYSICAL EXAM

- Ill appearing
- Joint
 - Warm, swollen, erythematous
 - Held in “position of comfort” maximizing intracapsular joint volume (e.g., hip held flexed, abducted, externally rotated)

- “Pseudoparalysis”: refusal to move the affected extremity
- Pain throughout entire range of motion (even passive motion)
- Presentation may be delayed and without external findings in deep joints (hip and shoulder).
- In the frightened or uncooperative child, it is possible to have the parent perform an examination for tenderness and range of motion while observing from a distance.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Synovial fluid analysis is critical for diagnosis:
 - WBC count: $>50\text{--}100,000/\text{mm}^3$ with $>75\%$ neutrophils
 - Glucose: $<50\%$ that of the serum
 - Gram stain: reveals organism in $\sim 50\%$ of cases
 - Culture: reveals organism in $\sim 75\%$ of cases (except for gonorrhea)
 - Emerging polymerase chain reaction (PCR) technology may allow higher yield and faster identification of causative organisms.
 - Inoculation of joint fluid into blood culture bottle facilitates recovery of *K. kingae*.
 - Real-time PCR for *K. kingae* toxin from joint fluid provides higher yield than routine Gram stain or culture alone.
- Other supportive blood tests:
 - WBC count: neither sensitive nor specific
 - Erythrocyte sedimentation rate (ESR): elevated ($>30\text{ mm/h}$) in 95% of cases
 - C-reactive protein (CRP): increased ($>1.0\text{ mg/dL}$). In one study, a CRP $<1.0\text{ mg/dL}$ had a negative predictive value of 87% .
 - Blood cultures: positive in $\sim 40\%$ of cases, sometimes yield pathogen when joint cultures are negative
- Serology for *Borrelia burgdorferi* or PCR of joint fluid may be helpful in differentiating between bacterial arthritis and Lyme disease.

Imaging

- Radiography
 - May show widening of joint space and/or displacement of normal

fat pads

- Ultrasound
 - Delineates amount of fluid within joint capsule
 - Increased blood flow with color Doppler is associated with infection. Bilateral effusions suggest transient synovitis.
 - Useful in guiding needle aspiration (especially of deep joints such as the hip)
- MRI and bone scan
 - Should not delay aspiration or antibiotic management
 - MRI: early detection of joint fluid; also will reveal adjacent bone abnormalities to suggest osteomyelitis
 - Bone scan: reveals increased uptake in the perimeter of the joint during the “blood pool” phase of the study
 - Such imaging should be considered to identify concomitant osteomyelitis in patients <4 years of age, involvement of the shoulder, or symptoms >6 days.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Osteomyelitis with or without contiguous spread to proximal joint
 - Infectious and postinfectious reactive arthritides: *N. meningitidis*, group A *Streptococcus*, *Salmonella*, *Mycoplasma*, *Campylobacter*, *Shigella*, *Yersinia*, *Chlamydia*
 - Cellulitis causing decreased range of motion of joint secondary to inflammation
 - Psoas abscess or retroperitoneal abscess
 - Tuberculous arthritis
 - Lyme arthritis (*B. burgdorferi*)
 - Septic bursitis
- Tumors
 - Osteogenic sarcoma (long bone pain spreading to joint space)
 - Leukemia/lymphoma
- Trauma
 - Occult fracture in proximity to growth plate
 - Ligamentous injury (sprain)
 - Foreign body synovitis

- Traumatic knee effusion/hemarthrosis
- Immunologic/rheumatic
 - Toxic (transient) synovitis: most common mimic; must examine joint aspirate to differentiate from septic arthritis
 - Acute rheumatic fever
 - Systemic lupus erythematosus
 - Juvenile rheumatoid arthritis
 - Henoch-Schönlein purpura
 - Reactive arthritis syndrome (after GI or chlamydial infection): arthritis, uveitis, urethritis
 - Behçet syndrome (iridocyclitis, genital, and oral ulcerations)
 - Serum sickness
 - Inflammatory bowel disease
- Musculoskeletal
 - Knee: apophysitis (e.g., Osgood-Schlatter disease), patellofemoral pain syndrome, osteochondritis dissecans
 - Hip: slipped capital femoral epiphysis
- Algorithm to differentiate septic arthritis and transient synovitis of the hip: Absence of all 4 factors is strongly associated with absence of septic arthritis.
 - Fever
 - ESR >20 mm/h
 - CRP >1.0 mg/dL
 - WBC >11,000 cells/mL
 - Joint space fluid apparent on plain radiograph

ALERT

- Clinical examination in conjunction with a history of acute onset should raise suspicion for septic arthritis, even in the face of “negative” laboratory screening tests. Analysis of the synovial fluid is necessary for diagnosis.
- Some children, especially neonates and young infants, will not manifest signs of systemic disease early in the course of the illness.

TREATMENT

MEDICATION

- Should be initiated immediately after blood and fluid cultures obtained
- Target empiric antibiotic therapy toward common organisms in age group; may be aided by Gram stain results
 - Typical 1st line: antistaphylococcal penicillin or 1st-generation cephalosporin
 - In areas of methicillin-resistant *Staphylococcus aureus* (MRSA) high prevalence (>15%), consider vancomycin or clindamycin as 1st-line treatment.
- Consider addition of 3rd-generation cephalosporin:
 - In neonates (alternatively could add gentamicin)
 - If gram-negative organism on Gram stain
 - If no organisms on Gram stain
 - High suspicion for *K. kingae*
 - In sexually active adolescents for coverage of *N. gonorrhea*
 - In patients with sickle cell for coverage of *Salmonella*
- Narrow coverage once organism is identified and susceptibilities known
- Duration of therapy depends on organism:
 - *Staphylococcus aureus*: 3 weeks
 - *Streptococcus pneumoniae*, *K. kingae*, and *N. meningitidis*: 2–3 weeks
 - Longer courses may be necessary for unusual organisms and in complicated courses.
 - May be able to transition to oral antibiotics after short course of intravenous therapy if improving exam and labs
- Pain management with analgesics
- Intra-articular injection of antibiotics is not recommended.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Orthopedic emergency: Drainage of infection should occur as soon as possible.
- Antibiotic administration immediately after joint aspiration is performed
- Indications for open surgical drainage and/or irrigation

- Hip involvement
- Shoulder involvement (controversial)
- Thick, purulent, loculated, or fibrinous exudate unable to pass through 18-gauge needle
- Lack of improvement within 3 days
- Immobilization of extremity
- Pain management

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Follow-up with orthopedic surgery.
- Physical therapy may be useful.
- When to expect improvement:
 - Symptoms typically improve with 2 days of appropriate antibacterial therapy.
 - CRP typically peaks on day 2 of therapy and quickly normalizes within 7–10 days.
- Concerning signs:
 - Continued pain, fever, or lack of improvement of range of motion after 3–4 days of appropriate antibiotic treatment
 - Rising ESR or CRP in the face of antibiotic treatment
 - Severe cases of septic arthritis may require serial drainage and debridement.

PROGNOSIS

- Depends on duration of illness prior to institution of appropriate therapy
 - If antibiotic therapy not instituted within first 4 days of illness, increased incidence of residual joint dysfunction

COMPLICATIONS

- Permanent limitation of range of motion due to tissue destruction and scarring
- Growth disturbance if the epiphysis is involved (leg length

discrepancy)

- Avascular necrosis of femoral head (due to increased pressure within joint interrupting blood flow)

CODES

ICD10

- M00.9 Pyogenic arthritis, unspecified
- M00.859 Arthritis due to other bacteria, unspecified hip
- M00.861 Arthritis due to other bacteria, right knee

FAQ

- Q: What is the optimal management of the child with suspected septic arthritis of the hip?
- A: Aspiration of the hip joint is indicated. If purulent fluid is found or analysis of the fluid is suspicious for infection, open drainage of the joint is indicated and must be performed to prevent long-term joint damage. This is a surgical emergency.

SERUM SICKNESS

Denise A. Salerno

BASICS

DESCRIPTION

- Serum sickness
 - Type III hypersensitivity reaction that occurs 7–21 days after injection of foreign protein or serum (usually in the form of antiserums)
 - Immune complexes deposit in the skin, joints, and other organs.
 - Clinical syndrome consists of skin rash, itching, fever, malaise, proteinuria, vasculitis, and joint pain.
- Serum sickness–like reactions
 - Characterized by fever, rash, lymphadenopathy, and arthralgia
 - Occur 1–3 weeks after drug exposure
 - Immune complexes, vasculitis, and hypocomplementemia are absent.
 - This type of reaction, most commonly associated with medications, is commonly referred to as serum sickness as well.
 - More common than true serum sickness because equine serum antitoxins have been replaced with human antitoxin sera
- Clinically, these entities present and are treated in the same manner.

EPIDEMIOLOGY

- Limited information is available regarding the incidence of adverse drug reactions in children; generally believed to occur less frequently in children than in adults.
- >90% of serum sickness cases are drug-induced.
- <5% of serum sickness cases are fatal.

RISK FACTORS

Genetics

People with a genetic predisposition to produce IgE are more susceptible.

GENERAL PREVENTION

- No known way to prevent first occurrence
- Take careful history of previous allergic reactions.
- Skin testing prior to antiserum administration will prevent anaphylaxis but not serum sickness.
- When the need for antiserum arises, consider prophylactic antihistamines.

PATHOPHYSIOLOGY

- Serum sickness—type III immune complex, antigen–antibody complement reaction
 - Antibodies form 6–10 days after the introduction of foreign material.
 - Antibodies interact with antigens, forming immune complexes that diffuse across the vascular walls.
 - They become fixated in tissue and activate the complement cascade.
 - C3a and C5a are produced, resulting in increased vascular permeability and activated inflammatory cells.
 - Polymorphonuclear cells and monocytes cause diffuse vasculitis.
- Serum sickness–like reaction
 - Abnormal inflammatory reaction in response to defective metabolism of drug by-products

ETIOLOGY

- Common causative agents:
 - Horse antithymocyte globulins
 - Human diploid-cell rabies vaccine
 - Streptokinase
 - Hymenoptera venom
 - Penicillins
 - Cephalosporins (especially cefaclor)
 - Sulfonamides
 - Hydralazine
 - Thiouracils
 - Metronidazole
 - Naproxen

- Dextrans
- Case-reported agents:
 - Minocycline
 - Amoxicillin
 - Infliximab
 - Bupropion
 - H1N1 vaccination

DIAGNOSIS

HISTORY

- Suspect in any patient who has been taking any new drug during the past 2 months and who has an unexplained vasculitic rash.
- Presentation and evolution of rash
 - Typically, the rash first appears on the sides of the fingers, hands, and feet before becoming widespread.
- Previous history of a similar rash
 - Was it associated with any medications in the past? The rash and symptoms of serum sickness will occur sooner on repeat exposure.
- Exposure history
 - Has patient had any drug or antitoxin exposure in the past month?
 - Especially exposures to penicillins, cephalosporins, sulfonamides, hydralazine, thiouracils, streptokinase, metronidazole, naproxen, monoclonal antibodies, or dextrans?
- Timing of the rash and exposure
 - Try to differentiate from simple drug rash; timing of rash after exposure is important in differentiating the two entities.
 - Hypersensitivity reactions occur closer to the time of administration of the offending agent.
- Pruritus is often present.
- Fever
 - Present in 10–20% of cases
 - Usually mild
- Arthritis or arthralgia
 - Present >50% of the time

- Usually involves the metacarpophalangeal and knee joints
- Associated abdominal pain
 - Some cases may have visceral involvement.
- History of hematuria
 - There can be modest renal involvement, usually presenting as proteinuria and microscopic hematuria.
 - Case reports of renal failure
- Neurologic symptoms
 - Peripheral neuropathy, brachial plexus involvement, and Guillain-Barré syndrome have been reported associations.

PHYSICAL EXAM

- Erythematous purpuric rash starts at the sides of the feet, toes, hands, and fingers and then becomes more widespread.
- Erythema multiforme, maculopapular, purpuric, or urticarial type rash
- Mild to severe fever
- Generalized lymphadenopathy; may be localized to lymph nodes that drain the injection site
- Splenomegaly, occasionally
- Edema of the face and neck
- Joint swelling and tenderness

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Not extremely helpful in establishing diagnosis because no abnormality is universally present. Diagnosis usually apparent by classic findings and history of foreign protein or drug exposure:
 - Urinalysis: may show proteinuria and/or hematuria
 - Complement levels variably reduced before returning to normal
 - Leukocytosis or leukopenia with or without eosinophilia
 - Erythrocyte sedimentation rate may be slightly elevated.
 - Skin biopsy of rash with direct immunofluorescent (not routinely recommended as part of workup) shows deposits of IgM and C3 complement in capillary walls.

DIFFERENTIAL DIAGNOSIS

- Erythema multiforme

- Mononucleosis
- Systemic lupus erythematosus
- Rocky Mountain spotted fever
- Henoch-Schönlein purpura
- Hypersensitivity syndrome reaction
- Drug-induced pseudoporphyria
- Acute generalized exanthematous pustulosis
- Granulomatosis with polyangiitis (Wegener granulomatosis)
- Pitfalls
 - A history of fever, rash, and arthralgias is commonly seen with many infectious childhood illnesses. One must always consider a broad set of differential diagnoses.
 - Symptoms may be so minimal that patient does not seek medical attention.
 - Often misdiagnosed as simple drug allergy

TREATMENT

GENERAL MEASURES

- Stop suspected medication/antigen immediately.
- Topical steroids to relieve itching
- Antihistamines to inhibit the action of vasoactive mediators
- Antipyretics for fever
- NSAIDs to relieve joint pain
- Oral corticosteroids for severe cases
 - Recommended to administer and taper over 10–14-day period
 - Shorter course may result in relapse, and recurrent symptoms are more difficult to alleviate.
- Admit if symptoms are severe or diagnosis is unclear.
- Future avoidance of triggering agent if identified

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

When to expect improvement:

- Usually self-limited illness that resolves in a few days to weeks
- If symptoms persist for more than 1 month, reconsider the diagnosis.

PATIENT EDUCATION

- An initial episode of serum sickness cannot be prevented.
- Future episodes can be prevented by avoiding the causative medication (and class of medications) if it has been identified.

PROGNOSIS

Excellent. Most cases are mild and transient with no long-term sequelae.

COMPLICATIONS

- Shock
- Digital necrosis
- Guillain-Barré syndrome (rare)
- Generalized vasculitis (rare)
- Peripheral neuropathy (rare)
- Glomerulonephritis (rare)
- Acute flaccid paralysis (case report)
- Increased risk of anaphylaxis with repeat exposure to precipitating substance
- Fatality (rare, usually due to continued administration of antigen)

FAQ

- Q: My child broke out all over her body with an itchy rash and hives a few days after taking cefaclor. Was this serum sickness?
- A: It is more likely that she is allergic to cefaclor. The difference is that drug allergies are type I IgE-mediated hypersensitivity reactions that occur very soon after drug exposure in a previously sensitized individual. Serum sickness is a type III antibody–antigen immune complex and complement amplified hypersensitivity reaction that occurs 1–3 weeks after an initial exposure.
- Q: If my child has had serum sickness, is she at risk for getting it again?
- A: Yes, if she receives the same medication or related medications again. The symptoms will occur more quickly, usually in 2–4 days, and may be more severe.
- Q: Can the vaccines that my doctor recommends for my child give my child serum sickness?
- A: It is possible but very rare. There have been a few reports of serum sickness–like reactions occurring after receiving vaccines submitted to the Vaccine Adverse Event Reporting System (VAERS).
- Q: Is there any way to prevent my child from getting serum sickness?
- A: Unfortunately, there is no way to predict if your child will have a serum sickness–like reaction to a particular medication. It is extremely important to be aware of your child’s exact allergies to medications and to inform all health care providers caring for your child.

- Q: My oldest child had serum sickness after taking cefaclor. Is it true that all my children should now avoid taking cefaclor?
- A: No. There is no known genetic predisposition to serum sickness. Your other children do not need to avoid the medication that caused serum sickness.
- Q: How is the Arthus reaction different from serum sickness?
- A: The Arthus reaction is also a type III hypersensitivity reaction but causes only a local reaction. This phenomenon was first described in 1903 by the French physiologist Nicolas Maurice Arthus. The Arthus reaction is a local vasculitis caused by formation of antigen–antibody complexes in local vessel walls, which then activate the inflammation process. The reaction occurs within hours after an individual is injected intradermally with an antigen against which he or she has been actively immunized.
- Q: My child was diagnosed with serum sickness 1 year ago. He still gets episodes of rash, fever, and joint pain every now and then. How can this be cured?
- A: Serum sickness is a self-limited disease, and as long as the offending agent is stopped, your child will completely recover. If there are continuing symptoms and your child is no longer taking the offending agent, then other causes for these symptoms need to be considered.
- Q: My child's best friend was recently diagnosed with serum sickness. Do I need to be concerned?
- A: No. Serum sickness is not contagious.

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

Nicholas Tsarouhas

BASICS

DESCRIPTION

- WHO clinical criteria (2003):
 - Suspect severe acute respiratory syndrome (SARS) case:
 - A person presenting after November 1, 2002, with high fever ($>38^{\circ}\text{C}$), and
 - Cough or difficulty breathing, and
 - Close contact with SARS patient or travel criteria to SARS area (see “[History](#)”)
 - Probable SARS case:
 - A suspect case with radiographic pneumonia or respiratory distress syndrome
 - A suspect case with confirmatory laboratory studies (see “[Lab](#)”)
 - A suspect case with autopsy findings
- CDC clinical criteria (2003):
 - Early illness
 - 2 or more constitutional symptoms—fever, chills, rigors, myalgia, headache, diarrhea, sore throat, or rhinorrhea
 - Mild to moderate illness
 - Temperature $>100.4^{\circ}\text{F}$ ($>38^{\circ}\text{C}$)
 - 1 or more lower respiratory findings—cough, shortness of breath, or difficulty breathing
 - Severe illness
 - Clinical criteria of mild to moderate illness, and
 - 1 or more of the following—radiographic evidence, acute respiratory distress syndrome, or autopsy findings
- Clinical criteria for SARS must be interpreted in the context of the prevailing epidemiologic laboratory criteria as published by the WHO and the CDC.

EPIDEMIOLOGY

- SARS time line
 - November 2002: A series of severe idiopathic respiratory illnesses begin occurring in Southeast Asian countries (China, Hong Kong, Vietnam, and Singapore).
 - February 2003
 - The Chinese Ministry of Health notifies the WHO that 305 cases of acute respiratory syndrome of unknown etiology have occurred in Guangdong province in southern China.
 - SARS outbreak in Toronto
 - March 2003
 - CDC activates emergency operations center with first confirmed death of SARS patient.
 - CDC implicates a coronavirus as the causative SARS agent.
 - May 2003: Deaths dramatically rise—7,761 cases, 623 deaths, 31 countries
 - June 2003: Reported cases slow—over 8,000 cases, >770 deaths, 32 countries
 - July 2003: WHO declares the SARS epidemic over.
 - Since July 2003, no further epidemics, but brief reemergence from accidental laboratory exposures in Singapore, Taiwan, and Beijing and from recurrent animal-to-human transmissions in Guangzhou in late 2003 and early 2004
- First emergence of an important human pathogen in the 21st century
- Final statistics of epidemics:
 - Worldwide: >8,000 cases, nearly 800 deaths, >30 countries affected
 - United States: 134 suspected cases, 19 probable cases, 8 confirmed cases, no deaths, 17 states affected

RISK FACTORS

- Transmission
 - Direct or indirect contact of mucous membranes with infectious respiratory droplets or fomites, thus simple masks and good hand hygiene are important.
 - Period of infectivity: most likely during period with active symptoms (fever, cough)

- Incubation period 2–14 days but may be as long as 21 days; mean 6 days
- All cases can be traced to contact with individuals from Asian countries or community, spread from an individual whose illness could be traced to Asia.
- There have been no suspected SARS cases among casual contacts of the U.S. cases.
- Many health care workers were infected after providing care to SARS patients.
- No evidence that SARS is transmitted from asymptomatic individuals
- However, health care workers who developed SARS may have been a source of transmission within health care facilities during early phases of illness, when symptoms were mild and not recognized as SARS.
- There is no evidence that SARS can be spread after recovery from the disease.
- Pediatric population
 - Children pose a lower risk of transmission than do adults; only 1 reported case of transmission of SARS from pediatric patient.
 - Vertical transmission of SARS coronavirus (SARS-CoV) from infected mothers to their newborns has not been observed.
 - None of the newborns had clinical, laboratory, or radiologic evidence suggestive of SARS-CoV infection.

GENERAL PREVENTION

- As there is no specific treatment, public health and infection control measures including contact tracing and quarantine of close contacts are paramount.
- Hospital infection control precautions:
 - Hospitalized patients meeting SARS case definition should be placed in a negative-pressure, single examination room.
 - Protective equipment appropriate for standard, contact, and airborne precautions (e.g., hand hygiene, gown, gloves, and N95 respirator) in addition to eye protection are recommended for health care workers to prevent transmission of SARS in health care settings.

- Pediatric patients with potential SARS exposure:
 - Children who have been exposed to an ill individual who is suspected of having SARS, or children who have traveled to an area where SARS is occurring, should be evaluated based on the following:
 - If well, parents should self-monitor the child's condition for fever or respiratory tract illness. Attendance at child care or school is not restricted.
 - If the child is not well, parents should contact their physician and the child should be isolated at home.
 - If the child is not well and is experiencing breathing difficulty, he or she should be hospitalized. Health care workers should be informed before the admission so SARS precautions can be initiated.
 - Children who have been exposed to individuals who are not ill but have traveled to areas where SARS is occurring do not require isolation.
- Vaccine
 - No effective human vaccine has been developed.
 - Safety concerns exist for vaccine production workers.

PATHOPHYSIOLOGY

The virus attaches to human receptor cells and initiates a nonspecific acute lung injury response leading to diffuse, severe alveolar damage.

ETIOLOGY

- SARS-CoV, a previously unrecognized single-stranded RNA coronavirus
- Coronaviruses are a common cause of mild to moderate upper respiratory infections in humans and have occasionally been linked to pneumonia.
- Many believe that the virus originated in an animal species in China, then mutated in such a way that it was able to attach itself to human receptor cells.

DIAGNOSIS

HISTORY

- Recent travel
 - Travel (including transit in an airport) within 10 days of onset of symptoms to an area with recently documented or suspected transmission of SARS is an important epidemiologic criterion for diagnosis.
 - At the height of the SARS epidemic, these areas included China, Hong Kong, Singapore, Taiwan, Toronto, and Hanoi.
- Recent contact with a SARS patient
 - Close contact within 10 days of onset of symptoms with a person known or suspected to have SARS infection is another important epidemiologic criterion.
- The clinical presentation of SARS in children >12 years of age is similar to that of adults.
- Constitutional symptoms, such as fever, chills, rigors, headache, malaise, myalgias, and diarrhea, are common in older patients.
- A meta-analysis (Stockman et al.) of 6 pediatric series of 135 SARS cases noted the following symptom prevalence: fever (98%), cough (60%), and nausea or vomiting (41%).
- Respiratory symptoms
 - At the onset of illness, most cases have mild respiratory symptoms.
 - After 3–7 days, a dry, nonproductive cough begins, often with dyspnea.

PHYSICAL EXAM

- Fever generally heralds the start of the illness.
- Tachypnea, increased work of breathing, or rales are common in adults.
- Adult patients generally present with some evidence of respiratory distress or hypoxemia.
- Importantly, however, although some children present with cough or difficulty breathing, many have remarkably normal examinations.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Detection of SARS coronavirus: confirmatory laboratory criteria for

the diagnosis of SARS:

- Antibody by enzyme-linked immunosorbent assay (ELISA) or indirect fluorescent-antibody assay (IFA)
- RNA by reverse transcriptase-polymerase chain reaction (RT-PCR) assays
- Viral culture
- SARS virus may be detected in blood, throat, nasopharyngeal aspirates, and stool samples.
- CBC: Hematologic abnormalities are common in children with SARS.
 - Leukopenia (lymphopenia or neutropenia)
 - Thrombocytopenia
- Liver enzymes: Elevated transaminases seen.
- Raised serum lactate dehydrogenase is also seen.

Imaging

- The characteristic feature of pulmonary SARS-CoV infection is patchy airspace consolidation predominantly located at the periphery of the lungs and in the lower lobes.
- Normal chest radiographs also possible.

DIFFERENTIAL DIAGNOSIS

- Bacterial infections
 - Pneumococcus
 - Staphylococcus
 - Legionella
 - Mycoplasma
 - Chlamydomphila pneumoniae
- Viral infections
 - Middle East respiratory syndrome (MERS)
 - Avian influenza A(H7N9) infection (bird flu)
 - Influenza A and B
 - Respiratory syncytial virus
 - Ebola viral infection

ALERT

- Even during an epidemic of SARS, other diseases should still be considered.

- Microbiologic studies should still be performed to confirm or rule out other infectious diseases.

TREATMENT

INPATIENT CONSIDERATIONS

Initial Stabilization

- There is no proven effective treatment.
- CDC currently recommends that patients with SARS receive the same treatment and supportive care that would be used for any patient with serious community-acquired atypical pneumonia of unknown cause.
- Steroids, interferon, convalescent plasma, ribavirin, oseltamivir, and other antivirals have been used without consistent success.

ONGOING CARE

PROGNOSIS

- Patients 12 years of age and younger
 - Milder disease
 - Fewer ICU admits
 - Decreased need for supplemental oxygen
 - No reported pediatric deaths
- Overall fatality rate: 9.5% (all adults)
 - Highest: 27% (Taiwan)
 - Lowest: 0 (United States)

COMPLICATIONS

- Overall, in 10–20% of cases, the respiratory illness was severe enough to require mechanical ventilation.
- In children, only 5% required admission to an ICU, and <1% required mechanical ventilation.

CODES

ICD10

- J12.81 Pneumonia due to SARS-associated coronavirus
- B97.21 SARS-associated coronavirus causing diseases classd elswhr

FAQ

- Q: Is the clinical presentation and course different in children?
- A: Fortunately, younger children tend to have a shorter and milder course, consisting mainly of low-grade fever, cough, and rhinorrhea. Adolescents, conversely, follow a more severe course, similar to that of adults.
- Q: What constitutes close contact with a SARS patient?
- A: Close contact includes having cared for or lived with a person known to have SARS or having a high likelihood of direct contact with respiratory secretions and/or body fluids of a patient known to have SARS.

SEVERE COMBINED IMMUNODEFICIENCY

M. Elizabeth M. Younger • Howard M. Lederman

BASICS

DESCRIPTION

Severe combined immunodeficiency (SCID) is a primary immunodeficiency characterized by functional defects in both the humoral and cellular immune systems. Most babies present with lymphopenia. Even the suspicion of SCID constitutes a pediatric emergency. Untreated, SCID is universally fatal, usually within the 1st year of life.

EPIDEMIOLOGY

Most patients present in the 1st year of life as immunity from maternal antibody wanes.

Incidence

- Estimated to be 1 in 100,000 births but may be underreported because of early infant mortality
- Highest in regions where consanguineous marriages take place
- SCID due to Artemis defects occurs in 1 in 2,500 births in the Navajo and Apache populations because of a founder mutation.

Genetics

- At least 13 known genetic defects that cause SCID
- Approximately 50% of cases are X-linked (mutation in the IL2 gamma chain); the others are autosomal recessive or de novo mutations.
- Classified by the lymphocytes subsets affected (e.g., T⁻ B⁺ NK⁺, T⁻ B⁻ NK⁺, etc.)

ETIOLOGY

Caused by mutations in genes required for T-cell growth and development, purine salvage pathway function (e.g., adenosine deaminase), and expression of histocompatibility (HLA) antigens.

DIAGNOSIS

HISTORY

- Failure to thrive
- Chronic diarrhea
- Chronic thrush or candidal diaper rash
- Frequent and/or severe infections with common pathogens
- Rotaviral infection after immunization
- Opportunistic infections
- Consanguinity
- Family history of SCID or unexplained infant deaths

PHYSICAL EXAM

- Emaciated or wasted appearance
- Atypical morbilliform rash
- Absence of lymphoid tissue (small or absent tonsils and lymph nodes)
- Evaluation for infection
 - Thrush or diaper dermatitis
 - Manifestations of graft-versus-host disease (skin rash, conjunctivitis, hepatitis, diarrhea) secondary to transplacental alloreactive maternal T cells or T cells from unirradiated blood products

DIAGNOSTIC TESTS & INTERPRETATION

- CBC with differential to assess for lymphopenia: should suspect SCID if absolute lymphocyte count (ALC) $< 3,000$ per microliter in the neonatal period or if ALC is $< 1,000$ per microliter in any child < 3 years of age
- Lymphocyte subsets: All populations are generally decreased, but T cells are almost always severely decreased.
- Serum immunoglobulins (IgG, IgA, IgM): usually low or absent, but IgG may be normal in first 4 months of life because of placental transfer
- T-cell receptor excision circles (TRECs) are part of newborn screening from Guthrie cards (now legally mandated by many states in the United States).
 - Identifies lymphopenia in the newborn

- TRECs are absent in infants with SCID.
- TRECs may be reduced in premature infants.
- Lymphocyte proliferation assay: Cells do not proliferate to antigenic stimulation.
- Appropriate cultures to identify pathogens
- Identification of causative mutation is necessary to allow for genetic counselling.

DIFFERENTIAL DIAGNOSIS

- HIV infection
- DiGeorge (22q11 deletion) syndrome
- Iatrogenic lymphopenia (e.g., steroid therapy)
- Other primary immunodeficiency (e.g., X-linked agammaglobulinemia, ataxia telangiectasia)

TREATMENT

- The only curative treatment is stem cell transplant.
 - Success rates >70% have been reported and increase to 96% when the transplant is done before the age of 3 1/2 months.
 - Preconditioning is generally not required because of the lack of T-cell function, but reduced intensity conditioning is often done to ensure engraftment.
- In patients with adenosine deaminase (ADA)–deficient SCID, for whom there is no identical stem cell match, enzyme replacement therapy with pegylated ADA (Adagen) can be given.

ONGOING CARE

- Pre-transplant supportive care
 - Pneumocystis prophylaxis with trimethoprim/sulfamethoxazole
 - Immunoglobulin replacement therapy (intravenous every 3–4 weeks, subcutaneously every 1–2 weeks)
 - Aggressive and early treatment of infections
 - Nutritional support

- Avoidance of crowds and persons with symptoms of infection (fever, cough, etc.)
- Routine immunization is unnecessary, as patients are unable to mount antibody responses.
- Live viral vaccines are absolutely contraindicated.
- If blood transfusion is required, only irradiated, CMV negative blood products should be used.
- Nontransplant treatment
 - Gene therapy trials are ongoing for patients with ADA-deficient and X-linked SCID.
- Post transplant care
 - Close monitoring for signs of graft-versus-host disease, engraftment failure, infection
 - Immunoglobulin replacement therapy may still be required if B-cell reconstitution is absent or impaired.
 - Genetic counseling for parents

COMPLICATIONS

- Pre- or posttransplant graft-versus-host disease
- Engraftment failure
- Omenn syndrome caused by clonal autoreactive T cells, resembling graft-versus-host disease seen in patients with RAG1 or RAG2 mutations
- Increased risk for lymphoreticular cancers
- Radiation sensitivity in patients with SCID caused by DNA repair syndromes (Artemis, Ligase-4, DNA-PKcs, Cernunnos)
- Growth failure and hearing impairment in patients with ADA-deficient SCID

CODES

ICD10

- D81.9 Combined immunodeficiency, unspecified
- D81.1 Severe combined immunodeficiency w low T- and B-cell numbers
- D81.2 Severe combined immunodef w low or normal B-cell numbers

FAQ

- Q: What should I do if I am notified that a newborn screen has identified a low number of TRECs?
- A: As a precaution while the child is being evaluated, prevent the infant's exposure to sick contacts and public places or places with large crowds (day care centers, malls, churches, large family gatherings). Consider the need for pneumocystis prophylaxis and immunoglobulin replacement therapy while the evaluation proceeds. Send blood for enumeration of T-cell subsets (CD4 and CD8), B-cells (CD19), and NK cells (CD 16/56) and refer the child to a clinical immunologist.
- Q: What vaccines should be given to a child with SCID or suspected SCID?
- A: Children with SCID do not benefit from immunizations, and live viral vaccines of any type (rotavirus, MMR, varicella, and BCG) are absolutely contraindicated.
- Q: What is the chance of another child in the family being affected with SCID?

- A: The answer to this question depends of the cause of SCID. If a child has X-linked SCID, then there is a 50% chance of SCID in any male child born to the mother. In other forms of SCID, the risk is 25% for any male or female. It is crucial that a genetic diagnosis is made for each case of SCID so that families can be given accurate information about recurrence risk, they can be offered prenatal testing, and other affected children can be identified as soon as possible after birth.
- Q: Is there gene therapy for SCID?
- A: There are active research protocols for treating children with X-linked SCID and children with ADA deficiency. These protocols are still investigative and not standard therapy. Bone marrow transplantation remains the standard of care at this point.

SEXUAL ABUSE

Mitchell A. Goldstein

BASICS

DESCRIPTION

Sexual abuse is the involvement of children in sexual activities that they cannot understand, for which they are not developmentally prepared, to which they cannot give informed consent, and/or that violate societal norms.

- Ranges from oral, genital, or anal contact; fondling; child pornography; prostitution; exhibitionism; and voyeurism
- Twenty-five percent of perpetrators are parents, and 30% are non-parental relatives.
- Most children sexually abused will have no discernible physical injury.

EPIDEMIOLOGY

- ~150,000 substantiated cases/year; most likely underestimates the incidence as these include only those cases reported
- Prevalence rates between 10 and 30%. The National Violence Survey reported 27% of adult women and 16 % adult men reported sexual abuse during childhood.

RISK FACTORS

- Peak age of vulnerability: 7–13 years of age
- Girls are victimized more than boys, although abuse of boys is underreported.
- Single-parent households, domestic violence, parental substance abuse and mental illness
- Children who experience other types of abuse are also more likely to be victimized sexually.
- Race and socioeconomic status do not appear to be risk factors for child sexual abuse.
- Risk factors for revictimization: younger aged children; more severe maltreatment; families with mental health and substance abuse

problems and violence histories

DIAGNOSIS

HISTORY

- Diagnosis is made based on the child's history because abnormal physical findings or lab tests are infrequent.
- Attempt to limit the number of interviews.
- Interview should be detailed enough to know whether a report to child protection or law enforcement is needed.
- If the medical provider is the first person to which the child has disclosed, then that person is an "an outcry witness," and that disclosure can be used in court testimony.
- Answers from the children that are obtained for the medical diagnosis and treatment may be admitted into evidence.
- The interview should be conducted with the child separate from family members.
- Ask open-ended, nonleading questions.
- Use developmentally appropriate language.
- Specific questions important to the triage of the child include the following:
 - Identity of alleged perpetrator/relationship to child
 - Time of last possible contact
 - Specific types of sexual contact
 - Review of systems including genital pain, bleeding, dysuria, constipation, painful bowel movements, and behavioral changes

PHYSICAL EXAM

- Serves to ensure the overall health of a child after an abusive event and to document any injuries or other forensically relevant evidence
- Most exams are normal.
- An emergency exam is indicated if the most recent assault was within 72 hours or if the patient has complaints of pain, dysuria, or bleeding. Beyond 72 hours, the exam can be scheduled at the local child advocacy center.

- A speculum should not be used for a prepubertal sexual abuse exam unless there is acute bleeding and its origin must be determined.
 - Use of the techniques of labial separation and labial traction (gently grasping the posterior portion of the labia majora and pulling laterally, down, and toward the examiner) allows for the best visualization of the hymenal edges.
 - Normal hymenal configurations: annular, crescentic, and fimbriated
 - Newborn hymen: thickened, pale, and redundant
 - Prepubertal hymen: thin, less redundant, with sharp well-defined edges.
 - Postpubertal hymen: thickened, pale, and redundant
- A few physical findings are diagnostic of abuse:
 - Presence of semen or sperm on the victim
 - Pregnancy
 - Acute genital/anal injuries without an adequate accidental explanation (bruising, lacerations, complete hymenal transection between 4 and 8 o'clock along hymenal rim)
 - Syphilis and Neisseria gonorrhoeae infection (excluding perinatal infection).
 - Chlamydia if the child is older than 3 years of age
 - Trichomoniasis in a child older than 1 year of age
- Many genital findings are unlikely to be related to abuse:
 - Normal variants including intravaginal ridges, hymenal mounds, linea vestibularis, diastasis ani
 - Perineal redness
 - Labial adhesions
 - Anal fissures
 - Venous pooling in perianal area
- Any finding on exam thought to be abnormal or diagnostic of child sexual abuse should be reviewed with a child abuse expert for confirmation.

DIAGNOSTIC TESTS & INTERPRETATION

Initial Lab Tests

- Forensic evidence collection
 - Standard rape kit if the last contact was 72 hours or less

- Always obtain consent.
- In prepubertal children, recovery of useful forensic evidence is rare beyond 24 hours.
- Some experts support forensic evidence recovery up to 5 days from the contact in pubertal children.
- Most positive forensic evidence comes from clothing and linens.
- Sexually transmitted illness (STI) screening: Universal screening is not appropriate unless the victim is a sexually active adolescent.
 - AAP and CDC guidelines recommends STI testing when
 - Child discloses contact that may have involved genital secretions.
 - Child's symptoms or physical exam suggest presence of STI.
 - Abuser is felt to be at risk for STI.
 - Community prevalence of STI is high.
 - Family member is infected with an STI.
 - Patient or family member requests testing.
 - Testing for *N. gonorrhoeae* and *Chlamydia trachomatis* may be performed with vaginal/urethral culture or nucleic acid amplification techniques (NAATs).
 - Cultures have historically been the gold standard method for diagnosing STIs in prepubertal children. NAATs have proven to be sensitive and specific for *N. gonorrhoeae* and *C. trachomatis* infection in this age group.
 - NAATs are not approved for rectal or pharyngeal specimens.
 - NAATs have a higher sensitivity than culture.
 - If an NAAT is done, then important not to treat empirically because if the NAAT is positive, the clinician will want to repeat with another NAAT or culture to reconfirm.
- Trichomoniasis in a child 1 year of age or older is diagnostic of child sexual abuse; can be tested for by wet prep, culture, or PCR
- Screen for syphilis (STT/RPR) and hepatitis B in any case, which meets other screening recommendations.
- HIV screening should also be considered.

Special Considerations

- Genital warts are not diagnostic of child sexual abuse. Neonatal transmission is common and human papilloma virus (HPV) may

remain latent for several years. Children who present after age 3–5 years should have a complete medical evaluation for sexual abuse.

- Herpes simplex infections in the genital area are most commonly (but not always) caused by sexual contact. Most mouth infections are caused by HSV-1 and most genital infections are caused by HSV-2, but this distinction is not absolute.

Follow-Up Lab Tests

- Any positive NAAT needs to be repeated with a different NAAT for confirmation prior to empiric treatment.
- Any positive STT/RPR should be confirmed with a treponemal test.
- If serologic testing for HIV, HBV, and syphilis is negative acutely, they should be repeated at 6 weeks, 3 months, and 6 months.

DIFFERENTIAL DIAGNOSIS

- Sexualized behaviors
 - Normal behaviors for age (e.g., masturbation)
 - Exposure to sexual activity (e.g., media)
- Abnormal GU exam
 - Normal variations in hymenal anatomy (e.g., septate, cribriform, imperforate)
 - Normal variations in perineal anatomy (e.g., hymenal mound, intravaginal ridge, vestibular bands)
 - Linea vestibularis: white streaks that run from inferior hymenal border to posterior commissure
 - Failure of midline fusion: presence of mucosal surface between fossa navicularis and anus that commonly resolves at puberty
 - Irritant, contact, and seborrheic dermatitis
 - Labial adhesions
 - Lichen sclerosis et atrophica: thinned white atrophic skin in figure-of-8 appearance which may have bruising or petechiae
 - Ureterocele
 - Urethral prolapse
 - Pearly pink papules in males
 - Balanitis in males
 - Phimosis or paraphimosis in males

- Accidental trauma, including straddle and impaling injuries
- Accidental tourniquet of genitals by hair
- Abnormal anal exam
 - Diastasis ani: absence of muscle fibers in middle of external anal sphincter
 - Anal skin tags
 - Anal dilatation from constipation or sedation
 - Group A streptococcal perianal cellulitis
- Urethral discharge/bleeding
 - Foreign body
 - UTI
 - Nonspecific vulvovaginitis
 - Group A Streptococcus
 - Haemophilus influenzae
 - Staphylococcus aureus
 - Mycoplasma hominis
 - Gardnerella vaginalis
 - Shigella flexneri (discharge commonly bloody)
- Genital ulcers
 - EBV, HSV
 - Behçet disease
 - Inflammatory bowel disease
- Genital irritation
 - Pinworms
 - Scabies
 - Candida albicans
 - Trauma

TREATMENT

MEDICATION

- Prophylactic antibiotics
 - Recommended following sexual abuse/assault in adolescents and adults to prevent *N. gonorrhoeae*, *C. trachomatis*, and *Trichomonas vaginalis*

- Not recommended in prepubertal victims because of the low likelihood of STI and the importance of establishing the diagnosis
- HIV postexposure prophylaxis (PEP)
 - Recommend consultation with pediatric infectious disease specialist before initiating PEP.
 - High-risk exposures: disclosure of penile anal or penile vaginal penetration by known HIV positive perpetrator
 - Moderate-risk exposures: disclosure of penile anal or penile vaginal penetration and the HIV status of perpetrator is unknown but there is no anogenital trauma but multiple assailants were involved; perpetrator is from a high-risk population; or there is coexisting infection in perpetrator or victim
 - PEP is not recommended in disclosures that do not involve anal, vaginal, or oral penetration; oral penetration without ejaculation
- N. gonorrhoeae treatment according to CDC guidelines
 - Adolescents: ceftriaxone 125 mg IM once or cefixime 400 mg PO once
 - Prepubertal child: ceftriaxone 125 mg IM once
- C. trachomatis treatment according to CDC guidelines
 - Adolescents: azithromycin 1 g PO one time or doxycycline 100 mg PO b.i.d. × 7 days
 - Prepubertal child
 - Weight less than 45 kg: erythromycin 50/mg/kg/day divided into 4 daily doses for 14 days
 - Weight greater than 45 kg but less than 8 years: azithromycin 1 g PO × 1; age greater than 8 years: azithromycin 1 g PO one time or doxycycline 100 mg PO b.i.d. × 7 days
- Syphilis treatment according to CDC guidelines: parenteral penicillin G; dose depends on stage of disease and child age
- Trichomoniasis treatment: metronidazole 2 g PO once
- Hepatitis B vaccination for unimmunized patients
- Hepatitis B immune globulin for patients with recent sexual contact with known positive perpetrator
- Consider pregnancy prevention (e.g., emergency hormonal contraceptive) for adolescents after ensuring the patient is not

pregnant.

- Tetanus booster for patients with acute, serious genital or other injuries.

ADDITIONAL TREATMENT

General Measures

Cases of child sexual abuse require a multidisciplinary approach that includes medical, social services, law enforcement, and states attorney expertise.

Admission Criteria

- Consider in children with injuries that require operative care
- Consider in cases where the clinician wants to ensure protection of the child and external forces preclude that assurance
- Consider in cases where there is a significant mental health concern

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Most children should be followed by a mental health provider.

PROGNOSIS

Varies greatly depending on specifics of abuse sustained and available support systems

COMPLICATIONS

- Posttraumatic stress disorder
- Depression
- Domestic violence and revictimization
- Substance abuse
- Chronic pelvic pain
- Males are more likely to have concerns about sexual orientation.

CODES

ICD10

- T74.22XA Child sexual abuse, confirmed, initial encounter
- T76.22XA Child sexual abuse, suspected, initial encounter

FAQ

- Q: How could there have been penetration with a normal physical examination?
- A: The vast majority of child sexual abuse exams are completely normal even with a history of penetration. The healing properties of genital tissues are quick and complete; past injuries are often difficult to detect on physical exam.
- Q: What should I do if I examine a patient with no history of sexual abuse and detect an anatomic abnormality that I think is suggestive of sexual abuse?

- A: Always have exams confirmed by a child abuse expert in your area, as nuances of exams can be hard to discern.
- Q: If child abuse evaluations rarely reveal any abnormalities, why should I subject my patient to such an invasive evaluation?
- A: The vast majority of sexual abuse medical evaluations are normal, but in the small percentage that are abnormal, the information derived can be important medically and forensically. Importantly, the exams allow for detection of other medical conditions which may have gone unnoticed secondary to lack of medical access. Exams also serve to reassure families and children that they are healthy.
- Q: Is an STI diagnosed in a prepubertal patient always indicative of abuse?
- A: No. All STIs may be transmitted vertically (from mother to infant). The incubation periods of different infections vary, so they are expressed at different ages accordingly. Gonorrhea and syphilis are considered diagnostic of sexual abuse outside of congenital infection. Chlamydia, herpes simplex virus 2, and Trichomonas are probably due to sexual abuse and should be reported for evaluation. Condyloma acuminata is probably related to sexual abuse in school-aged and older children but may be transmitted to younger children innocently during toileting or diaper changes.

SHORT STATURE

Himala Kashmiri • Susanne M. Cabrera

BASICS

DESCRIPTION

- Short stature is height <2 standard deviations (SD) below mean or <3 rd percentile for age and sex of the normal population.
- Growth failure defined as height <2 SD below midparental height (MPH) or height velocity (HV) <10 th percentile for age resulting in downward crossing of height percentiles
- The majority of children with short stature are essentially healthy. True growth failure is typically pathologic and requires evaluation.
- Failure to thrive (FTT) is failure of appropriate weight gain (decreased weight to height ratio). May be accompanied by poor linear growth.

RISK FACTORS

- Poor nutrition, systemic chronic illness, and psychosocial factors can contribute to clinical presentation of short stature or growth failure.
- A family history of short stature or delayed growth and puberty are well-established risk factors for childhood short stature.

PATHOPHYSIOLOGY

- Adequate nutrition and weight gain play major roles in linear growth during childhood.
- Throughout infancy and childhood, growth hormone (GH) and thyroid hormone exert major influences on normal growth.
- Pulsatile GH release stimulates insulin-like growth factor 1 (IGF-1) secretion from liver and other tissues to promote growth at growth plates.
- The pubertal growth spurt is largely mediated by androgen and estrogen activity at the growth plate as well as enhanced GH release.
- Chronic illnesses can cause growth failure.
- Glucocorticoid excess inhibits growth through downregulation of the GH/IGF-1 axis and suppressed osteogenesis.

DIAGNOSIS

HISTORY

- **Question:** Have length/height and weight been charted appropriately on a growth curve?
- Significance: Interpretation of growth depends on precise and accurate measurements that account for both year and month of age.
- **Question:** Is the child short for his or her MPH?
- Significance: Height can only be judged to be inappropriate in the context of the genetic potential as determined by MPH:
 - For boys: $[\text{father's height (cm)} + (\text{mother's height [cm]} + 13)]$ divided by 2
 - For girls: $[(\text{father's height [cm]} - 13) + \text{mother's height (cm)}]$ divided by 2
 - MPH target range (± 2 SD) is ± 10 cm.
 - If the child's height percentile is decreased relative to the MPH range, evaluation may be warranted.
- **Question:** Height velocity (HV)?
- Significance: A normal HV is reassuring, whereas a reduced HV, regardless of absolute height, can earlier detect a growth-slowng disorder.
 - The HV for an interval of at least 6 months (to minimize seasonal variation or measurement error) should be annualized and plotted on an HV curve.
 - Normal HV is >4 cm/year in children and >8 cm/year during pubertal growth spurt.
- **Question:** Birth measurements and gestational age?
- Significance: Intrauterine growth restriction (IUGR) and/or small for gestational age (SGA) can be associated with possible maternal disorders, genetic disorders, and intrauterine drug exposure or stress that later impact growth.
- **Question:** Postnatal history including hypoglycemia or prolonged jaundice?
- Significance: Birth trauma, prolonged jaundice, and postnatal hypoglycemia can be associated with hypopituitarism.

- **Question:** Family history of short stature or delayed puberty?
- Significance:
 - Short stature in family members may suggest a heritable growth disorder.
 - Consider a diagnosis of constitutional delay of growth and puberty.
- **Question:** Social situation?
- Significance: Psychosocial stressors affect growth and development.
- **Question:** Dietary and feeding history?
- Significance: Low daily intake, difficulty feeding, or inefficient use of calories may point to malabsorptive disorders, anorexia.
- **Question:** Developmental milestones?
- Significance: delays may signal associated syndrome, chromosomal or metabolic disorder.
- **Question:** Chronic illness or any prior hospitalization, surgery, or head trauma?
- Significance: Growth failure may be the only sign of disease such as rheumatoid arthritis, celiac disease, or inflammatory bowel disease (IBD). Previous hospitalizations, trauma, or surgery may be a sign of underlying or acquired pathology. Head trauma may cause hypopituitarism.
- **Question:** Any medication use?
- Significance: Use of oral or inhaled steroids as well as stimulant medications can lead to short stature or HV deceleration.
- The history should be completed by obtaining a full review of systems, specifically inquiring about general development, headache, emesis, vision change, anorexia, fatigue, weight change, bowel irregularities, pubertal development, exercise tolerance, polyuria and polydipsia, activity pattern, sleep hygiene.
- Although boys are more frequently referred for short stature, girls are more likely to have a pathologic reason for short stature.

PHYSICAL EXAM

- **Finding:** Low upper to lower segment ratio?
- Significance: suggests scoliosis
- **Finding:** Abnormal trunk-to-arm span ratio?
- Significance: suggests skeletal dysplasia

- **Finding:** Low weight-to-height ratio?
- Significance: FTT, malnutrition, psychosocial deprivation, stimulant medication, chronic systemic illness, or metabolic disorders
- **Finding:** Proportionate/high weight-to-height ratio?
- Significance: If normal/near normal HV, then familial short stature, genetic syndrome, SGA, constitutional delay, mild chronic disease, prior resolved growth-attenuating disorder, or acquired growth limitations. If associated with low HV, suggests endocrine disorder, chronic disease, or growth-affecting medications
- **Finding:** Dysmorphic features?
- Significance: Primary growth disorders
- **Finding:** Mid-facial hypoplasia, cherubic appearance, truncal fat deposition?
- Significance: suggests GH deficiency
- **Finding:** Goiter, edema, slow relaxation of deep tendon reflexes, hair loss, dry skin?
- Significance: hypothyroidism
- **Finding:** Abdominal distention or tenderness and gluteal wasting?
- Significance: malabsorption and celiac disease
- **Finding:** Webbed neck, increased carrying angle, shield chest, lymphedema?
- Significance: Turner or Noonan Syndrome
- **Finding:** Microphallus?
- Significance: hypogonadism, GH deficiency
- **Finding:** Abnormal funduscopic or cranial nerve exam? Midline abnormalities?
- Significance: CNS pathology ± associated hypopituitarism
- **Finding:** Signs of neglect or abuse?
- Significance: psychosocial dwarfism
- **Finding:** Round face, hypocalcemia, short 4th and 5th metacarpals, and mental retardation?
- Significance: pseudohypoparathyroidism
- **Finding:** Hypertension, virilization, moon face, buffalo hump, thick violaceous striae
- Significance: glucocorticoid excess

- **Finding:** Delayed pubertal maturation?
- **Significance:** Turner syndrome, constitutional delay, hypogonadism, hypothyroidism, IBD, chronic renal disease
- **Finding:** Leg bowing, widening of wrists, rachitic rosary, frontal bossing?
- **Significance:** rickets, malabsorption

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** X-ray study of the left hand and wrist
- **Significance:** bone age (BA) determination (not reliable in kids <2 years of age)
- **Test:** IgA and anti-tissue transglutaminase IgA
- **Significance:** celiac disease
- **Test:** CBC with differential
- **Significance:** anemia, infection, malignancy, or chronic inflammatory conditions
- **Test:** C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR)
- **Significance:** infection, inflammatory conditions
- **Test:** Complete metabolic panel
- **Significance:** Screen for renal/liver disorders, malnutrition, calcium disorders.
- **Test:** Urinalysis
- **Significance:** diabetes, renal/metabolic issue
- **Test:** Thyroxine and TSH
- **Significance:** hypothyroidism
- **Test:** Karyotype or targeted gene testing
- **Significance:** Turner syndrome in girls, SHOX mutation, or other chromosomal disorders
- **Test:** IGF-1 and IGFBP-3 concentrations, compared to pubertally matched norms
- **Significance:** Proxy measurements for GH secretory reserve and screen for GH deficiency. Not reliable <3 years of age and can be falsely low in poor nutrition states.

DIFFERENTIAL DIAGNOSIS

- Extremes of normal growth:
 - Familial short stature
 - Normal exam, no systemic illness
 - Consistent short stature with normal HV
 - Normal BA, onset of puberty
 - Adult height is short, close to MPH.
 - Constitutional short stature/delay of growth
 - Family history common
 - Normal exam, no systemic illness
 - Proportionately short; height percentile below MPH
 - Decelerating HV during first 3 years of life with normal to near-normal HV until puberty, when delays in pubertal timing lead to decreased HV compared to peers
 - Delayed BA and pubertal maturation
 - Adult height commensurate with MPH.
 - Idiopathic short stature
 - Categorizes otherwise normal patients who cannot be diagnosed with a variant of normal growth or other short stature cause
 - Predicted adult height is >2 SD below MPH.
 - Height is <3 rd percentile \pm delayed BA.
- Primary growth disorders: disorders intrinsic to skeletal system, BA normal
 - Skeletal dysplasia/defects: may lead to disproportionate short stature. Skeletal involvement can be subtle.
 - Skeletal radiographs with typical findings
 - Common forms: achondroplasia, hypochondroplasia, dyschondrosteosis (Leri-Weill and other SHOX mutations)
 - Syndromes
 - Usually associated with other abnormalities
 - Clinical findings may be subtle (mosaicism)
 - Common forms: trisomies (13, 18, 21), Turner or Noonan syndrome, Prader-Willi, DiGeorge, neurofibromatosis type 1
 - IUGR and SGA
 - Often due to maternal, fetal, or placental problems and/or exposures, or idiopathic

- SGA infants have relative GH resistance seen as elevated GH with low IGF-1 levels.
 - 10% of SGA don't have catch-up growth with height SD <-2 by 2 years and need endocrine evaluation.
- Primordial dwarfism: inherited intrinsic defect leading to prenatal and postnatal growth failure
- Secondary short stature
 - Malnutrition
 - Most common cause internationally
 - Poor nutrition (caloric, vitamin, mineral)
 - Especially <2 years of age
 - Chronic illness: Poor growth can be presenting symptom.
 - Hematopoietic (anemia, sickle cell)
 - Cardiovascular (congenital heart defect)
 - Pulmonary (severe asthma, cystic fibrosis)
 - GI/liver (IBD, celiac disease, malabsorption syndromes, chronic liver disease)
 - Renal (renal tubular acidosis, Fanconi syndrome, uropathy, congenital anomalies)
 - Metabolic (poorly controlled diabetes mellitus, storage disorders, disorders of calcium and phosphorous metabolism)
 - Infectious/Immunologic (HIV)
 - Iatrogenic
 - Medications: glucocorticoids, stimulants
 - Treatment of childhood malignancy, irradiation, chemotherapy
 - Psychosocial growth retardation
 - Emotional deprivation
 - Anorexia
 - Depression
 - Endocrine
 - GH or IGF-1 deficiency/resistance, hypogonadism, hypothyroidism, Cushing syndrome, short stature from earlier accelerated bone maturation (e.g., precocious puberty, hyperthyroidism, congenital adrenal hyperplasia)
 - Among secondary short stature, endocrine causes are least

frequent.

TREATMENT

ADDITIONAL TREATMENT

General Measures

Evaluation warranted if HV low for age or growth pattern deviates significantly from the MPH target.

- In the majority of short children, history and exam are unrevealing, and tests yield equivocal or normal results. These children are then considered to have idiopathic short stature.
- Observation is reasonable for familial short stature or constitutional delay.
- In cases of malnutrition, restoration of adequate nutrition results in HV acceleration.
- In cases of endocrinopathies, replacement of the deficient hormone (thyroid hormone for hypothyroidism, GH for GH deficiency, hydrocortisone for adrenal insufficiency) or removal of excess hormone (glucocorticoids) will normalize the HV.
- Children with short stature or poor predicted adult height, who do not have true GH deficiency, may receive different treatment options depending on costs, risks, physician practice, extent of family's concern, and presence of associated psychosocial stressors (e.g., teasing by peers).

ISSUES FOR REFERRAL

- Critical to obtain accurate measurements plotted appropriately to assess growth
- Referrals should be guided by abnormal laboratory evaluations or clinical suspicion (i.e., nephrology referral for elevated creatinine, pulmonary referral for clubbing).
- Endocrine referral warranted if slow HV, growth plateau, delayed bone age with short stature/ growth failure, or suggestive labs.
- If poor weight gain, consider nutritional deficiency, malabsorption syndromes. Initial referral to gastroenterologist appropriate.

- The evaluation of growth failure or short stature best done in outpatient setting.

CODES

ICD10

- R62.52 Short stature (child)
- E34.3 Short stature due to endocrine disorder
- E23.0 Hypopituitarism

FAQ

- Q: Does short stature portend worse psychosocial outcomes?
- A: This has not been found when studied in the general population. The degree of parent and child distress from short stature is also filtered by referral bias, as those who seek care have the highest degree of concern and anxiety.
- Q: How much height does a child with idiopathic short stature gain from treatment with recombinant growth hormone?
- A: 1.2–2.8 inches in final adult height, at a cost of \$10,000–\$60,000 per patient per year. Height gains are much better in other conditions such as true GH deficiency and Turner syndrome, but the cost remains steep.
- Q: What is a reasonable strategy for constitutional delay of growth and puberty?
- A: Observation and reassurance alone are frequently all that is needed.

In males of pubertal age (13–14 years), however, a course of low-dose intramuscular testosterone may be considered to “jump start” pubertal changes and the corresponding growth spurt.

SHORT-BOWEL SYNDROME

Christina Bales • Judith Kelsen

BASICS

DESCRIPTION

Malnutrition, malabsorption, and/or fluid and electrolyte loss after extensive small-bowel resection

PATHOPHYSIOLOGY

- Markedly decreased mucosal surface area due to resection
- Loss of trophic hormones
- Loss of peptide hormones that regulate motility
- Abnormal transit
- Malabsorption of protein, fat, carbohydrate, vitamins, electrolytes, and trace elements, depending on site of resected intestine
 - Patient can lose as much as half of intestine if the duodenum, distal ileum, and ileocecal valve (ICV) are present.
 - If the ICV is gone, patients may not be able to tolerate even a 25% loss of intestine without the help of parenteral nutrition (PN).
- Normal bowel length: 150–200 cm, 26 weeks' gestation; 200–300 cm at birth in full-term infant; 600–800 cm, adult
 - Infants have low intestinal reserve; do not tolerate resection as well as do adults.
 - However, long-term prognosis is often better because of hypertrophy and hyperplasia of the intestine.
- Gastric acid hypersecretion occurs soon after intestinal resection but is transient.
- Bowel adaptation can occur over time. Increased surface area due to bowel dilatation, villous hypertrophy, and bowel lengthening can occur. Stimulation of luminal contents is needed for bowel growth, and factors such as glutamine, short-chain fatty acids, trophic hormones, and growth factors may be important for bowel growth.

ETIOLOGY

- Infants: intestinal resection for necrotizing enterocolitis
- Congenital anomalies include intestinal atresias, gastroschisis, omphalocele, and meconium ileus.
- Malrotation may result in volvulus with bowel resection secondary to ischemic injury.
- Older children: neoplasms and radiation enteritis
- Intestinal resection secondary to Crohn disease, trauma, pseudoobstruction syndrome

DIAGNOSIS

HISTORY

- Defecation pattern: number, size, nature (watery, bulky, foul smelling), presence of blood and mucus
- Ostomy output: consistency (watery, viscous, thick), volume (≥ 50 mL/kg/day often leads to dehydration and electrolyte imbalance)
- Weight loss or gain; gaining length/height
- Abdominal distention and flatulence
- Intense perianal rashes related to stool acidity and malabsorption of carbohydrates
- Abdominal pain and characteristics
- Vomiting and characteristics
- Diet history: appetite, oral intake, tube feeds, PN
- Central line–associated bloodstream infection (CLABSI) history (if receiving PN)
- Medication history
- Surgical history

PHYSICAL EXAM

- Weight, length, and head circumference measurements (if applicable); obtain previous growth chart if available
- Signs of vitamin deficiencies in exam of mouth, lips, skin, hair, and skeleton and in assessment of healing difficulties
- Signs of liver disease (icterus, hepatomegaly, splenomegaly, dilated abdominal veins)

- Signs of vascular thrombosis (extremity swelling, dilated veins in neck region)
- Abdominal exam: surgical scars, ostomies, distention, bowel sounds
- Rectal exam: consistency of stool, heme positivity, perianal rash

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood tests
 - CBC: Check for anemia, mean corpuscular volume.
 - Electrolytes: Check for losses and adequacy of replacement.
 - Minerals: calcium, phosphorus, magnesium, iron, zinc; check for losses and adequacy of replacement therapy
 - Albumin and prealbumin: Check for protein stores and nutritional status.
 - Liver evaluation: Alanine aminotransferase (ALT), γ -glutamyl transpeptidase (GGT), and bilirubin may be elevated in PN-associated liver disease (PNALD).
 - Vitamin levels
 - ▢ Vitamin A, 25-hydroxy vitamin D, vitamin E, RBC folate, and vitamin B₁₂; check for adequacy
 - ▢ An elevated methylmalonic acid (MMA) level is a more sensitive marker of B₁₂ deficiency but may also be elevated in small-bowel bacterial overgrowth.
 - ▢ Prothrombin time/international normalized ratio (PT/INR) indirectly measures vitamin K deficiency. PIVKa (the protein induced in vitamin K absence) is a more sensitive marker of vitamin K deficiency.
 - Carnitine: Check status if on long-term PN and presence of liver disease.
 - Breath tests: lactose and lactulose breath test to check for lactase deficiency and bacterial overgrowth, respectively
- Stool tests
 - Stool for pH and reducing substances: Check for carbohydrate malabsorption.
 - Stool smear for fat (Sudan stain—qualitative): Check for excessive fat loss.

- Stool for blood: Check for mucosal damage.
- Stool elastase: measure of pancreatic insufficiency. May be falsely depressed if watery stools (dilutional effect)
- Tests of absorption
 - D-xylose absorption test and lactose breath test to check for carbohydrate malabsorption
 - 72-hour quantitative fecal fat collection along with concomitant diet record
 - Carotene levels to check for fat absorption
 - 24-hour stool collection for α -1-antitrypsin clearance to check for protein absorption

Imaging

Upper GI series with small-bowel follow-through and barium enema to evaluate length, caliber, and location of remaining bowel

Diagnostic Procedures/Other

Endoscopy

- Upper endoscopy: Look for presence of inflammation that may be contributing to malabsorption; obtain and culture duodenal aspirates to assess for bacterial overgrowth.
- Lower endoscopy: Look for presence of colitis, especially eosinophilic colitis. Evaluate caliber and quality of anastomosis site if in colon.

DIFFERENTIAL DIAGNOSIS

- Infants: necrotizing enterocolitis, volvulus, atresia (jejunal and ileal), gastroschisis, perforated meconium ileus, congenital short-bowel syndrome, aganglionosis of the intestine
- Older children: midgut volvulus (due to malrotation), Crohn disease, adhesions causing intestinal obstruction, strictures, trauma

TREATMENT

MEDICATION

- Supplementation of deficient vitamins (E, D, K, B₁₂, folic acid) calcium, magnesium, iron, and zinc

- H₂-receptor antagonists and proton pump inhibitors decrease gastric acid hypersecretion and reduce gastric secretory volume (particularly in the postoperative period).
- Antidiarrheal drugs codeine, diphenoxylate, and anticholinergic drugs (e.g., loperamide) to decrease motility (caution in patients with slow transit or bacterial overgrowth)
- Ion-exchange resins: Cholestyramine binds intraluminal dihydroxy bile acids to prevent bile acid–induced diarrhea.
- Octreotide/somatostatin: decreases gastric, pancreatic, and intestinal secretions; slows GI motility. Use with caution, though, as may reduce splanchnic blood flow.
- Bacterial overgrowth: Commonly used oral antibiotics are metronidazole, trimethoprim-sulfamethoxazole, ciprofloxacin, vancomycin, and gentamicin.
- Prokinetic agents: Reglan to treat delayed gastric emptying. Use with caution given potential side effects.
- Ethanol lock therapy has demonstrated some preliminary success in reducing CLABSI. Therapy may be associated with an increased risk of venous thrombosis. Randomized control trials in the pediatric short-bowel population are needed.
- Miscellaneous
 - Sucralfate to treat bile reflux
 - Probiotics to treat bacterial overgrowth
 - Ursodiol for cholestasis
 - Polycitra for electrolyte losses
 - Dietary fiber to enhance absorption; caution in infancy and in patients with bacterial overgrowth

SURGERY/OTHER PROCEDURES

- Surgery is useful in patients who develop strictures and partial obstruction or in those who have very short intestine length with one or more significantly dilated segments distal to the duodenum.
- Intestinal interpositions (isoperistaltic or antiperistaltic) historically are used to delay gastric emptying, slow intestinal transit, and increase absorption but have largely fallen out of favor.
- Intestinal lengthening and tapering procedures, including the Bianchi

and serial transverse enteroplasty (STEP) procedures, increase absorptive surface area.

- In patients with extremely short intestines and PN dependency, small-bowel transplantation or multivisceral transplantation is considered. Factors favoring consideration: advanced liver disease, recurrent prolonged hospitalizations, life-threatening bloodstream infections, and loss of central venous access sites.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Signs to watch for:
 - Vomiting, diarrhea, weight loss, severe fluid and electrolyte abnormalities, sepsis, bowel dilatation, intestinal obstruction
- Major cause of death: sepsis and cholestatic liver disease

DIET

- Fluid and electrolyte therapy: extremely important in the acute phase immediately after bowel resection. In the chronic phase, it is important to keep up with ongoing losses, especially when enteral feeds are started.
- Oral diet
 - For patients who are able to avoid PN or tube feeds, a low-lactose diet may be well tolerated.
 - Low-oxalate diets are helpful in preventing oxalate stones.
 - In general, a high-calorie diet regardless of carbohydrate and fat composition should be the mainstay of treatment.
- Enteral feeds: more successful in the patient with less extensive resection, intact ICV, and colon in continuity. In extensive loss, feeds are initiated after electrolytes are stabilized.
 - Feeds started very slowly, often started with elemental diet to facilitate absorption and for concern for allergic injury.
 - Enteral feeds stimulate intestinal adaptation. Before 1 year of age, formula should have low osmolality: higher fat content than

carbohydrate.

- After 1 year of age, there is no advantage of elemental formulas over intact formulas with respect to tolerance, unless small-bowel damage is present.
- Development of oral skills and oral feeding should be encouraged when possible, as introduction of solid foods with maturity slows transit and improves enteral capacity.
- PN: important in the acute phase postoperatively, when nutrition must be maintained in the face of paralytic ileus; indispensable in the chronic phase when full enteral feeds cannot be instituted.
 - Balanced solutions of protein, glucose, and fat should be administered.
 - Prophylactic measures to prevent PN-induced liver damage should be instituted (e.g., prevention of overfeeding, early introduction of enteral feeds, cycling of PN when patient is stable, limitation of IV fat emulsion).
 - If cholestasis is present, it may be necessary to modify amount of trace elements in PN.
 - Need permanent central access to deliver concentrated PN solutions
- IV fish-based oil emulsion (composed of omega-3 polyunsaturated fatty acids) has been studied as a preventive measure against PN-associated liver disease with promising results.

PROGNOSIS

- Contingent on site and amount of bowel resected
- Adaptation is better after jejunal resection than after ileal resection.
- More extensive resection (<40 cm of residual bowel in neonatal period) and loss of the ICV portend a worse prognosis.
- Duration of PN is inversely related to prognosis.
- Most progress is made in the 1st year after bowel resection. Children who are PN dependent at 5 years of age may be unlikely to wean from PN.
- Severe PN-associated liver disease portends a poor prognosis.

COMPLICATIONS

- Fluid and electrolyte loss, resulting in diarrhea, dehydration, and

metabolic acidosis

- Calcium and magnesium deficiency, resulting in bone disease and osteoporosis
- Carbohydrate malabsorption
- Fat malabsorption
- Vitamin A deficiency: increased susceptibility to infections
- Vitamin D deficiency: rickets
- Vitamin E deficiency: peripheral neuropathy, hemolysis
- Vitamin K deficiency: prolonged clotting time, bruising
- Vitamin B₁₂: macrocytic anemia and leukopenia
- Folic acid: macrocytic anemia
- Iron deficiency: microcytic anemia
- Copper deficiency: pancytopenia
- Zinc deficiency: poor wound healing, diarrhea, poor vertical growth
- Essential fatty acid deficiency: increased susceptibility to infection, decreased energy stores
- Gallstones: due to disturbed enterohepatic circulation of bile salts and lithogenic bile formation
- Renal stones: due to fat malabsorption and increased oxalate absorption
- Failure to thrive
- TPN-dependent liver disease: cholestasis, end-stage cirrhosis, and portal hypertension
- Carnitine deficiency: contributes to development of steatosis
- Sepsis
- Small-bowel bacterial overgrowth and D-lactic acidosis due to stasis, causing encephalopathy, ataxia, and other neurologic symptoms

CODES

ICD10

K91.2 Postsurgical malabsorption, not elsewhere classified

FAQ

- Q: What are the favorable prognostic factors in short-bowel syndrome?
- A: Greater length of residual small bowel, jejunal versus ileal resection, maintenance of the ICV, and lack of PN-associated liver disease. Neonates demonstrate better bowel adaptation than do adults.
- Q: Are elemental formulas better than intact formulas in the management of patients with short-bowel syndrome?
- A: Limited case series suggest that elemental formulas may be associated with a shorter duration of PN dependence than intact formula, which may be related to a higher incidence of food allergy in the short bowel population. However, elemental formulas have a higher cost and higher osmolarity, which may exacerbate diarrhea. Animal studies suggest that intestinal adaptation is improved with nutrient complexity, suggesting that elemental formula may be inferior to intact protein formula in this regard.

SICKLE CELL DISEASE

Keith Quirolo

BASICS

DESCRIPTION

Sickle cell disease (SCD) is a hemoglobinopathy caused by a one base pair change leading to an amino acid change in the beta globin gene at the sixth position: glutamic acid to valine. The mutation allows the polymerization of hemoglobin in the red cell.

PATHOPHYSIOLOGY

- Disruption of the red cell membrane: leading to increased adhesion to vascular endothelium, activation of cytokines leading to activation of platelets and leukocytes, activation of the coagulation system leading to a hypercoagulable state and ultimately to vaso-occlusion. Red cells release red cell membrane as microparticles.
- Red cell hemolysis: release of free hemoglobin, methemoglobin production, increased plasma ferric iron leading to oxidative stress, decreased nitric oxide leading to decreased production of cyclic GMP causing vasoconstriction, inflammation, and platelet activation

EPIDEMIOLOGY

- The incidence of SCD is 1 in 500 African Americans, 1 in 36,000 Hispanics, with a lesser frequency in other ethnic groups. The incidence of sickle cell trait in African Americans is 1 in 14.
- There are 70,000–100,000 affected individuals with SCD in the United States.

RISK FACTOR

Genetics

- SCD is autosomal recessive.
- Combinations leading to the disease state when inherited with hemoglobin S: SS, SC, S beta zero thalassemia, S beta plus thalassemia, S D^{Los Angeles}, and S O^{Arab} are examples.

DIAGNOSIS

HISTORY

- At diagnosis:
 - In the US, usually diagnosed on newborn screening
 - Often asymptomatic in early infancy (<6 months) due to protective effects of residual HbF production.
 - Family history
 - History of irritability/pain
 - History of pallor
- Subsequent to diagnosis
 - SCD genotype
 - History of:
 - ▣ Surgery
 - ▣ Transfusion (red cell phenotype)
 - ▣ Hospitalizations (particularly ICU)
 - ▣ Pain (sites and usual therapy)
 - ▣ Stroke and/or transcranial Doppler (TCD) abnormalities
 - ▣ Acute chest syndrome
 - Baseline hemoglobin and pulse oximetry
 - Current medication and therapy

PHYSICAL EXAM

- Pallor of anemia with flow murmur
- Scleral icterus
- Splenomegaly, hepatomegaly
- Respiratory effort, decreased breath sounds, or wheeze: obstructive lung disease
- Decreased range of motion: hip and shoulder avascular necrosis
- Neurologic examination: stroke
- Developmental assessment

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Diagnostic
 - All states have newborn screening.

- F: thalassemia major
- FA: normal hemoglobin
- FAS: A > S: sickle cell trait
- FSA: S > A: SCD, S beta plus thalassemia
- FS: hemoglobin S: sickle cell anemia or sickle beta zero thalassemia
- FSC: hemoglobin SC disease
- FSV: sickle hemoglobin with variant hemoglobin
- Alpha gene mapping
 - Alpha thalassemia trait influences the phenotype.
- Beta gene analysis
 - Beta thalassemia and beta variants
- Monitoring
 - CBC: Degree of anemia depends on genotype, leukocytosis, elevated platelet count, low mean corpuscular volume (MCV) with beta and alpha thalassemia, elevated MCV with hydroxyurea therapy, elevated reticulocyte count corresponding to degree of anemia.
 - Hemoglobin electrophoresis: hydroxyurea and transfusion therapy
 - Chemistry panel: elevated lactate dehydrogenase (LDH), unconjugated bilirubin, aspartate aminotransferase (AST)
 - Vitamin D 25-OH level
 - TCD annually: stroke risk, 2–16 years
 - Brain MRI/MRA: abnormal TCD or neurologic findings
 - Echocardiogram: pulmonary hypertension
 - Pulmonary function testing: obstructive lung disease
 - Ophthalmology: retinopathy
 - Neurocognitive testing: stroke or school delay

TREATMENT

GENERAL MEASURES

- Infection prophylaxis with oral penicillin 125 mg b.i.d. starting by 2 months of age, 250 mg b.i.d. at 36 months
- Pneumococcal vaccine (23-valent at 2 and 5 years of age)
- Meningococcal vaccine

- Recommended routine immunizations
- Folic acid and vitamin D supplementation as indicated
- Parent teaching for fever, splenic sequestration, anemia, stroke, acute chest, and home pain management
- Hospital pain management plan

ADDITIONAL TREATMENT

- Hydroxyurea: Patients who have two or more acute events leading to hospitalization a year or more frequent pain events not leading to hospitalization are considered for treatment.
 - Beginning doses are between 15 and 20 mg/kg/24h. If needed, increase dose by 5 mg/kg/24h every 2–6 months up to a maximum of 35 mg/kg/24h or 2,500 mg/24h (whichever is less).
 - Monitor initially at 2 weeks and 1 month.
 - Without toxicity, monitor every 2 months.
- Red cell transfusion can prevent complications, morbidity, and are lifesaving.
 - Phenotypically matched red cells (for ABO, D, C, c, E, e, Kell) decreases alloimmunization.
 - Optimum hemoglobin is 9–10 g/dL, higher levels increase viscosity, decrease oxygenation.
 - Percentage of hemoglobin S should be <30% in acute disease, for stroke and stroke prevention.
 - With elevated hemoglobin or when a low percent S is indicated, exchange transfusion is required.
 - Transfusion iron overload: All patients are monitored and treated with oral chelation.
- Progenitor cell transplant is the only cure for SCD.
 - Full siblings: HLA typing for the patient and the prospective donor
 - Cord blood collection for full siblings
 - Consultation with a transplant physician familiar with transplantation for sickle cell anemia

INPATIENT CONSIDERATIONS

- Fever
 - Patients with SCD and fever are presumed septic.

- History, physical exam, CBC with reticulocytes, blood culture, chest x-ray, urine culture, and other cultures as indicated
 - Parenteral antibiotic: (ceftriaxone) until culture negative
 - Children younger than the age of 3 years, admitted to hospital
 - Older children and adolescents with a benign examination, no pulmonary infiltrate, or urinary tract infection: ceftriaxone follow-up in 24 hours
- Acute chest syndrome
 - Defined as a new pulmonary infiltrate frequently accompanied by hypoxia, pain, fever, and severe anemia
 - Treat for fever (above).
 - Type and cross
 - Transfusion for severe anemia, progressive infiltrate, hypoxia
 - Add microlide antibiotic.
 - Oxygen to maintain O₂ saturation 95%.
 - Fluid overload can exacerbate pulmonary disease, monitor I and O.
 - Incentive spirometry q2h
- Pain (vaso-occlusive episode)
 - Severe pain is a medical emergency.
 - Hydration: 1.5 maintenance, avoid fluid overload.
 - Incentive spirometry: q2h
 - Pain assessment on pain scale
 - Analgesics
 - Mild pain: NSAIDs and mild oral opioids (20% will not metabolize codeine normally)
 - Moderate pain: may need parenteral therapy with opioids and ketorolac
 - Severe pain: admission with patient-controlled analgesia (PCA) parenteral opioids, may need antihistamine, ketorolac, H₂ blocker with ketorolac
 - Pain assessment after administration of medications
 - Adjunctive therapy: heating pad, visualization, distraction, other therapy
- Acute anemia
 - Parvoviral infection

- History of decreased energy, pallor
 - Exam with tachycardia, pallor
 - CBC with reticulocyte count: anemia with reticulocytopenia
 - Type and cross
 - Transfusion for severe anemia or cardiovascular compromise
 - Parvoviral B19 titers
 - Isolation precautions
- Splenic sequestration
 - History of decreased energy, pallor
 - Exam with splenomegaly
 - CBC with reticulocyte count: anemia with reticulocytosis
 - Slow transfusion for severe anemia or cardiovascular compromise: Spleen releases red cells increasing hemoglobin and viscosity.
 - Splenectomy for life-threatening or repeated episodes: Immunize prior to splenectomy.
- Stroke
 - Diagnosis by history and physical examination
 - Treatment should not be delayed for imaging.
 - Evidence suggests initial exchange transfusion, to hemoglobin of 9–10 g/dL, percent hemoglobin S of less than 30%, leads to improved long-term outcome.
 - All patients should have brain MRI and MRA urgently and be evaluated by neurology and physical therapy.
 - Eventually, all patients should have neuropsychological testing.
 - Chronic transfusion for life
- Intracranial hemorrhage
 - Initially present with headache only
 - CT scan is diagnostic.
 - More common in adolescents
 - History of cerebral vascular disease
 - Neurosurgical consultation
 - Exchange transfusion is indicated.
 - Prognosis is poor if not aggressively treated.
 - Chronic transfusion for life
- Stroke risk

- Abnormal TCD
- Time average maximum mean velocity: 200 cm/s or greater
- Transfusion to hemoglobin of 10 g/dL
- MRI–MRA for cerebral vascular disease or ischemic brain injury
- Transfusion for life with or without findings on MR
- Priapism
 - Diagnosis: unwanted erection with pain lasting for longer than 1 hour
 - Medical emergency
 - Initial management: pain management, intravenous hydration
 - Treatment with subcutaneous terbutaline has been used.
 - Definitive treatment: is aspiration and instillation of pseudoephedrine

ONGOING CARE

PROGNOSIS

The prognosis for children with sickle cell disease has improved dramatically due to hydroxyurea therapy, increased use of blood transfusion, and screening. Transition to adult care is a priority.

- Chronic complications:
 - Cholecystitis
 - Avascular necrosis (hip and shoulder)
 - Obstructive pulmonary disease
 - Pulmonary hypertension
 - Renal disease (proteinuria)
 - Hyposthenuria (enuresis, dehydration)
 - Retinopathy (increased: SC disease)
 - School failure due to hospitalization
 - Cerebral vascular disease/infarcts

CODES

ICD10

- D57.1 Sickle-cell disease without crisis
- D57.3 Sickle-cell trait
- D57.40 Sickle-cell thalassemia without crisis

FAQ

- Q: When can I stop penicillin prophylaxis?
- A: Most morbidity and mortality from infections in sickle cell anemia occur in the first 5 years of life. The risk of pneumococcal sepsis decreases with age but continues to be a significant risk of morbidity and mortality. Patients with surgical splenectomy need penicillin prophylaxis for life.
- Q: Are phenotypically matched red cells necessary for transfusion?
- A: Historically, the incidence of red cell alloimmunization is 30% for patients with SCD who do not receive phenotypically matched red cells. By providing phenotypically matched red cells, the rate of alloimmunization is significantly decreased.

SINUSITIS

Esther K. Chung • Julia Belkowitz

BASICS

DESCRIPTION

- Sinusitis is inflammation of the mucous membranes lining the paranasal sinuses.
- The term is most commonly used to describe bacterial rhinosinusitis, which is a clinical diagnosis made by the presence of upper respiratory tract symptoms that have not improved in 10 days or have worsened after 5–7 days. Diagnosis of sinusitis should be considered based on persistence and/or severity of symptoms.
- Classification based on duration of symptoms:
 - Acute: persistent nasal and sinus symptoms for 10–30 days; worsening or new onset of nasal discharge, daytime cough, or fever after initial improvement; or concurrent high fever and purulent nasal discharge for the first 3–4 days of an acute upper respiratory tract infection (URI)
 - Subacute: clinical symptoms for 30–90 days
 - Chronic: symptoms lasting >90 days
 - Recurrent: acute sinusitis with complete resolution of 10 days between episodes; 3 episodes in 6 months or 4 episodes in 1 year
- Classification by severity of illness:
 - Persistent: >10–14 days but <30 days; nasal discharge and/or daytime cough
 - Severe: temperature of $\geq 39^{\circ}\text{C}$ (102.2°F) with concurrent purulent nasal discharge for ≥ 3 days and/or facial pain, headache, or periorbital edema

GENERAL PREVENTION

- Avoid allergen exposure and treat allergies if present.
- Improve mucociliary clearance by increasing ambient humidity with a humidifier.

PATHOPHYSIOLOGY

- Normal sinus function depends on patency of paranasal sinus ostia, function of the ciliary apparatus, and secretion quality.
- A buildup of secretions is due to ostial obstruction, reduction in ciliary function, and overproduction of secretions.
- Viral URIs and/or allergic rhinitis often precede an acute bacterial infection.

ETIOLOGY

- Viral pathogens (e.g., rhinovirus, parainfluenza virus) have been recovered in respiratory isolates, but their significance is unknown.
- Most illnesses of short duration (<7 days) are thought to be from viral infections and should not be treated with antibiotics.
- Chronic sinusitis often secondary to allergic rhinitis, cystic fibrosis, environmental pollutants, or gastroesophageal reflux
- Bacterial pathogens: with an increasing prevalence of penicillin resistance
- Most common pathogens:
 - *Haemophilus influenzae*, nontypeable
 - *Streptococcus pneumoniae*
 - *Moraxella catarrhalis*
- Other pathogens:
 - Group A streptococci
 - Group C streptococci
 - *Peptostreptococci*
 - Other *Moraxella* species
 - *Streptococcus viridans*
 - *Eikenella corrodens*
 - *Staphylococcus aureus*
 - *Pseudomonas aeruginosa* (in patients with cystic fibrosis)
 - Anaerobic organisms
 - Polymicrobial
 - Fungal pathogen: *Aspergillus*

DIAGNOSIS

HISTORY

- Previous sinusitis, previous antibiotic use, allergies, child care attendance
- Key symptoms to differentiate from viral URI:
 - Duration of symptoms >10 days or worsening of symptoms after initial improvement
 - Onset of fever, especially with a duration of ≥ 3 –4 days, facial pain, purulent discharge at onset
- Some or all of the following may be present:
 - Nasal discharge: consistency, color. In older patients, nasal discharge may not be the primary complaint, but concurrent rhinitis is a common feature.
 - Postnasal drainage, nasal congestion
 - Fever
 - Recent history of a URI
 - Sore throat from mouth breathing due to nasal obstruction
 - Cough present during the day; may be worse at night
 - Malodorous breath
 - Hyposmia/anosmia
 - Maxillary dental pain
 - Facial swelling
 - Ear pressure or fullness
 - Headache and facial pain are uncommon in young children with sinusitis but may be seen in older children and adolescents.
 - Fatigue
 - Irritability
 - Snoring
 - Hyponasal speech

PHYSICAL EXAM

- Fever may be present.
- Nasal-sounding voice may be present.
- Malodorous breath may be noted but is not a specific indicator of sinusitis.
- Purulent drainage in the nose and/or oropharynx may be appreciated.
- Nasal mucosa may be erythematous, pale, and/or boggy, but these are

nonspecific findings.

- Frontal, maxillary, and ethmoid areas may be tender to palpation/percussion.
- Headache and/or facial pain may change with position, increasing in intensity as the patient leans forward.
- Transillumination is not a reliable aid in diagnosis.
- Proptosis, eye swelling, and impaired extraocular movements suggest orbital infection.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Gold standard is culture from sinuses via direct aspiration/ endoscopy; not indicated for diagnosis of acute, uncomplicated sinusitis
- For chronic or recurrent sinusitis, consider
 - Sweat chloride test to rule out cystic fibrosis
 - Immunoglobulin levels, IgG subclass levels, complement levels, and testing for human immunodeficiency virus (HIV) infection
 - Mucosal biopsy to assess ciliary function

Imaging

- Imaging is not recommended in uncomplicated cases of sinusitis.
- Sinus radiographs are of limited value with the exception of the Waters (occipitomental) view for identifying maxillary sinusitis.
 - Plain radiographs do not adequately identify ethmoid sinusitis.
 - Findings suggestive of sinusitis include complete sinus opacification, mucosal thickening ≥ 4 mm, and air–fluid levels.
- CT scan with contrast of the paranasal sinuses: useful in complicated, recurrent, and chronic sinusitis and/or history of polyposis
- CT scan of the head with contrast: indicated when sinusitis is accompanied by signs of increased intracranial pressure, meningeal irritation, proptosis, toxic appearance, limited extraocular movements, or focal neurologic deficits or in patients being considered for sinus-related surgery
- MRI of the sinuses: reserve for complicated cases and in immunocompromised patients in which fungal infection is suspected; will show mucosal thickening and fluid

- MRI with contrast of the head, as an alternative or adjunct to CT with contrast, when intracranial complications are suspected
- Pitfalls
 - Sinus radiographs may be abnormal in asymptomatic children or those with mild URIs.
 - Studies have shown a relatively high incidence of sinus abnormalities on CT scan in asymptomatic children, especially in infants <12 months of age. The significance of opacified sinuses in asymptomatic children is not well understood.
 - Up to 1/3 of patients with symptoms of chronic sinusitis may have normal CT scans.

DIFFERENTIAL DIAGNOSIS

- Infection: viral URI with or without mucopurulent rhinitis
- Environmental: allergic rhinitis
- Drug-induced: rhinitis medicamentosa
- Tumors
 - Nasal polyps
 - Hypertrophied adenoids
 - Neoplasms
- Trauma: foreign body (e.g., bead, cotton, tissue paper)
- Congenital
 - Septal deviation
 - Unilateral choanal atresia
 - Dysmotile cilia syndrome
- Dental disorder
- Other: vasomotor rhinitis

TREATMENT

GENERAL MEASURES

- New guidelines support the option of observing children with persistent symptoms, but not those with worsening or severe symptoms, for 3 days before treating with antibiotic therapy.
- If orbital or CNS infection is suspected by history and examination,

antibiotics should be started immediately, and emergency CT studies should be performed.

- Pitfalls
 - Diagnosis of sinusitis is being made with increasing frequency and may result in overtreatment, given that up to 50% will have spontaneous resolution.
 - With widespread antibiotic use, there are increasing numbers of resistant organisms.

MEDICATION

- Antibiotics
 - Appropriate drug choice depends on local resistance patterns.
 - High-risk children include age <2 years, hospitalization, antibiotic use within 3 months of diagnosis, and child care attendance.
 - 1st-line treatment: amoxicillin 45 mg/kg/day or 80–90 mg/kg/24 h of amoxicillin if high risk, local pneumococcal resistance >10%, severe symptoms or comorbidity, divided twice daily with a max of 2 g/dose
 - For non-type I penicillin allergy (late or delayed, >72 hours) or type I allergy (anaphylaxis) in children age 2 years and older, cefdinir (14 mg/kg/day), cefpodoxime (10 mg/kg/day), or cefuroxime axetil (30 mg/kg/24 h divided twice daily) may be used.
 - For type I penicillin allergy in children age <2 years, consider clindamycin combined with cefixime to cover resistant bacteria.
 - Macrolides and trimethoprim-sulfamethoxazole are not recommended due to high resistance rates.
 - Duration of treatment should be for 10 (minimum) to 28 days (and until 7 days beyond symptom resolution).
 - Consider changing antibiotic coverage and/or obtaining a culture if symptoms do not improve after 3–5 days of antibiotics, especially in a hospitalized patient.
 - Complicated sinusitis (CNS or orbital involvement) or children with toxic appearance: IV antibiotics and hospitalization; ceftriaxone (100 mg/kg/24 h in 2 doses) or ampicillin-sulbactam (200–400 mg ampicillin component/kg/day in 4 divided doses); cefotaxime 100–200 mg/kg/day divided every 6 hours or, if no other alternative,

- levofloxacin 10–20 mg/kg/day divided every 12–24 hours
- If a hospitalized, ill child is not improving on the IV antibiotics listed above, consider adding vancomycin (60 mg/kg/24 h divided into 4 doses) for penicillin-resistant *S. pneumoniae* +/- metronidazole (30 mg/kg/24 h divided into 4 doses) for anaerobic coverage.
 - Chronic sinusitis: consider broad-spectrum antibiotic (amoxicillin/clavulanate [80–90 mg/kg/24 h of amoxicillin divided in 2 doses]) for at least 3 weeks and use of adjuvants such as saline irrigation or intranasal steroids; consider culture if no resolution after 1 week of treatment.
 - Other pharmaceuticals:
 - Decongestants and antihistamines are not recommended due to side effects and lack of evidence of clinical improvement with use.
 - Mucolytics, such as guaifenesin, may improve mucous clearance.
 - Topical nasal steroids: may reduce and prevent mucosal swelling, which can lead to ostial occlusion, in patients with allergic rhinitis
 - Other treatments:
 - Humidifier: may improve mucociliary clearance
 - Normal saline: Although there is no evidence to support its efficacy in acute sinusitis, saline irrigation and or spray is used by some for symptom relief; increases humidity and enhances mucociliary transport; vasoconstricts and improves drainage and ventilation

SURGERY/OTHER PROCEDURES

- Maxillary sinus aspiration: if unresponsive to multiple antibiotics, severe facial pain, and orbital or intracranial complications; should be performed by a trained ear, nose, and throat (ENT) specialist
- Surgery: performed as a last resort after medical therapy attempted and in patients with orbital or CNS complications

ONGOING CARE

PROGNOSIS

- Spontaneous resolution in up to 50% of patients

- Usually improves within 72 hours of initiation of antibiotics
- Excellent for those who are otherwise healthy

COMPLICATIONS

- Periorbital cellulitis
- Orbital cellulitis
- Orbital abscess
- Subperiosteal abscess
- Meningitis
- Intracranial abscess
- Optic neuritis
- Cavernous or sagittal sinus thrombosis
- Epidural, subdural, and brain abscess(es)
- Osteomyelitis of the maxilla
- Osteomyelitis of the frontal bone (Pott puffy tumor)

PATIENT MONITORING

- Immediate referral is indicated if there are CNS symptoms, periorbital edema, visual changes, facial swelling, extraocular muscle involvement, or proptosis.
- Radiographic soft tissue changes may last for up to 8 weeks; therefore, reimaging is of limited value.
- Referral to an otolaryngologist (ENT specialist) when sinusitis is chronic and not responsive to medical therapy, recurrent, complicated, or when there is polyposis

CODES

ICD10

- J32.9 Chronic sinusitis, unspecified
- J01.90 Acute sinusitis, unspecified
- J01.10 Acute frontal sinusitis, unspecified

FAQ

- Q: Are all of the sinuses present at birth?
- A: No. The maxillary and ethmoid sinuses form during the 3rd and 4th gestational months and are present at birth. They continue to enlarge until the preteen years. The sphenoid sinuses are pneumatized by 5 years; isolated sphenoid sinusitis is rare. The frontal sinuses are present at age 7–8 years and are not completely developed until late adolescence.
- Q: Does the nasal discharge seen with sinusitis have to be purulent and thick?
- A: No. Although the nasal discharge is often described as purulent and thick, it may also be clear or mucoid or thick or thin. Multiple studies have shown that a change in color or consistency is not a specific sign of a bacterial infection.
- Q: Are radiographic studies useful in the diagnosis of sinusitis?
- A: There is evidence to suggest that plain radiographs (x-rays) have limited value in the diagnosis of sinusitis and are not recommended in

cases of uncomplicated sinusitis. Mucosal thickening may be seen with viral URIs and allergic rhinitis. Studies have shown that x-rays do not correlate well with CT scans in the diagnosis of chronic sinusitis.

- Q: Can one make the diagnosis of sinusitis based on CT scan results alone?
- A: No. Up to 50% of patients who had CT scans performed for other reasons had soft tissue changes in their sinuses. Mucosal thickening and opacification on CT imaging have been seen in large numbers of asymptomatic patients. These findings seem to occur more frequently in infants younger than 12 months of age. Given the poor specificity of CT imaging of the paranasal sinuses, results must be used in the context of the patient's clinical presentation.

SLEEP APNEA—OBSTRUCTIVE SLEEP APNEA SYNDROME

Akinyemi O. Ajayi

BASICS

DESCRIPTION

- Sleep-disordered breathing encompasses a range of breathing disorders occurring during sleep. These conditions include primary snoring (PS), respiratory events related to arousals (RERA), and obstructive sleep apnea syndrome (OSAS).
- Obstructive apnea is defined as the cessation of airflow at the nose and mouth despite respiratory effort, associated with some gas exchange abnormality and/or loss of regular sleep patterns.

PHYSIOLOGY

- OSAS may be subdivided into mild, moderate, and severe forms.
- Many children with OSAS exhibit partial airway obstruction. This is known as obstructive hypoventilation or hypopnea and is more commonly seen in children than is complete obstruction.
- OSAS is distinct from central apnea (cessation of airflow that is not accompanied by respiratory effort), which indicates brain immaturity or dysfunction.
- Upper airway resistance syndrome is a respiratory disorder characterized by partial airway obstruction and arousals leading to sleep fragmentation and is not associated with gas exchange abnormalities.
- Central apnea up to 20 seconds may be a normal finding in premature or newborn infants during the 1st month of life.
- Periodic breathing: 3 or more episodes of central apnea lasting at least 3 seconds each, separated by <20 seconds. Periodic breathing may be found in the newborn; however, it should not exceed >4% of sleep time (from a sleep study) and is not associated with bradycardia or hypoxemia.

RISK FACTORS

- In infants, OSAS is uncommon; however, it may exist with craniofacial anomalies, neurologic disorders associated with low muscle tone, laryngomalacia or tracheomalacia, and gastroesophageal reflux.
- Impaired arousal mechanisms also contribute to abnormalities seen in OSAS.
- In older children, OSAS may be associated with obesity. This form may resemble the adult type of OSAS.
- PS or habitual snoring implies snoring that does not lead to abnormalities in gas exchange or sleep fragmentation; however, 20–50% of children with habitual snoring may have OSAS.

Genetics

- Several genetic disorders with associated craniofacial anomalies, hypotonia, and obesity may lead to OSAS. These include the following:
 - Pierre Robin syndrome
 - Treacher Collins syndrome
 - Down syndrome
 - Mucopolysaccharide disorders
 - Arnold-Chiari malformations
 - Prader-Willi syndrome
 - Hereditary neuromuscular disorders

COMMONLY ASSOCIATED CONDITIONS

- Adenotonsillar hypertrophy
- Craniofacial anomalies including midfacial hypoplasia and mandibular hypoplasia
- Laryngomalacia
- Neurologic and neuromuscular disorders that cause hypotonia may underlie poor ventilation during sleep.
- Gastroesophageal reflux
- Obesity
- Metabolic disorders
- Allergic rhinitis, nasal septum deviation, nasal polyps
- Sedatives, seizure medications, and anesthesia

DIAGNOSIS

HISTORY

- Nocturnal symptoms include difficulty breathing when asleep, snoring, apnea, and restless sleep with frequent arousals.
- Daytime symptoms: excessive sleepiness, frequent upper respiratory/ear infections, conductive hearing loss, mouth breathing, poor appetite, and a hyponasal voice
- Other concerns: attention-deficit/hyperactivity disorder (ADHD), gastroesophageal reflux, poor school performance, and headaches (especially in the morning and upon awakening)
 - OSAS rarely produces these symptoms acutely but tends to occur over weeks to months.
 - Parents may notice that symptoms worsen with upper respiratory infections.
- The possibility of sleep-disordered breathing or a primary sleep disorder should be considered in children evaluated for ADHD.

PHYSICAL EXAM

- Assessment of the child's growth. In severe cases of OSAS, failure to thrive has been reported.
- Obesity remains a risk factor, especially in older children.
- Assessment of tonsillar size

ALERT

Normal-sized tonsils do not exclude OSAS.

- Presence of mouth breathing, hyponasal speech, adenoidal facies, midfacial hypoplasia, retrognathia, micrognathia, or other craniofacial anomalies may be present at times and may suggest the diagnosis.
- Nasal obstruction due to polyps, nasal septum deviation, turbinate hypertrophy, or congestion
- Tongue size
- Mobility and elevation of the soft palate; hard palate integrity
- In extreme cases, cardiac involvement may lead to cor pulmonale and heart failure. Examination may suggest signs of pulmonary

hypertension or congestive heart failure, such as an increased second heart sound.

- A neurologic examination to evaluate general muscle strength, tone, and developmental status, especially in infants and children who do not improve after adenotonsillectomy

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Polysomnography
 - The gold standard for the diagnosis of OSAS is nocturnal polysomnography to differentiate the type of sleep apnea and to assess severity.
 - Polysomnography is an 8–10-hour-long multichannel study performed in a controlled setting to assess respiratory and/or sleep abnormalities.
 - Indices such as oxygenation, ventilation, apnea index (AI), apnea–hypopnea index (AHI), arousal index, arousal awakening index, and periodic limb movements index are determined along with sleep efficiency and sleep stages.
 - Monitoring includes electroencephalogram, electrooculogram, electromyogram, arterial oxygen saturation, end tidal CO₂ tension, airflow, respiratory effort, and electrocardiogram.
 - Normative respiratory and sleep variables for children have recently been published and include an AHI of <1 being normal.
 - Scoring for pediatric polysomnography differs from that of adults. This includes using 2 respiratory cycles to define both obstructive apnea and central apnea or 2 respiratory cycles associated with a 30% decline in airflow and a >4% decline in oxygen level to define hypopnea. Lower AHI values are considered significant in children compared with adults.
- Other studies
 - Validated questionnaires are helpful to screen for OSAS in the office.
 - Routine blood work is generally noncontributory; in severe forms, polycythemia, hypercarbia, and elevated bicarbonate may be noted.
 - Evaluation for gastroesophageal reflux may include pH monitoring

- during sleep, barium swallow, or radionuclide studies (milk scan).
- Home testing is not approved for use in children with suspected OSAS.

Imaging

- Lateral neck x-ray is easy to perform to assess adenoid and tonsillar size as well as patency of the nasopharyngeal airway.
- Nocturnal audio- and videotaping, as well as abbreviated nap polysomnography, are useful studies if the results are positive but generally have a poor negative predictive value.
- Upper airway endoscopy as well as bronchoscopy may be performed to evaluate anatomic or dynamic causes for airway obstruction (pharyngeal hypotonia, pharyngeal stenosis, laryngotracheomalacia, vocal cord polyps, papilloma).
- Head or neck computed tomography or magnetic resonance imaging (MRI) should be considered for complex craniofacial anomalies. If central apnea is noted, then MRI studies should also evaluate the brainstem to evaluate for an Arnold-Chiari malformation.
- In severe cases of OSAS, a cardiac evaluation, including electrocardiogram, chest x-ray, and echocardiogram, may be indicated.

DIFFERENTIAL DIAGNOSIS

- PS or habitual snoring
- Upper airway resistance syndrome: This condition is associated with sleep fragmentation and daytime sleepiness.
- Obesity–hypoventilation syndrome: a variant of OSAS
- Central apnea and periodic breathing
- Congenital central hypoventilation syndrome
- Other causes of excessive daytime sleepiness include the following:
 - Disorganized home environment, emotional stress
 - Substance abuse/drug intoxication: psychotropic medications, antihistamines, anticonvulsants, narcotics
 - Narcolepsy: Onset typically around adolescence, but cataplexy may occur later and delay the diagnosis.
 - Epilepsy: absence spells of unresponsiveness, electroencephalogram changes

- Causes of obstructive apnea include any cause of lymphoidal hypertrophy in the upper airway (allergies, viral/bacterial tonsillitis, neoplasm, epiglottitis, retropharyngeal abscess), chronic phenytoin exposure, and excessive storage material in upper airway submucosa.
- Causes of abnormal laxity of upper airway soft tissues: Down syndrome, acute polyneuropathy (Guillain-Barré syndrome), chronic neuromuscular disease, Prader-Willi syndrome, myasthenia gravis
- Causes of abnormal control/coordination of upper airway musculature: almost any cause of diffuse CNS dysfunction, including cerebral palsy and acquired lesions of the CNS such as stroke and head trauma
- Causes of central apnea: beyond infancy, most commonly due to drugs that suppress ventilatory drive; in premature infants, may be due to nonspecific immaturity of neural ventilatory control mechanism; sepsis, seizures, brainstem compression, brain tumors, Arnold-Chiari type 2 (although increasingly seen with type 1)
- Gastroesophageal reflux may potentiate central apnea and should be investigated.
- Androgen steroids may cause central apnea in adults.

TREATMENT

INITIAL STABILIZATION

- Severe cases may require urgent intervention.
- Severe cases of upper airway obstruction are usually diagnosed during polysomnography or during procedures involving sedation or anesthesia.
 - Ensure adequate ventilation and oxygenation, with quick assessment of the cause.
 - Temporary relief of the obstruction should be undertaken by an experienced team.
 - Transfer to an intensive care unit where the airway can be monitored carefully
 - Following relief of airway obstruction, pulmonary and airway edema, as well as copious secretion production, may develop.
 - Modalities of care should include placement of a nasopharyngeal

airway, noninvasive ventilation with continuous positive airway pressure/bilevel positive airway pressure (CPAP/BiPAP), or placement of an endotracheal tube for mechanical ventilation.

- Risk factors for postoperative complications in children with OSAS include age <3 years, severe OSAS, pulmonary hypertension, obesity, prematurity, failure to thrive, craniofacial or neuromuscular disorders, and/or upper respiratory tract infection.

GENERAL MEASURES

- In most cases, adenotonsillectomy is 1st-line therapy. However, some patients continue to have significant postoperative OSAS that requires further evaluation.
- Noninvasive ventilatory support with CPAP or BiPAP may be helpful.
- Intranasal steroids and leukotriene modifiers have been shown to have a positive effect in children with mild sleep apnea. Duration of use and long-term outcomes remain unclear.
- In complicated cases, when craniofacial malformations are involved, surgical procedures such as tongue reduction, uvulopalatopharyngoplasty, or mandibular or maxillary advancement may be indicated.
- When there is evidence of gastroesophageal reflux, treatment with acid-suppression agents and chalcia precautions are indicated.
- Weight loss may be useful in obese children.
- Laser surgery and dental appliances may be useful in adults with mild OSAS, but there is no experience with these approaches in children.
- In extreme cases, a tracheostomy may be indicated, especially when significant craniofacial abnormalities exist.

ALERT

Treatment of gastroesophageal reflux in infants with obstructive apnea may be helpful even in the absence of obvious symptoms of reflux.

ONGOING CARE

COMPLICATIONS

Complications are due to chronic hypoxemia, hypercarbia, acidosis, as

well as impaired sleep and include the following:

- Pulmonary hypertension, later cor pulmonale (rare)
- Systemic hypertension has been reported in adults and a few pediatric cases.
- Congestive heart failure; arrhythmias are common in adults with underlying coronary artery disease.
- Neurodevelopmental complications: daytime somnolence, poor school performance, hyperactivity, and social withdrawal
- Poor growth and failure to thrive
- Postanesthesia respiratory failure and death have been reported in children with OSAS.

FOLLOW-UP

- Clinical improvement is expected soon after adenotonsillectomy. In children <1 year of age with severe forms of OSAS, underlying craniofacial anomalies, or neurologic disorders, repeat overnight polysomnography is indicated 6–8 weeks after surgery.
- Regrowth of adenoid tissue may occur months to years after adenoidectomy. Therefore, if clinical symptoms, such as snoring, difficulty breathing while asleep, or a decline in school performance recur, a reevaluation is indicated.

FAQ

- Q: Can my child still have OSAS after adenotonsillectomy?
- A: Yes. At times, the adenoid tissue can grow back again. In addition, some cases of OSAS are related to a small upper airway that is restricted by anatomic or neurologic conditions. In these cases, adenotonsillectomy will not always resolve OSAS.
- Q: Does OSAS cause neurologic problems?
- A: Several studies suggest neurocognitive deficits in children with OSAS. The most common findings include reduced school performance and ADHD.

SLIPPED CAPITAL FEMORAL EPIPHYSIS

David D. Sherry

BASICS

DESCRIPTION

Slipped capital femoral epiphysis (SCFE) is displacement of the epiphysis of the head of the femur.

EPIDEMIOLOGY

- Males > females (3:2)
- Left hip twice as often as right, 25% bilateral
- Associated with obesity, increased height, genital underdevelopment, pituitary tumors, growth hormone therapy

Incidence

- 1–5 per 100,000
- Age of onset: boys, 14–16 years; girls, 11–13 years (essentially, premenarche)

RISK FACTORS

Genetics

5% of children affected have a parent with SCFE.

PATHOPHYSIOLOGY

- Unclear: abnormal stress on normal physeal plate versus a process that weakens the plate
- The femoral head slips posteriorly and inferiorly, exposing the anterior and superior aspects of the metaphysis of the femoral neck.

COMMONLY ASSOCIATED CONDITIONS

- Obesity
- Endocrine dysfunction
- Primary hypothyroidism
- Pituitary dysfunction
- Hypogonadism
- Cryptorchidism

- Chemotherapy
- Pelvic radiotherapy
- Renal rickets

DIAGNOSIS

HISTORY

Pain in hip or knee

ALERT

Hip pain may be absent; there may be no pain, or only thigh or knee pain due to referred pain.

- Occasional history of trauma; however, usually not sufficient to explain the findings
- 3 patterns
 - Chronic: most common, onset of symptoms >3 weeks, lack of full internal rotation of hip
 - Acute: sudden onset with inability to walk or severe pain and difficulty walking
 - Acute-on-chronic: sudden exacerbation of symptoms that have been present for a while

PHYSICAL EXAM

- Limp if unilateral or waddling gait if bilateral
- Positive Trendelenburg sign
- Tenderness and occasional palpable thickening over hip
- Thigh atrophy
- Lack of full internal rotation of hip and decreased motion in all planes secondary to mechanical limitation due to the slip
- Maneuver: When the hip is flexed, the thigh is forced into external rotation.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Anteroposterior and lateral view (frog leg or Lowenstein)
- Measure degree of displacement.

- Minimal: alteration in plane of epiphysis relative to femoral neck; significant if angle <82 degrees
- Mild: displacement <1 cm
- Moderate: displacement >1 cm, $<2/3$ diameter of femoral neck
- Epiphyseal plate widened and irregular
- Decreased height of physis
- “Blanch sign”: dense area in femoral neck
- A “Klein line” drawn along the superior femoral neck on the anteroposterior view should transect the epiphysis but not on the slipped side.
- Hormonal evaluation if suspected

Pathologic Findings

Histologic findings include widening of the epiphyseal plate, large clefts, and necrotic debris in the cartilage and synovitis.

DIFFERENTIAL DIAGNOSIS

- Septic arthritis of the hip
- Ischemic necrosis (Legg-Calve-Perthes)
- Tuberculosis of the hip; however, pain is associated with movement in all directions, and there should be other evidence of disease.
- Renal rickets
- Achondroplasia
- Shwachman syndrome: metaphyseal chondrodysplasia with pancreatic insufficiency

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Designed to prevent complications and further slipping; urgent orthopedic consultation mandatory
- Conservative: bed rest with traction; probably does not reduce slipping; temporizing until surgery can be scheduled
- Manipulative reduction: risk of damage to epiphyseal vessels or breakdown of callus, probably only to be considered if within 24 hours

of acute slip

- Epiphyseal fixation: risk of damage to articular surface or growth plate
- Intertrochanteric osteotomy
- Salvage: hip fusion

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Chondrolysis and avascular necrosis are uncommon side effects of slipped capital femoral epiphysis.

COMPLICATIONS

- Ischemic necrosis of epiphysis
 - Usually due to manipulative reduction of the slippage
 - More common in males
 - Radiographs reveal increased density, irregularity, and ultimately collapse of epiphysis.
- Chondrolysis (acute cartilage necrosis)
 - Seen in 1–40%
 - More common in females and blacks
 - Etiology unclear
 - Radiographs reveal narrowed joint space, sclerosis of acetabular rim, and osteoporosis of femoral head.

PROGNOSIS

- Most patients with SCFE can return to activities 3–6 months postoperatively.
- Compared to chronic SCFE, acute SCFE has higher likelihood of poor outcome.
- Satisfactory outcomes associated with in situ fixation of chronic SCFE

SMALLPOX (VARIOLA VIRUS)

Hamid Bassiri

BASICS

DESCRIPTION

- Smallpox is a life-threatening, acute, eruptive, contagious disease caused by variola virus.
- The disease is characterized by a febrile prodrome followed by the development of rash.
- Rash evolves in a characteristic fashion: macules → papules → vesicles → pustules; scabs form and fall off, leaving scars called pockmarks.
- There are 2 clinical forms of smallpox:
 - Variola minor is a less common and less severe form of disease.
 - There are 5 types of variola major, the more common and serious form of disease.
 - Ordinary smallpox
 - Modified smallpox
 - Flat smallpox
 - Hemorrhagic smallpox
 - Variola sine eruptione

EPIDEMIOLOGY

- The last documented case of endemic smallpox was in Somalia in 1977.
- The last case in the United States was in the late 1940s.
- Smallpox was declared eradicated by the World Health Organization in 1979.
- Historically in unvaccinated individuals, ordinary smallpox accounted for 90% of cases, hemorrhagic smallpox for 7% of cases, and flat and modified smallpox for the remainder.
- Modified smallpox was rare in unvaccinated individuals but accounted for 25% of cases of disease in vaccinated individuals.

GENERAL PREVENTION

- Prior to 1972, all U.S. children were vaccinated.
- Vaccines were produced from the vaccinia virus, a closely related orthopoxvirus to variola.
- Historically, the vaccine was prepared from virus grown on the skin of animals, and in some cases, the vaccine was contaminated with animal proteins, bacteria, and other viruses.
- Newer smallpox vaccines are developed from vaccinia clones grown in tissue culture and therefore are free of contamination from bacteria and other viruses.
- Only laboratories in the United States and Russia currently have stockpiles of smallpox virus.
- Due to concern for use of smallpox as an agent of bioterrorism, the U.S. Strategic National Stockpile still stores smallpox vaccine.
- The only currently FDA-licensed smallpox vaccine, ACAM2000 (which replaced Dryvax), is used for active immunization of persons determined to be at highest risk for infection.
- The Advisory Committee on Immunization Practices recommends smallpox vaccination for the following:
 - Public health response teams responsible for investigating suspected smallpox cases
 - Hospital-based health care teams responsible for assessing and caring for suspected smallpox cases
- Vaccine efficacy
 - 95% efficacious in preventing disease if given prior to exposure
 - May prevent smallpox or decrease severity if given 1–3 days after exposure
 - May decrease severity of disease if given 4–7 days after exposure
- Vaccination is estimated to provide protective immunity for 3–10 years but may decrease the severity of disease for 10–20 years.
- Vaccine administration
 - A skin abrasion is created using a bifurcated needle dipped in vaccine.
 - The vaccine site should be loosely covered to prevent the spread of virus to others.

- After 3–4 days, a red pruritic papule appears at the vaccination site, which evolves into a vesicle followed by a pustule; after a few weeks, a scab forms, then falls off leaving a scar.
- Contraindications to vaccine:
 - Atopic dermatitis or exfoliative skin disorder
 - Immunosuppression
 - Pregnancy or breastfeeding
 - Close contact of someone who is pregnant, immunosuppressed, or has skin disease
 - Allergy to vaccine component
 - Moderate or severe acute illness
 - Inflammatory eye disease
 - Heart disease (myocardial infarction, stroke, cardiomyopathy, heart failure, or angina) or ≥ 3 risk factors for heart disease
 - Age < 1 year
 - These contraindications may be reevaluated if smallpox is reintroduced into the population.
- Common adverse reactions to vaccination:
 - Fever, swelling, lymphadenitis, and headache are seen in 2–16% of adults receiving the vaccine for the first time.
 - A mild rash occurs in ~8% of cases.
- Less common vaccine reactions:
 - Vaccinia keratitis and/or vision loss
 - Accidental inoculation with blister formation
 - Moderate to severe generalized rash
 - Eczema vaccinatum
 - Encephalitis
 - Congenital or generalized vaccinia
 - Myopericarditis
 - Progressive vaccinia/vaccinia gangrenosum
 - Bacterial superinfection

PATHOPHYSIOLOGY

- The virus infects the upper respiratory tract and replicates; rarely, primary infections can occur via skin, conjunctival, or placental routes.
- The virus enters the bloodstream (primary viremia) and is taken up by

macrophages.

- Patient is asymptomatic during this time.
- Next, the virus enters the reticuloendothelial system where it continues to replicate.
- Secondary viremia occurs as the virus reenters the bloodstream and infects organs.
 - Can cause epidermal necrosis and swelling
 - Infections of the bone marrow, kidneys, liver, lymph nodes, spleen, and other organs result in coagulopathy and multiorgan system failure.
- Exact mechanisms of viral toxicity are not understood but may involve both viral cytopathic effects and inflammatory pathology.

ETIOLOGY

- Variola virus is a member of the poxvirus family and (Orthopox genus).
- Variola is a double-stranded DNA virus most commonly transmitted during face-to-face contact via respiratory aerosols or direct contact with infected skin lesions.
- Transmission of the virus via air in enclosed settings or via infected fomites is uncommon.
- Humans are the only vectors.

DIAGNOSIS

- Ordinary smallpox
 - Incubation period lasts 7–17 days, followed by a 1–4 day febrile prodrome characterized by high fever, headache, back pain, chills, abdominal pain, and emesis.
 - Eruptive phase begins with lesions of the mouth, tongue, and oropharynx.
 - The rash
 - Often starts on face and spreads to rest of body within 24–48 hours
 - On day 1, rash is macular.

- On day 2, rash becomes papular.
 - On days 4 and 5, rash becomes vesicular.
 - By day 7, rash becomes pustular.
 - By 2–3 weeks, scabs form.
 - Scabs fall off and leave pockmarks.
- Modified smallpox
 - Milder than ordinary smallpox
 - Accelerated course
 - Lesions are not as deep
- Flat smallpox
 - Characterized by soft, flat, semiconfluent or confluent rash that does not evolve to pustules but can still result in significant skin loss
- Hemorrhagic smallpox
 - Shorter incubation time
 - Skin becomes dusky
 - Bleeding in skin and mucous membranes
 - Can be difficult to diagnose unless exposure to variola virus is known
- Variola sine eruptione
 - May be asymptomatic or cause an influenza-like illness
 - Noncontagious
 - Seen in infants with protective maternal antibodies and in vaccinated individuals
- If there has not been a release or circulation of smallpox, the CDC protocol for evaluating patients for smallpox can be used to guide the assessment of a suspicious rash illness.
- The CDC risk evaluation tool can be found at <http://www.bt.cdc.gov/agent/smallpox/diagnosis/riskalgorithm/>
 - If a patient has an acute, generalized rash on the body with vesicles or pustules, use the major and minor criteria to assess the likelihood of smallpox.
 - Major criteria
 - Febrile prodrome: 1–4 days prior to rash onset, including a temperature $\geq 101^{\circ}\text{F}$ and 1 or more of the following: prostration, headache, backache, chills, vomiting, or severe abdominal pain

- Classic smallpox lesions are deep-seated, firm/hard, round, well-circumscribed vesicles or pustules that can become umbilicated or confluent as they evolve on any one part of the body (e.g., the face or arm); all the lesions are in the same stage of development.
- Minor criteria
 - Centrifugal distribution with greatest concentration of lesions on face and extremities
 - First lesions appear on the oral mucosa, palate, face, or forearms.
 - Patient appears toxic or moribund
 - Slow evolution: Lesions evolve from macules to papules to pustules over days (each stage lasts 1–2 days).
 - Lesions on the palms and soles
- High risk of smallpox
 - Febrile prodrome and classic lesions in same stage of development
- Moderate risk of smallpox
 - Febrile prodrome and either 1 other major criterion or ≥ 4 minor criteria
- Low risk of smallpox
 - No febrile prodrome, or febrile prodrome and < 4 minor criteria

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Use the CDC smallpox evaluation protocol to guide testing.
 - If high risk of smallpox:
 - Consult infectious disease and/or dermatology.
 - Public health agency will advise on management and collection of samples.
 - Testing will be performed at an approved laboratory prior to other tests.
 - If moderate risk of smallpox:
 - Consult infectious disease and/or dermatology.
 - Perform testing for varicella and other disorders including herpes simplex virus as indicated.
 - If no diagnosis is made after testing, ensure adequacy of specimen and have consultants reevaluate.

- If smallpox still cannot be ruled out, then classify case as high-risk case.
- If low risk of smallpox, and history and physical exam are highly suggestive of varicella, then varicella testing is optional.
- If low risk of smallpox and diagnosis is uncertain, then testing should be done for varicella and other disorders as indicated.
- Variola testing
 - Should not be performed in low- and moderate-risk cases because of risk of false positives
 - Should only be performed in designated high-containment facilities
 - Lesion specimens (fluid, cells, and scabs) are preferred for testing, but blood, tonsillar swabs, and biopsy specimens may be used.
 - Serologic studies and electron microscopy cannot distinguish between the variola virus and other orthopoxviruses.
 - Polymerase chain reaction (PCR) assays can distinguish variola virus from other orthopoxviruses.
 - Variola virus can be cultured.

DIFFERENTIAL DIAGNOSIS

- Multiple rash illnesses, including the following, can be confused with smallpox:
 - Varicella and herpes zoster
 - Herpes simplex virus
 - Measles
 - Rubella
 - Monkeypox, cowpox, and tanapox
 - Viral exanthema including enterovirus
 - Disseminated molluscum contagiosum
 - Impetigo, insect bites, or scabies
 - Post-smallpox vaccine rash (vaccinia)
 - Secondary syphilis
 - Acne and contact dermatitis
 - Drug reactions including erythema multiforme
 - Meningococcemia can be confused with hemorrhagic smallpox.

ALERT

- Varicella can be confused with smallpox.
- Varicella lesions present in different stages, are superficial, and concentrate on the trunk and face, sparing the palms and soles.
- Smallpox lesions all present in the same stage, are deep, and concentrated on the face and limbs, often involving the palms and soles.

TREATMENT

MEDICATION

- Patients suspected of having smallpox should be vaccinated against smallpox, especially if they are in the early stages of the disease.
- The efficacy of antiviral drugs are not known; however, cidofovir has shown efficacy in reducing smallpox virus replication in vitro and in animal studies, and tecovirimat (ST-246) shows promise and is currently in clinical trials.
- The use of vaccinia immune globulin (VIG) can be considered for complications from vaccinia immunization but not for smallpox therapy or postexposure prophylaxis.
- Cidofovir or VIG are available through the Strategic National Stockpile.

ADDITIONAL TREATMENT

General Measures

- Suspected cases of smallpox require notification of state and local authorities, who should then notify the CDC.
- For patients with acute, generalized vesicular or pustular rash, institute airborne and contact precautions and alert infection control.
 - If high risk, report to state and local public health agency immediately.
- Individuals recently exposed (within 3–4 days) to someone with contagious smallpox (e.g., someone with oral or skin lesions) should receive postexposure vaccination, as this offers the potential to limit disease and also provides significant protection from death.
- Individuals with smallpox may be contagious during the febrile

prodrome, are contagious during the early rash phase, and remain contagious until all the scabs have fallen off.

ONGOING CARE

PROGNOSIS

- The mortality rate for variola minor was <1%.
- Historically, the overall mortality rate for variola major was 30% but was close to 100% for the flat and hemorrhagic forms of the disease.
- The highest mortality rates occurred among young children, pregnant women, elderly individuals, and those with immunodeficiency.
- Long-term sequelae include pockmarks, vision loss, and limb deformities.

COMPLICATIONS

- Dehydration and electrolyte abnormalities can occur during the vesicular and pustular stages and should be corrected.
- Secondary bacterial superinfections may require antibiotic treatment.
- Corneal ulcers or keratitis, arthritis, or encephalitis may develop.

CODES

ICD10

B03 Smallpox

SNAKE AND INSECT BITES

Payal K. Gala • Jill C. Posner

BASICS

DESCRIPTION

- Injury to the human skin and/or subcutaneous tissues caused by bite, envenomation, or sting, causing local but sometimes systemic effects
- Snake bites
 - Crotalinae (pit vipers: cottonmouths, copperheads, and rattlesnakes)
 - Elapidae (coral snakes)
- Spider bites
 - Black widow (*Latrodectus mactans*)
 - Brown recluse (*Loxosceles reclusa*)
- Insect stings: Hymenoptera, fire ants (*Solenopsis*), wasps (including hornets and yellow jackets), bees

EPIDEMIOLOGY

- Only 15% of all snake bites are from poisonous snakes, and only ~2/3 of those involve true envenomation. Crotaline snakes are the most common cause of venomous snake bites in the United States. Almost 3,500 Crotaline exposures were reported to U.S. poison control centers in 2010. Coral snake bites constitute <1% of all snake bites.
- The black widow spider is found in most areas of North America but especially in southern New England. The brown recluse spider is found in southern and midwestern states.
- 1–4% of the U.S. population is at risk for anaphylaxis from Hymenoptera stings.

Incidence

- Annually, ~8,000 people sustain a poisonous snake bite in the United States, 99% of which are from crotaline snakes, and 5–6 fatalities occur.
- The incidences of black widow and brown recluse spider bites are unknown.

- 50–150 people die each year from sting anaphylaxis.

PATHOPHYSIOLOGY

- Snake bites
 - Snake venom consists of numerous enzymes and polypeptides that are neurotoxic, cytotoxic, and/or hemotoxic.
 - Pit viper venom produces significant local inflammation and injury to vascular endothelium and may lead to coagulopathy, thrombocytopenia, and shock.
 - The venom of the coral snake is primarily neurotoxic and may produce neuromuscular paralysis and respiratory depression.
- Spider bites
 - Most of the 20,000 species of predominantly venomous spiders in the United States lack fangs capable of penetrating human skin or toxin strong enough to produce more than a mild reaction. However, the black widow and brown recluse spiders can cause significant harm.
 - The black widow venom, α -latrotoxin, is a neurotoxin that stimulates myoneural junctions and nerve terminals by increasing synaptic release of acetylcholine and by initiating a massive influx of calcium, causing severe skeletal muscle pain and cramping and autonomic disturbances such as hypertension, tachycardia, and diaphoresis. Pediatric patients are more severely inflicted given the ratio of milligram of venom to kilogram of body weight.
 - The brown recluse venom, mainly sphingomyelinase D and hyaluronidase, acts on erythrocyte membranes, platelets, endothelial cells, and other cells, resulting in tissue infarction and necrosis. Systemic symptoms are more likely to occur in children, presumably because of a smaller ratio of body weight to venom volume. Hemolysis, hemoglobinuria, renal failure, DIC, shock, seizures, and death may occur.
- Insect stings
 - The fire ant bites with its jaws and then swings its head around to inflict multiple stings. The venom has a direct toxic effect on mast cell membranes, causing an immediate urticarial reaction at the bite site.

- The venoms of the bee and wasp (hornet and yellow jacket) contain antigens that trigger an IgE antibody response, resulting in allergic reactions that vary in severity from mild local effects to anaphylaxis.
- Cross reaction between Hymenoptera species occurs. Those who react to fire ants may also react to bees and wasps.

DIAGNOSIS

HISTORY

ALERT

- If the snake is brought in for identification, use caution! The head of a dead snake can deliver a venomous bite for up to 1 hour after death/decapitation.
- Snake bites
 - Poisonous snakes have triangular-shaped heads, a pit (heat sensor in front of each eye), fangs, slit-like pupils, and a single row of subcaudal plates and may have a rattle:
 - The corals have oval heads and round pupils yet are still poisonous.
 - Nonpoisonous snakes have oval heads, no pits, rows of small teeth, round pupils, a double row of subcaudal plates, and no rattles.
 - In the Elapidae family, the coral snake can be differentiated from the benign king snake by the pattern of the colored bands: “Red on yellow, kill a fellow; red on black, venom lack.”
- Spider bites: identification of spider (rare): The black widow is about the size of a quarter, glossy black, gray, or brown, with a red, orange, or yellow hourglass-shaped marking on the ventral surface. A single bite can deliver a lethal dose of venom. The brown recluse is small (1–1.5 cm), gray, or reddish/brown, with a violin-shaped mark on the dorsum of the cephalothorax.
- Insect bites
 - Identify type of insect (bee, wasp, ant).
 - Assess for history of insect bite allergy.

PHYSICAL EXAM

- Crotalinae (pit viper) bites
 - Intense local pain/burning occur in the 1st few minutes, followed by edema and perioral numbness that may extend to the scalp and periphery. Paresthesias may be accompanied by a metallic taste.
 - Local ecchymosis and vesicles appear within the 1st few hours, and by 24 hours, hemorrhagic blebs are present.
 - Without treatment, edema and tissue necrosis through the bitten extremity may occur. Compartment syndrome is rare.
 - Nausea, vomiting, weakness, chills, and sweating can also occur with systemic absorption of venom.
 - Neuromuscular involvement (e.g., diplopia, dysphagia, lethargy) can develop within several hours.
 - Signs of hypovolemic shock, hemorrhagic diathesis, coagulopathy, and neuromuscular dysfunction may occur in life-threatening envenomations.
- Elapidae (coral snake) bites
 - Mild, often unimpressive local signs and symptoms (pain, swelling) but significant neurologic effects that include extremity paresthesias, weakness, fasciculations, and bulbar dysfunction that can progress to flaccid paralysis and respiratory failure
 - Inspect bite wound for fang punctures.
 - Carefully assess neurovascular integrity, and consider compartment pressures if severe edema.
- Black widow spider bites
 - No local symptoms associated with bite
 - Within 8 hours after bite, regional or generalized pain and muscle cramping, fasciculations; abdominal rigidity without tenderness is a hallmark sign.
 - Children often have nausea and vomiting.
 - Respiratory difficulty may occur.
 - Hypertension, tachycardia, and cholinergic effects (diaphoresis, salivation, lacrimation, and bronchorrhea)
 - Death may occur from respiratory or cardiovascular collapse.
 - Syndrome can last 3–6 days.

- Brown recluse spider bites
 - Spectrum from minor local reaction to severe necrosis
 - Local reaction: pain, erythema, swelling, and pruritus; classic “bull’s eye” lesion or “red-white-and-blue” sign
 - Ischemia and skin necrosis: A bright red papule appears within a few hours of the bite and can evolve within 48–72 hours into a hemorrhagic vesicle surrounded by blue discoloration (necrosis) or white blanching (vasospasm), the bull’s eye. Shortly after, a firm, purple necrotic lesion appears, and within 7–14 days, black eschar is visible. Ulcer healing can take weeks to months, leaving a deep scar.
- Insect bites
 - Small local reactions: painful, pruritic, urticarial lesion at the sting site
 - Large local reaction: edema and erythema, may be several centimeters in diameter
 - Anaphylaxis is rare with fire ants but occurs more frequently with bee stings.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Snake bites: CBC, platelet count, PT/PTT, fibrinogen, fibrin split products, electrolytes, creatine kinase, creatinine, urinalysis
- Spider bites: CBC, PT/PTT, fibrinogen, electrolytes, creatinine, creatine kinase, urinalysis, Coombs test
- Insect bites: no tests done routinely

DIFFERENTIAL DIAGNOSIS

- Black widow spider bites: acute abdomen, renal colic, opioid withdrawal, tetanus
- Poisonous snake bites: nonpoisonous snake bite (leaves scratches, not punctures), rodent bites, thorn wounds
- Brown recluse spider bite: other spider bites, insect bites and stings (including Lyme), cellulitis, poison ivy/oak, Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema nodosum, chronic herpes simplex, purpura fulminans, diabetic ulcer, gonococcal hemorrhagic lesion, pyoderma

TREATMENT

- Crotalinae (pit vipers) bites
 - Remove constrictive items (jewelry or clothing) and immobilize extremity at or below level of heart. Cryotherapy, arterial tourniquets, ice immersion, incision, excision, and oral suctioning are not recommended!
 - Focus on rapid transport to medical facility.
 - Address airway, breathing, and circulation.
 - The use of a constrictive band is controversial. Main indication is for cases of prolonged transport time to a medical facility or rapid progression of systemic symptoms. A flat band is placed 5–10 cm proximal to the bite, with enough pressure to impede lymphatic and superficial venous flow but not arterial flow. 1–2 fingers should fit easily between the band and patient's extremity. Be careful of progressive edema leading to tightening of constrictive band if applied. Also remember that these bands can worsen local cytotoxic effects.
 - Another option is a compression bandage alone with immobilization of the involved extremity (pressure-immobilization method). This is thought to delay systemic absorption of venom.
- Elapidae (coral snakes)
 - Constriction band, suction, and drainage do not prevent coral snake venom absorption.

ADDITIONAL TREATMENT

General Measures

Consider contacting your local poison control center to assist with diagnosis and management. The national phone number for all centers is 1-800-222-1222.

- Crotalinae (pit vipers) bites
 - Wound care: irrigation and dressing
 - Determine if envenomation has occurred via serial examinations (q30min) and laboratory studies (q4h).
 - Antivenom: Administration of antivenom should be made in

consultation with a toxicologist and/or herpetologist. General indications include progressive local swelling, pain or ecchymosis, and any systemic signs or symptoms.

- Crotalidae Polyvalent Immune Fab (CroFab) is the Crotalinae antivenom product approved by the FDA. Antivenin (Crotalidae) Polyvalent (ACP) was often associated with serum sickness and anaphylaxis and is no longer manufactured.
- Data suggest that the use of CroFab is safe and effective and is associated with fewer immediate and delayed hypersensitivity reactions than ACP, although they do occur and must be monitored.
- Some hospitals (in endemic areas) and many zoos stock antivenoms. In addition, the regional poison control center may have access to the Antivenom Index and will be able to help locate the nearest supply.
- Early administration of Fab within 6 hours is advised. Initial dose is 4–6 vials of Fab diluted in 250 mL normal saline infused over 1 hour. Dosing is based on amount of venom injected, not weight of patient.
- Supportive care: volume replacement, packed red blood cells, platelets, fresh frozen plasma, cryoprecipitate as indicated for hypovolemia and bleeding diathesis. Observe for respiratory and renal failure.
- Frequent assessment of tissue perfusion and measurement of compartment pressure; fasciotomy only for elevated compartment pressures
- Empiric antibiotics are controversial but may be indicated in cases of extensive tissue involvement.
- Analgesia and tetanus prophylaxis
- Elapidae (coral snakes)
 - Crotalinae antivenom is ineffective in treating Elapidae envenomation. Antivenom formerly manufactured by Wyeth Laboratories is no longer in production. Currently, there are only 2 lots of FDA-approved Elapidae antivenom in the United States, both of which have expired on October 2014. It is not known at this time when more will be manufactured.

- Any degree of neurotoxicity or systemic symptoms is an indication for antivenom therapy. Prophylactic therapy should be avoided due to limited supply and need to preserve antivenom.
- Local wound care, supportive care, analgesia, and tetanus vaccination
- Black widow spider bites
 - To alleviate muscle pain and cramping, parenteral opioids and benzodiazepines can be administered.
 - Calcium infusions had been used anecdotally but have not proven to be effective.
 - Latrodectus-specific antivenom is available for more severe envenomations given via IV infusion. Specific indications include young age, pregnancy, life-threatening hypertension and tachycardia, respiratory difficulties, or severe symptoms refractory to other treatment measures. Administration of an equine serum preparation has been associated with hypersensitivity reactions and occasionally death. 1 vial is generally sufficient.
- Brown recluse spider bites
 - Most bites can be treated on an outpatient basis with local wound care with Burow solution or hydrogen peroxide and symptom treatment for pain and pruritus.
 - No antivenom is available in the United States.
 - Patients with systemic symptoms, serious infection, or extensive necrosis warrant hospitalization, IV fluids, and aggressive supportive care.
 - Skin grafting or debridement may be warranted for wound management. Surgical excision is no longer indicated.
 - Neither dapsone nor hyperbaric oxygen therapy has proved to be effective; dapsone in children is associated with methemoglobinemia.
- Insect bites or stings
 - Rarely require more than ice and antihistamine for pruritus
 - If stinger remains in skin, remove by pinching with forceps or scraping. Emphasis should be on quick removal to decrease exposure to venom. Do not squeeze venom gland.

- Life-threatening anaphylaxis should be treated with subcutaneous epinephrine (0.01 mL/kg 1:1,000 or 1 mg/mL, max 0.3 mL), methylprednisolone IV/IM (2 mg/kg), and/or diphenhydramine IV/IM (1.25 mg/kg).
- Bacterial superinfection is rare but, if present, can usually be treated with oral and/or topical antibiotics.

ONGOING CARE

PROGNOSIS

- Snake bites: Because the majority of snake bites are from nonvenomous snakes, and ~1/3 of bites from venomous snakes do not involve envenomation, the majority of bites cause only local injury. However, once serious injury is established, prognosis becomes unclear.
- Spider bites: Children have severe reactions and rare fatalities.
- Insect bites: Most bites and stings cause minimal local effects, although some cause serious systemic reactions and, rarely, death. For those patients with severe anaphylactic reactions, discharge the patient with a subcutaneous epinephrine autoinjector.

SOCIAL ANXIETY DISORDER

David Becker • Anna E. Ordóñez

BASICS

DESCRIPTION

- Social anxiety disorder, also known as social phobia, is a psychological condition with developmental underpinnings.
- The disorder is characterized by marked and persistent fear of social situations in which the person is exposed to unfamiliar people or possible scrutiny by others.
- DSM-5 criteria:
 - Marked fear or anxiety of one or more social situations in which the individual is exposed to possible scrutiny by others (In children: anxiety must occur in peer situations, not just in interactions with adults)
 - The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated.
 - The social situations almost always provoke fear or anxiety and are avoided or endured with intense fear or anxiety.
 - The fear/anxiety is out of proportion to the actual threat posed by the situation/context and is persistent, typically lasting 6 months or more.
 - The fear/anxiety or avoidance causes significant distress or impairment in social, occupational, or other areas of functioning.
 - The fear/anxiety is not attributable to psychological effects of substances, a medical condition, or by another psychiatric diagnosis.
 - Specify if performance only (fear/anxiety restricted to speaking/performing in public)

EPIDEMIOLOGY

- Approximately 7% of youths suffer from social anxiety disorder.
- The prevalence is somewhat higher in girls than in boys.

RISK FACTORS

- Preexisting shyness or social inhibition
- Avoidant temperament
- Behavioral inhibition
- Family history: 1st-degree relatives have 2–6 times greater chance of having the disorder.
- Moderate genetic component based on twin studies

COMMONLY ASSOCIATED CONDITIONS

- Anxiety disorders
 - Generalized anxiety disorder
 - Specific phobia
 - Selective mutism
 - Obsessive-compulsive disorder
 - Panic disorder
- ADHD
- Depression

DIAGNOSIS

HISTORY

- The diagnostic evaluation should entail gathering of data through separate interviews with the child/adolescent and the parents.
- Current symptoms should be elicited with attention to severity, duration, and level of functional impairment.
- Core symptoms of marked anxiety in social situations, fear of negative scrutiny by others, and avoidance of these situations should be present.
- Distress can be manifested by physical symptoms such as
 - Blushing
 - Palpitations
 - Trembling
 - Gastrointestinal (GI) upset
- Younger children may exhibit periods of selective mutism in social situations while having the ability to talk freely while at home.
- Older children may appear oppositional and exhibit school refusal.
- Symptoms may be exacerbated by environmental transitions such as a

new school or the family moving.

PHYSICAL EXAM

There are no pertinent findings on physical exam.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Consider additional screening if symptoms are more pervasive than just social situations.

Diagnostic Procedures/Other

- Diagnostic scales:
 - Multidimensional Anxiety Scale for Children (MASC): broad anxiety scale (ages 8–18 years), self-report
 - Social Phobia and Anxiety Inventory for Children (SPAI-C) (ages 8–17 years), self-report
 - Social Anxiety Scale for Children-Revised (SASC-R) (ages 8–14 years) and Adolescents (SAS-A) (ages 13–18 years), self-administered
 - Liebowitz Social Anxiety Scale for Children and Adolescents (LSAS-CA) (ages 13–17 years), clinician-administered

DIFFERENTIAL DIAGNOSIS

- Normative shyness (personality trait without significant adverse impact on functioning)
- Anxiety disorders
- Depression
- Autistic spectrum disorders

TREATMENT

GENERAL MEASURES

- Potential pitfalls
 - Incomplete assessment of the comorbid psychiatric illnesses
 - Parental accommodation of the child's avoidant patterns
- Both psychotherapy and medications have roles in core treatment and symptom alleviation.

- Additional therapies such as group therapy, individual and family psychoeducation, and/or self-regulation strategies can be considered first line in mild cases or adjuncts for more clinically impairing cases.
- Combination treatment with SSRIs and CBT may be superior to either treatment alone.

ADDITIONAL THERAPIES

- The most studied and most supported by structured clinical trials is cognitive behavioral therapy (CBT).
 - Exposure to a hierarchy of avoided situations with concomitant cognitive reframing is core to CBT.
- Other psychotherapeutic approaches such as play therapy, interpersonal, or psychodynamic therapy may be better suited in some cases.
- Supportive psychosocial treatments can include mind–body strategies to support self-regulation skills. These may include the following:
 - Biofeedback
 - Progressive muscle relaxation
 - Self-hypnosis
 - Mindfulness techniques
- Group therapy may also be helpful.
- Family therapy or collaborative work with parents may be important to decrease parental accommodation or help with other dysfunctional dynamics.

MEDICATION

- Selective serotonin reuptake inhibitors (SSRIs)
 - First line for symptom control and adjunctive psychopharmacologic support.
 - Begin half the recommended starting dose for children with anxiety disorders.
 - Side effects include GI upset, headaches, dizziness, and agitation.
 - There is a black box warning by the FDA indicating that all antidepressants may increase suicidal thinking and behavior in children and adolescents. It is not clear how this warning may apply to treatment of social anxiety disorder that presents without

depression.

- Close monitoring is important following initiation of treatment.
 - Fluoxetine (Prozac) (10–60 mg)
 - Sertraline (Zoloft) (25–200 mg)
 - Paroxetine (Paxil) (10–40 mg)
 - Citalopram (Celexa) (10–40 mg)
 - Escitalopram (Lexapro) (10–20 mg)
 - Fluvoxamine (Luvox) (25–200 mg)
- Serotonin-norepinephrine reuptake inhibitor (SNRI)
 - Second-line
 - Side effects include somnolence, insomnia, dizziness, anxiety, headache, sweating, and tremor.
 - There is a black box warning by the FDA indicating that all antidepressants may increase suicidal thinking and behavior in children and adolescents.
 - Venlafaxine extended release (Effexor XR) (25–225 mg)
- Benzodiazepines
 - May be considered for short-term symptomatic relief in rare circumstances
 - Not appropriate for long-term therapy
 - Side effects include sedation, dizziness, and weakness.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Psychotherapy on a weekly or twice-weekly regimen
- If medication is initiated, close monitoring on a weekly basis is recommended for the first 4 weeks followed by monthly monitoring.
- The primary care provider should monitor the response to the chosen treatment plan at least every 2–3 months.
- Monitoring of any emerging comorbidities is suggested.

PROGNOSIS

- Among patients who come to the attention of clinicians, social anxiety

disorder is generally considered a chronic condition that does not significantly improve without intervention.

- Significant comorbidities may develop in adulthood, such as depression and alcohol dependence.

- F41.8 Other specified anxiety disorders
- F40.11 Social phobia, generalized

SORE THROAT

Daniel E. Felten

BASICS

DESCRIPTION

Throat pain with swallowing (odynophagia) or without swallowing may be a lone complaint or accompanied by a variety of other complaints. The most likely etiologies are self-limited but must rule out potentially life-threatening causes.

EPIDEMIOLOGY

- Sore throat is a common complaint year-round, but etiology depends on season and age of patient.
- In winter months, viral agents are more active.
- In spring and fall, postnasal drip from allergic rhinitis is a common cause of throat irritation.

GENERAL PREVENTION

- Careful hand washing and avoidance of respiratory secretions are key to minimizing spread of most infectious agents.
- Noninfectious etiology often triggered by specific exposure, so avoidance of that trigger would limit symptoms

ETIOLOGY

- Infectious
 - Urgent/emergent: epiglottitis, peritonsillar cellulitis/abscess, retropharyngeal abscess, Lemierre syndrome
 - Viral: adenovirus, influenza, coxsackie, parainfluenza, Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex virus (HSV), human immunodeficiency virus
 - Bacterial: group A β -hemolytic *Streptococcus* (GAS, *Streptococcus pyogenes*), *Mycoplasma pneumoniae*, groups C and G streptococci, diphtheria, *Neisseria gonorrhoeae*, anaerobic bacteria, tularemia, *Arcanobacterium haemolyticum*

- Fungal: Candida
- Environmental
 - Tobacco smoke or aerosolized irritant
- Trauma
 - Foreign body: either retained or causing laceration to posterior pharynx
 - Burns: hot liquids/foods
 - Caustic ingestion
 - Voice overuse
- Tumor
 - Acute lymphocytic leukemia or T-cell lymphoma can rarely present as sore throat and fever.
- Allergic/inflammatory
 - Postnasal drip from allergic rhinitis
- Miscellaneous
 - Kawasaki disease
 - PFAPA: periodic fever, aphthous stomatitis, pharyngitis, adenitis
 - GERD
 - Eosinophilic esophagitis
 - Psychogenic pain
 - Referred pain

DIAGNOSIS

HISTORY

- Drooling, inability to swallow, rapid progression of symptoms, or respiratory distress may suggest more urgent/emergent problem: epiglottitis, peritonsillar abscess (especially with unilateral symptoms), or retropharyngeal abscess.
- Exposures, ingestions, foreign bodies: need to elicit whether patient was exposed to agent that could cause progression of symptoms
 - Caustic ingestion burns may progress rapidly and require transfer to higher level of care.
 - Foreign body ingestion may require removal or endoscopic visualization.

- Outbreaks in child care setting or school: GAS, influenza, and coxsackie can spread rapidly.
- Sexual activity or concern for sexual abuse: oral sex a risk factor for development of pharyngitis due to *N. gonorrhoeae*
- Children who are immunocompromised or children on chronic inhaled corticosteroids who are otherwise immune competent are at risk for esophageal candidiasis. Throat pain is often chronic and not responsive to other treatments.
- Associated symptoms
 - Fever, headache (HA), stomach pain: Consider GAS.
 - Fever, HA, rhinorrhea myalgias, fatigue: Consider influenza.
 - Rhinorrhea, cough, conjunctivitis: more likely viral
 - Runny nose, itchy nose, congestion: Consider postnasal drip from allergic rhinitis.

PHYSICAL EXAM

ALERT

- Although rare since the introduction of the vaccine for *Haemophilus influenzae* type b, patients may present with epiglottitis.
- Caution approaching a febrile, toxic-appearing patient who is unable to control secretions and exhibiting any respiratory distress. Defer exam or imaging until patient is in a setting where an emergent airway could be established if epiglottitis is suspected.
- General
 - Ill appearing, respiratory distress: epiglottitis, retropharyngeal abscess
- Pharynx and oral cavity
 - Exudative tonsillitis: usually GAS but also present in EBV, *N. gonorrhoeae*, *Arcanobacterium*, HSV, adenovirus
 - Vesicles or ulceration on tonsils, tonsillar pillars, or buccal mucosa; inflammation of gums: HSV, coxsackievirus, echovirus
 - Posterior pharyngeal cobblestoning: postnasal drip from allergic rhinitis
 - Asymmetry in tonsil size or deviation of uvula: peritonsillar abscess
 - Burns on lips or tongue: hot liquid or caustic ingestion

- Eyes, ears, nose
 - Conjunctivitis with sore throat: adenovirus
 - Rhinorrhea: viral etiology most likely
 - Boggy nasal turbinates, allergic shiners: postnasal drip from allergic rhinitis
- Lymph nodes
 - Tender anterior cervical lymph nodes: classic for GAS
 - Diffuse lymphadenopathy +/- splenomegaly: EBV, less likely CMV
- Skin
 - Scarlatiniform rash (diffuse, erythematous, fine-papular, “sand-papery” rash): scarlet fever from GAS pharyngitis but can be seen with infections due to *A. haemolyticum* and in Kawasaki disease
 - Vesicular rash, particularly on palms, soles, and/or buttocks: coxsackievirus

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Rapid antigen detection test
 - Initial test of choice if GAS pharyngitis suspected
 - High specificity ($\geq 95\%$), variable sensitivity (55–90%)
 - Need to confirm negatives with culture or DNA probe for GAS
- Heterophile antibody test (Monospot)
 - Can be used to confirm EBV infection
 - Not reliable under age 4 years
- Cultures for other bacteria (e.g., *N. gonorrhoeae*, *A. haemolyticum*) require special handling and specific medium for growth.

Imaging

- Lateral neck x-ray
 - Thumb print sign: enlarged epiglottis. Do not get x-ray in unstable patient.
 - Widened prevertebral soft tissue space suggestive of retropharyngeal abscess
- Chest x-ray if foreign body is suspected
 - Must ensure object passes out of esophagus
 - Look for free air indicating perforation

- CT scan of neck
 - For diagnosis of retropharyngeal abscess in setting of suggestive lateral neck x-ray or peritonsillar abscess if suggested by physical exam

TREATMENT

The treatment of sore throat is primarily supportive, including fluids and pain control. Additional treatment depends on underlying etiology.

MEDICATION

- Pain relievers such as ibuprofen or acetaminophen are generally sufficient to manage pain.
 - Rarely, addition of codeine or other opioid may be warranted in patients who are unable to maintain sufficient PO intake.
 - Use codeine with caution due to variability in metabolism by cytochrome P450 CYP2D6. Patients who are “ultra-rapid metabolizers” of codeine convert up to 15% (vs. 3%) of the drug to morphine, which can lead to toxicity.
 - Alternatively, for less severe pain, topical treatments such as throat lozenges or throat sprays may provide additional comfort with fewer potential side effects.
- GAS pharyngitis: penicillin G benzathine IM (600,000 U <27 kg, 1.2 million U >27 kg) or penicillin V potassium PO (250 mg b.i.d. <27 kg, 500 mg b.i.d. >27 kg × 10 days) or amoxicillin (50 mg/kg/day; max 1,000 mg) first line
 - 1st-generation cephalosporin for penicillin-allergic patients with nonanaphylactic reactions
 - Clindamycin for patients with type I hypersensitivity to penicillin
 - Macrolides are also acceptable alternatives.
- Some studies have shown steroids (oral or IM) to be of benefit to patients with severe symptoms. However, they should be used only in limited circumstances due to side effects.
- Esophageal candidiasis: fluconazole (6 mg/kg × 1, then 3 mg/kg daily; max 400 mg/day) or itraconazole (5–10 mg/kg/day divided daily or

b.i.d.; max 600 mg/day) × 14–21 days after resolution of symptoms

ISSUES FOR REFERRAL

- Epiglottitis: Exam, airway stabilization, and ongoing management must be done in controlled setting.
- Peritonsillar abscess: often requires drainage either by needle aspiration, incision and drainage, or tonsillectomy
- Presence of foreign body: may need removal

INPATIENT CONSIDERATIONS

Initial Stabilization

- Patients with signs of airway compromise or respiratory distress may require emergent airway management.
 - Patients suspected to have epiglottitis must have airway stabilized prior to any other treatment or diagnostic testing.
 - If no impending airway obstruction, can undertake diagnostic and therapeutic interventions, including IV placement for administration of IV fluids if patient is not tolerating PO, antibiotics for treatment of abscess or cellulitis, or anesthetic agents if endotracheal intubation becomes necessary
 - Supplemental O₂ as needed
 - Make NPO if surgical intervention is required.

Admission Criteria

- Patients with conditions causing airway compromise require monitoring until they demonstrate response to treatment.
- Pain control or hydration: Patients with uncontrolled throat pain may be unable to take adequate PO to maintain hydration at home.

CODES

ICD10

- J02.9 Acute pharyngitis, unspecified
- R07.0 Pain in throat
- J02.0 Streptococcal pharyngitis

FAQ

- Q: Are steroids effective adjuvant therapy for sore throat?
- A: There have been a number of good studies that have shown that giving steroids to patients with GAS pharyngitis has decreased time to improvement in symptoms on average about 5.2 hours. However, there was no significant difference in pain at 24 hours. In patients with non-GAS-associated sore throat, the results are more mixed. One study did show significant decrease in time to improvement in symptoms in patients with severe symptoms.
- Q: What is the risk of giving steroids to a patient with sore throat?
- A: None of the studies of steroid use in treatment of acute throat pain reported any significant side effects in the treatment groups. There were some reports of GI upset that often were attributed to concurrent use of antibiotics. However, sore throat and fever is rarely the presentation of acute lymphocytic leukemia (ALL), and it has been shown that steroid administration prior to the diagnosis of ALL has a significant adverse effect of the chance a patient will achieve complete remission. Current COG protocol may assign children with ALL who have received steroids prior to diagnosis to more intensive treatment

groups depending on time of steroid administration.

- Q: Should antibiotics be given to children with sore throat based on physical exam findings that suggest GAS pharyngitis?
- A: No. Most cases of sore throat in children are due to viruses, and the rapid antigen detection test (RADT) is a widely available screening test that is easy to administer. The test has an excellent specificity, and patients with a positive RADT should be treated. Negative results should be sent for culture or DNA probe, which may delay treatment by 24–48 hours. However, the primary reason for treating GAS pharyngitis with antibiotics is to prevent rheumatic fever, which can be accomplished as long as antibiotics are administered within 10 days of onset of symptoms.

SPEECH DELAY

Maureen C. McMahon

BASICS

DESCRIPTION

- Speech delay is delay in the acquisition of spoken language.
- Language is a system of symbols through which humans communicate thoughts, feelings, and ideas. It has 3 components—receptive, expressive, and visual language.
 - Receptive language is the ability to process and understand language.
 - Expressive language is the ability to communicate through speech, written, or formal sign language.
 - Visual elements include eye contact, pointing, and gestures.
- Speech delay can be primary as in specific language impairment (SLI) or developmental language disorder (DLD), or secondary to another condition such as a syndrome or neurologic disorder. SLI is impaired speech/language in an otherwise normally developing child who lacks signs or stigmata of other conditions.
- Constitutional language delay, a retrospective diagnosis, is language delay associated with eventual achievement of normal speech and language milestones by school age. There are no subsequent difficulties with learning to read or write.
- Expressive language disorders include the following:
 - Verbal dyspraxia: little speech produced with great effort, very dysfluent, single words most common
 - Speech programming deficit disorder: poorly organized, difficult-to-understand speech
- Mixed receptive and expressive disorders
 - Verbal auditory agnosia: impaired ability to decode speech, resulting in a severe expressive impairment. Can often learn language visually
 - Phonologic/syntactic deficit disorder: most common type of DLD.

Comprehension exceeds spoken ability. Speech is dysfluent, grammatically incorrect with short utterances.

- Most frequent causes of speech delay:
 - Hearing loss
 - SLI
 - Autism spectrum disorder
 - Intellectual disability (formerly mental retardation)

EPIDEMIOLOGY

- Up to 15% of 2-year-old have speech and language delays.
- 5% of school-aged children have speech and language delays.
- 3:1 male-to-female ratio in DLD

RISK FACTORS

- Family history of speech/language delay or disorder
- Male gender
- Low maternal education
- Maternal depression
- Prematurity
- Birth weight <1,000 g

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hearing loss
 - Isolated genetic hearing loss
 - Hearing loss secondary to in utero cytomegalovirus (CMV) infection: full syndrome at birth or asymptomatic infection with delayed onset of progressive hearing loss
 - Acquired hearing loss: following head trauma, tumor-associated, complication of bacterial meningitis, end result of frequent acute otitis media or chronic otitis media with effusion
- Intellectual disability
- Autism spectrum disorder
- SLI
- Constitutional language delay

- Selective mutism
- Environmental
 - Lack of stimulation and/or poor linguistic environment
 - Child abuse or neglect
 - Lead poisoning
- Congenital
 - Cerebral palsy
 - Hydrocephalus
 - Down syndrome
 - Fragile X syndrome
 - 22q11 microdeletion syndrome
 - Fetal alcohol syndrome
 - Turner syndrome
 - Klinefelter syndrome
 - Prader-Willi syndrome
 - Angelman syndrome
 - Muscular dystrophy
 - Tuberous sclerosis
 - Neurofibromatosis
 - Williams syndrome
 - Branchio-oto-renal (BOR) syndrome
 - Craniofacial anomalies such as Treacher Collins and Goldenhar syndromes
- Nutritional
 - Malnutrition
 - Iron deficiency
- Infectious
 - HIV encephalopathy
 - Other in utero viral infection
 - Congenital toxoplasmosis
 - Congenital syphilis

ALERT

- Avoid late referral of congenital hearing loss: Amplification and therapy by 6 months of age can result in near-normal rate of speech/language acquisition.

- Constitutional language delay is a retrospective diagnosis. Do not miss a language disorder if assuming a delayed toddler is a “late bloomer.”
- Avoid overlooking fine or gross motor delays.
- Avoid missing a genetic or neurologic diagnosis.

HISTORY

Does the family note a concern about speech delay or hearing impairment?

- **Question:** Perinatal history?
- Significance: prenatal care, maternal illness, NICU admission, hyperbilirubinemia requiring exchange transfusion, treatment with ototoxic drugs such as gentamicin, newborn hearing screen results
- **Question:** Full developmental history?
- Significance: to determine if global delay or isolated speech and language delay
- **Question:** Parental concern about delayed expressive language?
- Significance: often the presentation of autism
- **Question:** History of feeding, swallowing difficulties, or poor acceptance of textured foods?
- Significance: signs of oromotor dysfunction which may indicate a neurologic problem
- **Question:** Family history of speech delay, hearing loss, neurologic disorder, or syndrome?
- Significance: may direct further evaluation
- **Question:** Any regression or loss of language milestones?
- Significance: should prompt a neurologic and metabolic workup
- **Question:** What is the social interaction of the child?
- Significance: Lack of interest in playing is a red flag for autism.
- **Question:** Any concern regarding child abuse or neglect or psychosocial deprivation?
- Significance: may have occurred as the result of a parental, genetic, or developmental disorder; drug or alcohol abuse; poverty; child malnutrition; or environmental toxins such as lead
- **Question:** History of frequent acute otitis media or otitis media with effusion and conductive hearing loss?
- Significance: may precede speech delay
- **Question:** Visual impairments?

- Significance: may impact speech development because interpretation of facial expressions and gestures is a component of infant receptive language development
- **Question:** History of traumatic brain injury?
- Significance: Speech delay may occur with a seizure disorder.

PHYSICAL EXAM

Complete examination looking for signs that may be associated with speech delay.

- **Finding:** Microcephaly?
- Significance: associated with intellectual disability, in utero CMV infection, or dysmorphic features
- **Finding:** Macrocephaly?
- Significance: associated with hydrocephalus, various syndromes
- **Finding:** Dysmorphic features?
- Significance: suggestive of a syndrome
- **Finding:** Excess drooling and open-mouth posture?
- Significance: signs of poor oral motor control of muscles used for speech production
- **Finding:** Craniofacial abnormalities?
- Significance: Articulation difficulty may be due to velopalatal insufficiency (VPI) seen with unrepaired cleft lip or palate.
- **Finding:** Scarred tympanic membranes or middle ear fluid?
- Significance: may be clue to acquired intermittent or chronic conductive hearing loss
- **Finding:** Macroorchidism?
- Significance: fragile X syndrome
- **Finding:** Neurologic exam—hypertonia or hypotonia, abnormal reflexes, other focal findings?
- Significance: suggestive of neurologic impairment
- **Finding:** Café au lait spots, hypopigmented macules, shagreen patch, axillary or inguinal freckling?
- Significance: skin findings suggestive of a neurocutaneous syndrome

DIAGNOSTIC TESTS & INTERPRETATION

- The American Academy of Pediatrics recommends a specific

development screening tool be administered at the 9, 18, and 24 or 30-month well-child care visits and an autism-specific tool be administered at the 18- and 24-month visits.

- Office development screening tools
 - Denver Developmental Assessment II
- Early Language Milestone Scale (ELMS)
- Clinical Linguistic and Auditory Milestone Scale (CLAMS)
- Hearing evaluation
 - Most states have mandated Universal Newborn Hearing Screening Programs.
 - Screening tests: automated auditory brainstem response (AABR) and transient evoked otoacoustic emissions (OAEs)
 - Hearing should be tested in all speech-delayed children, even if the newborn hearing screen was normal.
 - <6 months of age: The definitive test is brainstem auditory evoked response (BAER).
 - >6 months of age in a neurologically normal child: The definitive test is behavioral audiometry, such as visual reinforcement audiometry (VRA), performed by a trained audiologist.
- Selected speech/language milestones
 - 2 months: cooing, response to voice
 - 6 months: babbling
 - 4–9 months: turns to sound, responds to name
 - 9 months: dada/mama nonspecific, begins to understand “no”
 - 9–12 months: jargon
 - 12 months: dada, mama specific, 1 additional word, jargon is complex, points to gesture, follows 1-step command
 - 18 months: 10 words, knows body parts
 - 2 years: 50 words, 2-word phrases, 50% intelligible by strangers, pronouns, can point to specific objects in a picture, may know 1 color, follows 2-step commands
 - 3 years: 300–500 words, tells stories, 75% intelligible by strangers
 - 4 years: grammatically correct sentences, 100% intelligible by strangers
- Routine cranial imaging or screening tests for metabolic diseases are

not recommended.

- **Test:** Full speech and language evaluation
- **Significance:** To delineate the disorder and determine therapy
- **Test:** Individuals with Disabilities Education Act (IDEA) mandates early intervention services from birth to 3 years.
- **Significance:** Children can get a full developmental evaluation and appropriate therapy if sufficient delays are demonstrated.
- **Test:** EEG
- **Significance:** Indicated if there is concern for seizures
- **Test:** Genetics evaluation
- **Significance:** Should be obtained for congenital hearing loss or if there is concern for a syndrome or genetic diagnosis
- **Test:** Prolonged sleep EEG
- **Significance:** Indicated with loss of language milestones (consider the diagnosis of Landau–Kleffner syndrome)

TREATMENT

GENERAL MEASURES

- Congenital hearing loss is managed by a team consisting of an otolaryngologist, audiologist, and speech/language therapist who individualize management. Options are amplification, cochlear implant for the severely impaired, or use of sign language.
- Speech and language therapy can be provided through physician referral or parent-generated referral to early intervention programs.
- Sign language can be used as a bridge to promote communication while the child learns verbal skills. It will not preclude or delay the development of speech.
- Augmentative communication devices such as picture boards or programmed computers with voice synthesizers can be used by children with physical impairments such as cerebral palsy.
- Children with DLD usually speak adequately by school age. Some percentage will go on to have difficulty reading and writing.
- Children with constitutional language delay will achieve normal milestones by school entrance without reading disability or other

learning problem.

CODES

ICD10

- F80.9 Developmental disorder of speech and language, unspecified
- F80.4 Speech and language development delay due to hearing loss
- F80.1 Expressive language disorder

FAQ

- Q: Do 2nd- and 3rd-born children speak later than 1st-born children?
- A: No. The norms for expected speech/language development are the same regardless of birth order. 2nd- and 3rd-born children should have the same degree of motivation to speak as their 1st-born sibling.
- Q: When should I refer a child for speech/language evaluation?
- A: If the parents or physician have any concern for speech delay, then referral for evaluation is wise. Some speech-delayed children will eventually normalize and meet all milestones. It is difficult to distinguish who is constitutionally delayed from those who have

another disorder. There are several indications for a prompt referral: no pointing or babbling by 1 year, no single words by 16 months, no 2-word spontaneous phrases by 2 years, no sentences by 3 years, poor intelligibility for age, child has behavioral “melt downs” or tantrums with efforts to communicate, or any regression in language skills.

- Q: Do children raised in bilingual households have expressive language delay?
- A: No. Living in a bilingual household is not a cause of expressive language delay. However, toddlers who are learning 2 languages may interchange words in both languages. Total vocabulary and phrase length are typically normal in these children by 2–3 years of age.

SPEECH PROBLEMS

Helen M. Sharp • Kathryn Hillenbrand

BASICS

DESCRIPTION

- Communication is the exchange of ideas between two or more individuals.
- Language is a systematic means of communication that relies on a socially agreed upon set of symbols and rules for combining those symbols. Language includes comprehension, expression, and social-pragmatic rules (e.g., eye contact and turn-taking).
- Speech is produced through vocal and articulatory movements using neuromotor control of respiration, phonation (vocalization), and articulation to shape airflow and vocal sounds into strings of speech sounds (phonemes) to form words and word combinations.
- Articulation refers to the use of oral and pharyngeal structures (lips, tongue, palate, teeth) to shape vocal sounds and airflow into recognizable speech.
- Hearing is the process of transferring sound from the environment to the brain via the outer, middle, and inner ear systems.
- Speech disorders have three general points of origin: (1) neurologic, (2) structural, or (3) functional. Functional disorders are those that are unrelated to neurologic or structural disorders. More than one of these causes may be present in the same child.
- Speech disorders can be classified and are described as follows:
 - Articulation or phonologic disorders
 - Disrupt the way a child says one or more speech sounds
 - Simplifications of complex adult speech are often normal very early in speech development but should be evaluated if these changes linger or are atypical.
 - Fluency disorders
 - Disrupt the easy flow of speech production and include the conditions of stuttering and cluttering.

- Examples of stuttering include repetitions of sounds, syllables, words, or phrases, pauses, blocks, or hesitations.
 - Easy repetitions are common in children ages 2–4 years and typically resolve quickly. Persistence, visible struggle, or avoidance of talking warrant referral.
- Motor speech disorders
 - Disrupt timing, coordination, or the execution of the motor plan for speech
 - Divided into two major categories: (1) dysarthrias, which are most often related to neuromotor weakness or paralysis, and (2) apraxia, a motor planning disorder in the absence of neuromotor weakness or paralysis
- Voice disorders
 - Heard as atypical laryngeal quality such as hoarseness (dysphonia) or completely absent voice (aphonia)
- Resonance disorders
 - Describe speech quality usually described as nasality
 - Hypernasality (excessively nasal quality) is associated with velopharyngeal dysfunction and is atypical.
 - Hyponasality (inadequate nasality) is common in young children in association with acute upper respiratory infection or adenoid hypertrophy.
- Language disorders may occur in receptive, expressive, pragmatic, or some combination of these domains. Language disorders may occur in conjunction with other developmental, sensory, neurologic, or structural concerns but may also be isolated as an area of delay (see “Language Delay” and “[Autism](#)” chapters).

EPIDEMIOLOGY

- The American Speech-Language Hearing Association states that communication disorders occur in 1 of every 8 people in the population.
 - Newborn screening identifies hearing loss or deafness in 1–6 per 1,000 newborns, with higher rates in neonatal intensive care.
- Speech sound disorders including articulation, phonologic, and developmental apraxia of speech are considered the most prevalent

communication problem diagnosed in 10–15% of preschoolers and 6% of school-aged children.

- Fluency disorders affect 11% of children by age 4 years. Boys are nearly three times more likely to persist in stuttering beyond age 4 years.
- Cerebral palsy affects 1 in 500 children born each year and may include mild to severe motor speech disorders and risk of other communication disorders.
- Voice disorders such as chronic hoarseness are reported in 6–23% of children.

DIAGNOSIS

HISTORY

- Prenatal history
 - Prenatal exposures to alcohol, prescription or nonprescription medications, or infections are known to relate to developmental delay and/or hearing loss.
- Medical history
 - Prematurity, trauma, seizure disorders, major surgeries, and systemic infections are all risk factors for communication disorders.
 - Multiple anomalies may relate to an underlying syndrome.
- Feeding history
 - Neuromotor and structural disorders may be noted in early feeding history
 - Ask about failure to thrive, frequent pneumonia, prolonged feeding time, or chronic nasal regurgitation.
- Family history
 - Heredity may be a factor associated with stuttering, specific language impairment, autism spectrum disorders, cleft palate, developmental apraxia of speech, hearing loss, deafness, and other speech-language disorders.
- Social history
 - Evaluate for history of abuse, trauma, or neglect.
 - Smoking in the home is a known risk for middle ear infections.

- Frequent verbal interaction and reading promote speech and language skills.
- Speech and language history
 - Routine screening for speech and language milestones aid early identification.
 - Duration of symptoms for voice and resonance disorders will separate acute infection from true disorders.
 - Regression of speech or language skills may be associated with autism spectrum disorders or trauma.
- Key milestones
 - By 1 year of age
 - Points to (or gazes toward) known person or object name (Where's mama?)
 - Produces at least one true word; may not be recognized by all but is consistent
 - By 2 years of age
 - Identifies body parts, follows one-element commands (Get your book.)
 - Uses about 50 expressive words and starts to combine 2 words together (up dada)
 - By 3 years of age
 - Follows 2–3 element commands, combines 3-word phrases, and uses short questions (e.g., Why?)
 - Speech is understood by familiar listeners the majority of the time.
 - By 4 years of age
 - Uses longer sentences and tells short stories/sequences of events
 - Answers who, what, where, and when questions
 - Speech is understood by an unfamiliar listener nearly all the time.
- Physical and social development
 - Missed physical or social milestones are indicative of overall delay. Delayed or absent social milestones may aid in early identification of autism spectrum disorders.

PHYSICAL EXAM

- Face. Evaluate for facial symmetry at rest (structural) and during

movement (neurologic). Drooling is typical during early infancy and teething but should resolve by 18–24 months.

- Eye color. Iris heterotropia together with white forelock frequently associate with hearing loss in Waardenburg syndrome.
- Skin. Café au lait spots are associated with neurofibromatosis and hearing loss.
- Head shape and size. Microcephaly, macrocephaly, or plagiocephaly or other skull asymmetries may be associated with developmental delay, hypotonia, or craniosynostosis conditions.
- Symmetry, structure, and height of ears. Ear tags, atresia, and low-set ears have high association with hearing loss and should prompt audiologic and otolaryngology evaluation.
- Intraoral exam. Dental health, palatal shape, and jaw relationships should be noted. Soft palate (velar) elevation should be symmetric on “ah.” Bifid uvula, bluish color of velum, or V-shaped notch at the border of the hard and soft palate are indicative of a submucous cleft palate. Absent gag response is not a contraindication to feeding but should be noted.
- Phonation. Listen to vocal quality on sustained “ah.” Wet voice may indicate swallowing disorder. Rough, hoarse, or strained vocal quality is atypical and requires evaluation.

DIAGNOSTIC TESTS & INTERPRETATION

Screening Procedures

- Speech-language screening
 - Brief check on domains of communication designed to determine whether to refer child for full speech-language evaluation
 - Results often reported as “Pass/Refer” with minimal or no interpretation.
 - May be conducted by speech-language pathologist, audiologist, teacher, or other professional
- Hearing screening
 - Brief assessment that may be conducted for newborns or older children to detect presence or absence of response to sound at a set hearing level across frequencies
 - Results often reported as “Pass/Refer” with minimal or no

interpretation.

- Screening may be conducted by an audiologist, speech-language pathologist, nurse, or trained paraprofessional.

Diagnostic Procedures/Other

- Speech-language evaluation
 - Measurement of receptive, expressive, and/or pragmatic language skills; articulatory/phonologic development; and oral structural and physiologic examination with interpretation of findings and recommendations
 - Conducted by speech-language pathologist
- Hearing evaluation
 - Testing to obtain auditory thresholds (in decibels, dB) across sound frequencies (in Hertz, Hz) in both ears
 - If hearing loss is identified, further testing to determine if the source is middle ear (conductive) or inner ear (sensorineural) or mixed (both conductive and sensorineural)
 - Very young children may be tested using auditory brainstem response (ABR) or otoacoustic emissions (OAE).
 - Conducted by an audiologist
- Cognitive evaluation
 - Testing to assess overall cognitive development across verbal and nonverbal domains with results interpreted together with recommendations for interventions and/or school placement
 - Typically conducted by a psychologist
- Genetics evaluation and testing
 - Comprehensive family history, physical exam, metabolic, and/or cytogenetic testing often to identify or rule out specific diagnoses (e.g., fragile X, 22q deletion syndrome, neurofibromatosis, or genes associated with hereditary hearing impairment)
 - Interpretation of findings includes explanation to family of carrier status and recurrence risk.
 - Typically conducted by clinical geneticist or interdisciplinary genetics clinic
- Radiologic or other imaging studies: rarely used to assess underlying cause of speech or language disorders but may be used to rule out or

identify related conditions such as intraventricular hemorrhage or swallowing and resonance disorders

DIFFERENTIAL DIAGNOSIS

Communication disorders may be associated with other underlying conditions. A diagnosis of speech or language delay should include a process of evaluating the child for underlying causes, which alter the treatment approach:

- Hearing loss. Evaluate for familial or congenital loss; chronic middle ear infection; or acquired loss (e.g., ototoxic medications, systemic infection, underlying syndrome, or noise exposure).
- Developmental delay or autism spectrum disorders. Failure to develop verbal language in the absence of hearing loss should yield examination of physical and social–behavioral milestones to rule out overall delay and/or autism spectrum disorders.
- Neuromotor disorders. Neuromotor disorders may yield low facial/oral tone, weakness, or paralysis that may reduce speech intelligibility. Developmental apraxia of speech requires assessment and may coincide with limb apraxia.
- Vocal overuse or trauma. Evaluate for overuse patterns from habitual screaming, poor singing technique, and cheerleading.
- Structural and dental changes. Dental malocclusion or oral structural anomalies may reduce speech intelligibility for particular speech sounds.
- Sleep apnea. Poor sleep may be the cause of behavioral and learning concerns.
- Selective mutism. Specific situations in which the child will not speak in the absence of evident speech or language disorder. May coincide with social withdrawal, shyness, social anxiety
- Social isolation, neglect, or malnutrition should be ruled out, as these may associate with delays or losses of communication skills.
- Seizure disorders such as Landau-Kleffner syndrome can be associated with loss of language skills.

TREATMENT

- Direct service
 - In-home services
 - Evaluation and treatment for high-risk infants and toddlers in family-centered, natural environment, with minimal or no expense to family
 - Clinic-based services. Evaluation and individual or group treatment through a hospital, private, or university speech–language–hearing clinic
 - May be needed for specialized services
 - School-based services
 - Evaluation, individual or group treatment usually through special education services that yield an Individualized Education Plan (IEP)
 - Service delivery is often limited to conditions that impact the child’s educational performance.
- Related services
 - Interdisciplinary team care
 - Children with complex medical needs should be served by an interdisciplinary team such as a cleft palate/craniofacial, spina bifida, autism, feeding, or multiple disability clinic.
 - Provides comprehensive physical, functional, and psychosocial care of the child and family in collaboration with primary care providers
 - Otolaryngology. Detailed examination of laryngeal structures, airway, palatal structures, enlarged tonsils, and/or management of otologic concerns

ONGOING CARE

- Early identification of hearing, speech, or language problems is critical and leads to better outcomes.
- Children who have untreated hearing, speech sound, and language disorders are at risk for academic difficulties.
- Many speech problems can be resolved with short-term treatment. Some conditions may require longer term management extending

through adolescence.

- Adenoid removal is usually contraindicated for children with cleft palate, including submucous cleft palate. Airway and apnea management may be an exception that requires interdisciplinary decision making.

CODES

ICD10

- R47.9 Unspecified speech disturbances
- F80.81 Childhood onset fluency disorder
- R48.2 Apraxia

FAQ

- Q: Does ankyloglossia negatively affect speech production?
- A: The tongue tip is used for speech sounds /t, d, n, l, s, z/. If the child can make one or more of these sounds, then ankyloglossia can go untreated.
- Q: Does “baby sign” help or delay the acquisition of speech and language?
- A: Evidence suggests teaching gestural communication is associated with slightly advanced auditory–verbal language skills before 24 months of age and may decrease toddler–parent frustration. By 30–36 months of age, no significant differences are observed between

children who used baby sign and those who did not.

- Q: Does chronic otitis media slow the acquisition of speech or language?
- A: Early speech and language may be delayed in the presence of otitis media. If treated, differences in language skills typically resolve by school age.

SPINAL MUSCULAR ATROPHY

Jennifer A. Markowitz

BASICS

DESCRIPTION

- Spinal muscular atrophy (SMA) is a progressive disorder of motor neurons in the spinal cord and brainstem.
- Major symptom is proximal weakness.
- 3 forms are described based on clinical features:
 - Type I, also known as Werdnig-Hoffman disease, typically presents by 6 months of age; these children never sit.
 - Type II typically presents between 6 and 18 months of age; these children sit independently but never walk.
 - Type III, also known as Kugelberg-Welander disease, may be diagnosed later; these children stand and walk at some point.
- There appears to be a spectrum of severity within and between each type.

EPIDEMIOLOGY

The most common genetic cause of infant mortality

Incidence

Incidence estimated at 1 in 6,000–10,000 live births; carrier frequency 1 in 40–50, although some variation between populations seems to exist.

RISK FACTORS

Genetics

- Genetic testing is recommended in all cases, even when the diagnosis appears clear.
- Genetic counseling is critical for all families with children affected by SMA, as the chance of recurrence is 25%.
- SMN2 copy number varies among the general population and is loosely correlated with SMA type (type I likely to have fewer copies); however, all copies of SMN2 are not equal (some make more SMN protein than others), and an individual patient's SMN2 copy number

should not be used for prognostic purposes.

- Universal newborn screening is strongly recommended by some but is controversial; a pilot study has been approved in limited states.

ETIOLOGY

- All 3 types of proximal SMA follow an autosomal recessive inheritance and are caused by mutations in the survival motor neuron (SMN) gene on 5q11.2 to 13.3.
- 2 copies of SMN on each chromosome. SMN1 (SMNt), the telomeric copy, produces stable SMN protein. SMN2 (SMNc), the centromeric copy, is an inverted duplication of SMN1 with a single nucleotide change in an exonic splice enhancer, which produces mostly an unstable, truncated protein product and a smaller percentage of stable, full-length SMN protein.
- Individuals with SMA harbor homozygous deletions of exon 7 in the SMN1 gene, which renders it nonfunctional. The presence of SMN2 essentially “rescues” individuals with SMN1 deletions because complete absence of SMN protein appears to be embryonically lethal. The level of SMN protein roughly correlates with the severity of disease, making this a target of therapeutics development.
- The SMN protein plays a role in RNA processing; it is unclear why motor neurons (anterior horn cells) are selectively vulnerable to this defect, although a role in axonal mRNA trafficking and splicing is being explored.
- SMA appears to affect other organ systems, especially in those with the most severe form; cardiovascular, autonomic, and metabolic abnormalities are reported.

COMMONLY ASSOCIATED CONDITIONS

Other anterior horn cell diseases:

- SMA with respiratory distress (SMARD) or diaphragmatic SMA due to mutations in the IGHMBP2 gene on chromosome 11q
- Distal SMAs, a group of disorders with distal weakness, genetically heterogeneous
- Other variants are associated with arthrogryposis, pontocerebellar hypoplasia, congenital fractures, and congenital heart disease. Few

such cases have been shown to have SMN mutations.

- Fazio-Londe disease: rare degeneration of anterior horn cells in the brainstem, childhood onset
- Kennedy disease, or X-linked spinal and bulbar muscular atrophy: anterior horn cell disease with adult onset; affected men have gynecomastia, bulbar weakness, and reduced fertility.

DIAGNOSIS

HISTORY

- Hypotonia and weakness are the primary features. Infants with SMA I will be floppy and less active and have delayed motor milestones, with preserved language/social interaction (a bright, alert demeanor is often remarked upon).
- Some babies with type I present with feeding problems and failure to thrive.
- History of reduced vigor of prenatal movements

PHYSICAL EXAM

- Weakness and absent or reduced reflexes suggest a neuromuscular rather than central etiology for hypotonia. A proximal pattern of weakness is consistent with SMA, myopathies, and muscular dystrophies; a distal pattern usually suggests polyneuropathies.
- Weakness is almost universally symmetric, but occasional cases of asymmetric weakness have been reported in SMA III.
- Extraocular movements remain intact in SMA.
- Facial strength diminishes in children with type I over time, and jaw contractures may be present in type II.
- Dysmorphic features, or involvement of other organs, may point to alternative diagnoses. Occasionally, SMA presents with contractures (spectrum of arthrogryposis multiplex congenita).
- Tongue fasciculations strongly suggest SMA, but their absence does not exclude the diagnosis.
- Tremor of a specific type, polyminimyoclonus, is often present in type II.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial screening tests: Serum creatinine kinase may be mildly elevated.
- Genetic testing
 - Genetic testing of DNA extracted from blood (SMN deletions): now the gold standard in diagnosis, may be done prenatally, >95% sensitive
 - Genetic testing for Prader-Willi syndrome (fluorescence in situ hybridization and methylation) may be indicated if there is no SMN gene deletion and electromyography (EMG) is normal in an infant who appears to have SMA.
- Other testing
 - EMG may be helpful if the clinical presentation is atypical for SMA or if genetic testing is negative. EMG shows high-amplitude, long-duration motor units with a reduced recruitment pattern.
 - With the advent of molecular testing, muscle biopsy is rarely performed. Use when genetic testing is unrevealing. The characteristic findings are fiber-type grouping with generalized atrophy of muscle fibers.
 - If the entire evaluation is negative, MRI of the spine may be indicated to evaluate for an anomaly or mass lesion.

DIFFERENTIAL DIAGNOSIS

- Other genetic neuromuscular disorders include congenital muscular dystrophy, congenital myopathy, glycogen storage disorders (Pompe disease), myotonic dystrophy, mitochondrial disease, congenital myasthenia gravis, and Prader-Willi syndrome.
- More acute course may suggest infant botulism or Guillain-Barré syndrome, although the latter is rare in this age group.
- Systemic disorders: sepsis, meningitis, acute bowel syndromes
- SMA II differential: congenital muscular dystrophy, congenital myopathy, and congenital myasthenia gravis
- SMA III differential includes Duchenne, Becker, and the limb girdle muscular dystrophies; Lambert-Eaton myasthenic syndrome; and limb girdle congenital myasthenic syndromes.
- Spinal cord mass lesions may rarely resemble SMA.

TREATMENT

ALERT

An apparently minor respiratory infection may carry a higher risk of respiratory failure in SMA I and later stages of SMA II and III. Depending on family/patient wishes regarding respiratory support, consider admitting such a patient to the hospital for observation. Infants with SMA may be exquisitely sensitive to postural shifts—watch for hypoventilation, for example, with forward truncal flexion associated with some seating arrangements.

ADDITIONAL TREATMENT

General Measures

- A multidisciplinary approach to care is recommended, with early and proactive involvement of orthopedics, nutrition, pulmonary, and physical and occupational therapy as well as social work and psychological support for families and patients.
- Physical therapy is appropriate for all 3 types; although it may not affect the course in SMA I, it can lessen discomfort and make care easier by improving range of motion and preventing contractures.
- A wheelchair provides mobility in SMA II. Children as young as age 2 years may be considered for a motorized wheelchair, depending on developmental level. Adults with SMA III may require the use of a wheelchair later in their course.
- Bracing of ankles, wrists, and back can help reduce contractures and slow progression of scoliosis.
- Spinal fusion surgery may preserve respiratory function.
- Low threshold for empiric antibiotics for respiratory infection is appropriate.
- Chest physiotherapy and early implementation of cough-assist device can help prevent pneumonia and atelectasis.
- Be wary of symptoms of hypoventilation (disturbed sleep, daytime fatigue, moodiness, morning headaches), which may occur prior to other symptoms of respiratory insufficiency.
- Low threshold to order a sleep study if hypoventilation is suspected

- In acute respiratory illness, supplemental oxygen is appropriate as long as the patient is also evaluated and treated for hypercarbia.
- Noninvasive positive pressure ventilation (bilevel positive airway pressure [BiPAP] and other regimens) may improve quality of life and life expectancy in patients with decreased respiratory function. More aggressive respiratory management is becoming more common and accepted among families and physicians, but the extent of interventions varies widely. Start discussions about family/patient preferences early, as respiratory decompensation can occur very quickly.
- Avoid catabolic state with proactive nutritional support, including tube feeding.
- However, note that type II patients may have increased adiposity, and overweight is also a risk.
- Monitor for osteopenia, which is almost universal in types I and II, and ensure adequate calcium and vitamin D intake.
- Social and psychological support for caregivers and patients

ONGOING CARE

PATIENT EDUCATION

- Families of SMA: <http://www.curesma.org>
- Fight SMA: <http://www.fightsma.org>
- Muscular Dystrophy Association: <http://www.mdausa.org>
- Spinal Muscular Atrophy Foundation: <http://www.smafoundation.org>

PROGNOSIS

- Survival in all 3 forms has been increasing with improved supportive care and, in type I, ventilatory support.
- Most children with SMA type I die by 2 years without major pulmonary interventions. With ventilatory support, patients may survive several years longer; survival as long as 2 decades has been observed with tracheostomy and full mechanical ventilation.
- Children with SMA type II typically survive into late adolescence or early adulthood; this life expectancy is increasing with more aggressive pulmonary management.

- Individuals with SMA type III survive well into adulthood and often have a normal life expectancy. In 1 study of patients with SMA type III with onset <3 years, 50% could not walk 20 years later; for those with onset >3 years, 30% could not walk 20 years later.
- Intelligence is generally preserved.
- Death typically ensues from respiratory complications. Discuss the level of respiratory interventions, including resuscitation, early in SMA I and in the advanced stages of SMA II and III.

COMPLICATIONS

- Recurrent pneumonias, hypoventilation
- Swallowing difficulties may require tube feeding.
- Scoliosis may require surgery.

CODES

ICD10

- G12.9 Spinal muscular atrophy, unspecified
- G12.0 Infantile spinal muscular atrophy, type I [Werdnig-Hoffman]
- G12.1 Other inherited spinal muscular atrophy

FAQ

- Q: Can routine vaccinations be given to children with SMA?
- A: Yes. In addition to routine vaccinations, yearly influenza and respiratory syncytial virus (RSV) vaccinations are recommended.
- Q: How much respiratory support should a child with SMA receive?

- A: Standards of care are evolving rapidly, and a consensus remains elusive. Noninvasive respiratory interventions are becoming more widely accepted. Noninvasive respiratory options should be offered to all patients with SMA I and those in the later stages of SMA II. Tracheostomy is more controversial.
- Q: Are more effective therapies for SMA being developed?
- A: There are ongoing studies in animal models and on humans, involving both pharmacologic and gene-based therapies. Patients and families should be informed about clinical trials that may be available to them. Families of SMA, the Muscular Dystrophy Association, and other groups, as well as [Clinicaltrials.gov](https://clinicaltrials.gov), are sources of information on such research.

SPLENOMEGALY

Matthew J. Ryan

BASICS

DESCRIPTION

- A palpable spleen is found in most premature infants and in 30% of term infants. A spleen tip is still palpable in 10% of infants at 1 year of age and in 1% of children at 10 years of age.
- Normal spleens are not greater than 6 cm at 3 months, 7 cm at 12 months, 9.5 cm at 6 years, 11.5 cm at 12 years, and not greater than 13 cm for adolescents.
- Splenomegaly can also be a spleen width >4 cm or diameter >7 cm.
- Normal spleen size varies but is typically less than 250 g.
- The clinical significance of splenomegaly found on radiologic study, but not palpable on physical exam, is unclear in the absence of other laboratory or clinical data.
- Normal spleens are soft at the midclavicular line, nontender, and often palpable only on deep inspiration.
- Dullness on percussion beyond the 11th intercostal space suggests splenomegaly.
- A spleen edge palpated >2 cm below the costal margin is always an abnormal finding.
- Splenic tenderness is always abnormal.

PATHOPHYSIOLOGY

- The spleen is a hematopoietic organ with 2 main parts:
 - White pulp is the lymphoid tissue.
 - Red pulp is the red cell mass.
- Splenic sinusoids are lined with macrophages that destroy abnormal red cells.
- The spleen also serves as a reservoir for platelets. A normal-sized spleen can hold 1/3 of the circulating platelets; an enlarged spleen can hold up to 90% of the circulating platelet mass.
- Normal splenic volume by CT scan is 214.6 cm³ (range, 107.2 cm³–

314.5 cm³).

- Splenic size does correlate with height.

DIAGNOSIS

HISTORY

- **Question:** History of acute illness?
- Significance: Suggests infection
- **Question:** History of GI bleeding with splenomegaly?
- Significance: Suggests portal hypertension
- **Question:** Familial history of hematologic or immune disease?
- Significance: Suggests genetic etiology
- **Question:** An enlarged liver, developmental delay, or neurologic findings?
- Significance: May suggest a storage disease or metabolic disorder

PHYSICAL EXAM

Begin the abdominal examination in the lower left quadrant because an enlarged spleen may be missed in the upper quadrant exam. Stand to the right of the patient; use the right hand to palpate and the left hand to support the patient's left lower rib cage. Flexing the legs at the knees may help to relax the abdominal musculature.

- **Finding:** Auscultate for rub or bruit?
- Significance: Vascular malformation
- **Finding:** Look for signs of storage disease?
- Significance: Retinal exam, coarse facies
- **Finding:** Complete evaluation of lymph nodes?
- Significance: Enlargement suggests infection or neoplasia.
- **Finding:** Palpate for ascites or hepatomegaly?
- Significance: Suggests underlying hepatic disease
- **Finding:** Prominent abdominal veins or hemorrhoids?
- Significance: Suggest increased portal venous pressure
- **Finding:** Pain/tenderness?
- Significance: Suggests capsular distention secondary to perisplenitis or trauma; also raises the question of splenic infarct

- **Finding:** Asthmatic patients may have palpable spleen?
- **Significance:** Secondary to overinflation of lungs with a depressed diaphragm

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- **Test:** Blood culture, thick smear of blood for malaria, viral testing
- **Significance:** evaluate for infection
- **Test:** CBC with manual differential and smear
- **Significance:** For sickle cell disease, hemolytic anemia, leukemia
- **Test:** Decreased WBC count and platelets
- **Significance:** Often seen with splenic sequestration or portal hypertension
- **Test:** Reticulocyte count
- **Significance:** For hemolytic anemia
- **Test:** Hepatic function panel (liver enzymes, albumin, bilirubin) and prothrombin time (PT)/international normalized ratio (INR), partial thromboplastin time (PTT)
- **Significance:** For cirrhosis, hepatic obstruction
- **Test:** Serum lactate dehydrogenase (LDH)
- **Significance:** For hemolysis or tumor screen

Imaging

- If no hemolytic disease, no sign of infection, no sign of congestion:
 - Ultrasound with Doppler
 - Liver spleen scan
- If no hemolytic disease, no sign of infection but signs of congestion:
 - Ultrasound with Doppler
 - MRI; consider MRA/MRV

Diagnostic Procedures/Other

Biopsy of lymph node, liver, or other tissue, depending on findings

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Bacterial
 - Bacteremia

- ▣ Pneumonia
 - ▣ Sepsis
 - ▣ Subacute bacterial endocarditis
 - ▣ Salmonellosis
 - ▣ Tuberculosis
 - ▣ Brucellosis

 - ▣ Babesiosis
 - ▣ Schistosomiasis
 - ▣ Visceral larval migrans
 - ▣ Kala azar
- Fungal
 - ▣ Histoplasmosis
 - ▣ Coccidioidomycosis
- Hematologic disorders
 - Hereditary spherocytosis
 - Sickle cell disease in early childhood or during splenic sequestration crisis
 - Hemoglobin C disease
 - Thalassemia major

- Autoimmune hemolytic anemia
- Glucose-6-phosphate dehydrogenase deficiency
- Isoimmunization disorders
- Infantile pyknocytosis
- Iron deficiency anemia (rare)
- Thrombocytopenic purpura
- Vascular disorders
 - Cavernous transformation of the portal vein
 - Budd-Chiari syndrome
 - Splenic vein thrombosis
 - Congenital portal vein stenosis or atresia
 - Splenic hematoma
 - Splenic hemangioma
- Liver disease/cirrhosis (examples include, but are not limited to)
 - Biliary atresia
 - Wilson disease
 - Cystic fibrosis
 - α -1-Antitrypsin deficiency
 - Hereditary hemochromatosis
 - Congenital hepatic fibrosis
 - Autoimmune hepatitis
 - Primary sclerosing cholangitis
- Metabolic diseases (storage)
 - Gangliosidoses
 - Mucopolysaccharidoses
 - Metachromatic leukodystrophy
 - Wolman disease
 - Gaucher disease
 - Niemann-Pick disease
 - Amyloidosis
- Neoplastic diseases
 - Leukemia
 - Lymphoma
 - Lymphosarcoma
 - Neuroblastoma

- Histiocytosis X
- Familial hemophagocytic lymphohistiocytosis
- Miscellaneous
 - Serum sickness
 - Connective tissue disorders
 - Juvenile rheumatoid arthritis
 - Systemic lupus erythematosus
 - Sarcoidosis
 - Splenic hamartoma
 - Splenic cysts: congenital and posttraumatic
 - Trauma: subcapsular hematoma
- Nonsplenic upper left quadrant abdominal masses
 - Large kidney
 - Retroperitoneal tumor
 - Adrenal neoplasm
 - Ovarian cyst
 - Pancreatic cyst
 - Mesenteric cyst
 - Rib anomaly

ALERT

- Life-threatening causes: sepsis, severe hemolytic anemia, trauma, splenic sequestration
- A large-bore IV access route should be rapidly placed when a life-threatening cause is suspected.

TREATMENT

GENERAL MEASURES

- Treatment depends on underlying etiology.
- Spleen guards can be used to protect from traumatic splenic rupture.

ISSUES FOR REFERRAL

- Increasing size over serial examinations (hepatology, hematology/oncology)
- Unexplained lymphadenopathy (oncology)

- Liver dysfunction and or ascites (hepatology)
- Signs of storage or metabolic disease (metabolism, GI)
- Howell-Jolly bodies on peripheral smear, suggesting splenic dysfunction (hematology)

SURGERY/OTHER PROCEDURES

Splenectomy indicated in certain situations including symptomatic hematologic disorders, abscess, and neoplasms.

ONGOING CARE

General goal is to determine the etiology of the large spleen.

- Establish the presence of enlarged spleen, not a palpable spleen that is pushed down by inflated lungs.
- Rule out common causes such as a viral infection, bacterial infection, or anemia.
- Rule out malignancy or storage disease or other rare causes of large spleen.
- Ensure proper immunizations or antibiotic prophylaxis.
- Ongoing care depends on the underlying etiology of the splenomegaly.

CODES

ICD10

- R16.1 Splenomegaly, not elsewhere classified
- D73.5 Infarction of spleen
- D18.03 Hemangioma of intra-abdominal structures

FAQ

- Q: How long will the enlarged spleen secondary to a viral infection be present?
- A: The enlarged spleen may persist for several months.
- Q: Should patients with decreased splenic function due to splenomegaly be immunized?
- A: Immunization with a pneumococcal conjugate and/or polysaccharide vaccine should be carried out in all patients with compromised splenic function. In those patients who will be undergoing a scheduled splenectomy, the Streptococcus pneumoniae, meningococcus, and Haemophilus influenzae type B vaccines should be given at least 14 days prior to the operation.
- Q: Should a child with an enlarged spleen refrain from sports?
- A: Contact sports should be avoided for a child with an enlarged spleen. An enlarged spleen is engorged with blood, and a splenic rupture would be a catastrophic event. Children with persistent splenomegaly should be considered for a spleen guard.

SPONDYLOARTHROPATHY

Melissa L. Mannion • Randy Q. Cron

BASICS

DESCRIPTION

A group of inflammatory arthritides associated with enthesitis (inflammation at the bony insertion of tendons and ligaments) and axial involvement, typically sacroiliitis

- Enthesitis-related arthritis
- Ankylosing spondylitis (AS)
- Psoriatic arthritis
- Inflammatory bowel disease–associated arthropathy

EPIDEMIOLOGY

- Spondyloarthritis accounts for 15–20% of juvenile arthritis.
- AS typically affects adolescent boys. Much less common in blacks:
 - HLA-B27 occurs in 70–90% of patients and is present in 8% of whites and 6% of blacks in the general population.

Prevalence

~1/10,000 white boys

RISK FACTORS

Genetics

- HLA-B27 associated
- Usually a family history of a male relative with disease

PATHOPHYSIOLOGY

Inflammatory synovitis of joints and inflammation at sites of ligament and tendon attachment (entheses). Progression to ankylosis is a result of calcification of the anterior and posterior longitudinal ligaments of the spine.

ETIOLOGY

Autoimmune or autoinflammatory arthritis of unknown etiology, microbiome may play a role in disease

DIAGNOSIS

- Inflammatory back pain (better with exercise, not relieved by rest) of insidious onset that has been present for at least 6 weeks
- Inactivity stiffness resulting in gelling of peripheral joints and back

HISTORY

- Back pain and joint pain/swelling
- Family history

PHYSICAL EXAM

- Sacroiliac (SI) tenderness
 - Indicates site of inflammation
- Pain on direct palpation at insertion of Achilles tendon and plantar fascia at calcaneal insertion (location of entheses)
 - Indicates site of inflammation
- Patrick test (FABER)
 - FABER stands for “Flexion, ABduction and External Rotation”
 - A series of maneuvers to screen for issues with the sacroiliac and hip joints
- Psoriasis, nail pitting, or dactylitis

DIAGNOSTIC TESTS & INTERPRETATION

- Schober test of lumbar spine flexibility
 - Mark 15-cm vertical span at mid-lower back at level of iliac crest while patient is standing.
 - Have patient bend forward at the waist as far as possible without bending knees.
 - Remeasure span.
 - Abnormal if <5 cm increase in span

Lab

CBC, erythrocyte sedimentation rate (ESR), HLA-B27, rheumatoid factor (RF), and antinuclear antibody (ANA) tests

- ESR is occasionally not elevated.
- RF and ANA are typically negative.

Imaging

Sacroiliac views

- Demonstrate evidence of pseudowidening, erosions, and/or sclerosis, with fusion being a late finding.
- Because x-ray findings may take years to develop in the presence of disease, MRI is supplanting x-ray as the initial modality to assess SI involvement in some centers.

DIFFERENTIAL DIAGNOSIS

- Caution
 - Overdiagnosis in HLA-B27–positive individuals in whom other causes for joint swelling should be considered
- Infection
 - Reactive arthritis caused by enteric pathogens or Chlamydia species
 - Whipple disease
 - Intestinal bypass–associated arthritis
 - Discitis
 - Pott disease (vertebral tuberculosis)
- Tumors
 - Osteoid osteoma
- Trauma
 - Traumatic injury causing lower back pain/spasm
 - Herniated disc
- Metabolic
 - Ochronosis
- Congenital
 - Kyphosis
- Immunologic
 - Oligoarticular juvenile idiopathic arthritis
- Psychological
 - Feigning lower back pain/stiffness
- Miscellaneous
 - Fibromyalgia

TREATMENT

MEDICATION

- NSAIDs
 - Naproxen
 - Indomethacin
 - Diclofenac
- Disease-modifying drugs
 - Sulfasalazine
 - Methotrexate
 - Leflunomide
 - Tumor necrosis factor (TNF) inhibitors

ADDITIONAL TREATMENT

General Measures

- Therapy may need to be lifelong.
- After initiation of therapy, should see some improvement in stiffness, synovitis, and range of motion over weeks to several months
- Only TNF inhibitors are effective for axial involvement.

ADDITIONAL THERAPIES

Physical therapy

- Physical therapy is an essential component of treatment.
- Must encourage range-of-motion exercises and avoid prolonged neck flexion

SURGERY/OTHER PROCEDURES

In advanced cases, total hip replacement, C-spine fusion, and/or spinal wedge osteotomy (the latter if posture is severely affected)

ONGOING CARE

DIET

- Ensure food intake with NSAIDs.
- Ensure folate intake with methotrexate.

PATIENT EDUCATION

Activity

- As tolerated. In cases of severe/advanced disease, modify behaviors

accordingly in consideration of reduced spine flexibility and subsequent risk of serious injury.

PROGNOSIS

Poor if disease remains active for 10 years or more.

COMPLICATIONS

- Acute anterior uveitis
- Aortic insufficiency
- Worsening stiffness
- Ankylosis with risk of vertebral subluxation, fracture, and nerve damage, including cauda equina syndrome
- Acute or chronic eye pain
- Chest pain or shortness of breath

ALERT

A red, painful eye in a patient with HLA-B27–positive spondyloarthropathy should not be assumed to be infectious conjunctivitis. Slit-lamp exam is required to diagnose acute anterior uveitis.

CODES

ICD10

- M12.88 Oth specific arthropathies, NEC, vertebrae
- M46.1 Sacroiliitis, not elsewhere classified
- M45.9 Ankylosing spondylitis of unspecified sites in spine

FAQ

- Q: Should HLA-B27 be checked routinely in boys with back pain?
- A: Inflammatory back, joint, or enthesal pain; family history; and exam findings should increase your suspicion for HLA-B27–positive disease. Detection of HLA-B27 alone should not precipitate an extensive workup because it is so common in the normal healthy population. However, the risk for developing a spondyloarthropathy is 16 times greater than in HLA-B27–negative individuals.
- Q: Can affected individuals play contact sports?
- A: This is probably not a good idea in patients with ankylosis because as the spine fuses, the risk for fracture of the spine (especially the cervical spine) increases. However, children with milder forms of disease, such as enthesitis-related arthritis, should not be discouraged.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Lauren G. Solan • Craig H. Gosdin

BASICS

DESCRIPTION

- A spectrum of generalized exfoliative skin disease with blistering of the upper layer of skin caused by an epidermolytic toxin produced by certain strains of *Staphylococcus aureus*
- In neonates and young infants, also known as Ritter disease or pemphigus neonatorum
- Classically described as skin tenderness and erythema, with bullae formation and desquamation
- Severity of the disease ranges from
 - Few blisters localized to site of infection
 - Mild illness with desquamation of skinfolds following impetigo
 - Generalized severe exfoliation involving much of the body (typically seen in neonates)
 - Classic staphylococcal scalded skin syndrome (SSSS): tenderness, erythema, desquamation, or bullae formation. May resemble scalding injury
- Pitfalls
 - Failure to differentiate from streptococcal disease, as SSSS requires treatment with penicillinase-resistant antibiotic therapy (e.g., nafcillin)
 - Late recognition leading to delayed therapy and shock
 - Not appreciating increased fluid losses through affected skin
 - Differentiation from toxic epidermal necrolysis (TEN) is critical, as therapy is very different.

EPIDEMIOLOGY

- Most cases occur in neonates and children.
 - 62% of affected children are <2 years of age.

- 98% of affected children are <6 years of age.
- Rare in adults due to increased circulating antibodies and adult kidney excretion of the toxin

Incidence

- No differences in incidence based on gender in children; however, in adults, the male-to-female ratio is 2:1.

RISK FACTORS

- Immunocompromised state (in children or adults)
 - Maternal antibodies transferred via breast milk are partially protective, but neonatal cases can still occur.
- Increased *S. aureus* carriage and susceptibility to toxin (usually in adults)
- Renal impairment either due to immature renal clearance of toxin in children or underlying renal disease

GENERAL PREVENTION

- Good hand hygiene practices, including adherence to contact precautions in hospitalized patients, to prevent spread from asymptomatic carriers
- Prevent skin from becoming overly moist or macerated.
- Isolation of hospitalized patient
 - Suspected or documented cases should be placed in contact isolation.

PATHOPHYSIOLOGY

- Exfoliative toxins circulate throughout the body, causing blisters at sites distant from the infection.
- Destruction of protein desmoglein 1 (attachment protein found only in the superficial epidermis) by exfoliative toxin A (ETA) and exfoliative toxin B (ETB) cause intraepidermal splitting leading to bullae development and skin desquamation.

ETIOLOGY

- Exfoliative toxin released by *S. aureus*:
 - 2 major serotypes of the toxin: ETA and ETB
 - Mostly caused by *S. aureus* belonging to phage group II, types 71

and 55

COMMONLY ASSOCIATED CONDITIONS

- Skin and soft tissue infections or abscesses
- Bullous impetigo

DIAGNOSIS

ALERT

- **Diagnosis is primarily clinical; do not delay treatment.** Cultures and other diagnostic tests are largely confirmatory.
- Confusion with TEN may lead to use of corticosteroids or discontinuation of antibiotics, resulting in worsening infection from prolonged toxin production.

HISTORY

- Nonspecific virus-like prodrome with irritability, sore throat, conjunctivitis, and upper respiratory infection is typical.
- Usual onset of fever within 48 hours after prodrome
- Rash typically begins periorally, then extends to the trunk and extremities, and finally desquamates.
- Recent localized extracutaneous infection is common.
 - Infections involving the nasopharynx, middle ear, conjunctivae, pharynx, tonsils, umbilicus, or urinary tract are frequently recalled.
- A history of recent drug use suggests other etiology such as TEN.

PHYSICAL EXAM

- Erythroderma: red, painful skin
- Large flaccid bullae that leave behind denuded skin resembling a burn after rupturing appear within 1–2 days
 - Bullae often appear in areas of trauma or in areas that are rubbed or touched, including intertriginous zones.
- Nikolsky sign (gentle friction applied to apparently healthy skin will cause blistering and sloughing) appears within 1–2 days.
- Distribution of lesions: most commonly face, neck, axilla, perineum
- Facial edema with perioral and periocular crustiness is typical and may

be the primary clinical features.

- Conjunctivitis with or without periorbital edema may also be present.

ALERT

- Nikolsky sign can be seen in both TEN and SSSS, but in SSSS, it is often noted over areas of unaffected skin as well.
- SSSS does NOT involve the mucous membranes, but TEN does.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- General: CBC may be normal; erythrocyte sedimentation rate (ESR) typically elevated; electrolytes and renal function should be followed closely in severe cases and cases with dehydration.
- Microbiologic diagnosis: Culture of the original infected site, other involved sites/abnormal skin, blood, urine, nasopharynx, and umbilicus should be performed to determine the organism and antibiotic susceptibility.
 - Typically isolate phage group II *S. aureus*
 - Some immunologic methods exist to specifically identify the exfoliative exotoxins.
 - Intact bullae are sterile.
 - Blood cultures are typically negative.
- Histologic diagnosis: Skin biopsy can be used to differentiate SSSS from TEN; SSSS demonstrates separation of the epidermis at the granular layer, whereas with TEN, there is necrosis of the entire epidermis with a deeper plane of separation at the basement membrane.

DIFFERENTIAL DIAGNOSIS

- TEN
- Kawasaki disease
- Bullous impetigo
- Erythema multiforme bullosum
- Erythema multiforme major (Stevens-Johnson syndrome)
- Streptococcal scarlet fever
- Streptococcal or staphylococcal toxic shock syndrome (TSS)
- Bullous varicella

- Burns, including inflicted burns in suspected child abuse
- Primary bullous disorders (e.g., bullous mastocytosis)
- Chronic bullous disease of childhood
- Pemphigus vulgaris or foliaceus
- Epidermolysis bullosa

TREATMENT

GENERAL MEASURES

- Hospitalization is necessary for antibiotic therapy and supportive care.
- Consider consultation with infectious disease and/or dermatology.
- Apply principles of good burn care in severe cases, including the following:
 - Consideration of management in a critical care setting
 - Aggressive and early fluid and electrolyte management including daily maintenance requirements in addition to replacement of increased insensible skin losses
 - Petrolatum gauze should cover eroded areas to prevent further skin trauma.
 - Blisters should be left intact.
 - Children should be allowed to rest unclothed on clean linens, and handling of the child should be kept to a minimum.
 - Use of pressure-relieving mattresses

MEDICATION

- 1st-line agent: parenteral antistaphylococcal antibiotics: nafcillin, oxacillin, or 1st-generation cephalosporin (e.g., cefazolin)
- Some experts add clindamycin to inhibit exotoxin production.
- Clindamycin or vancomycin can be used for penicillin-allergic patients (severe allergies).
- 2nd-line agent: vancomycin for severe cases with toxic-appearing patient or concern for methicillin-resistant *Staphylococcus aureus* (MRSA)
- MRSA is rare but can occur.
- Antibiotic therapy can be tailored once sensitivities are known.

- Topical antibiotics are of no benefit.
- Oral antibiotics are not effective initially, but once a clear response has been noted with parenteral antibiotics, an oral antibiotic active against *S. aureus* can be used to complete the course of therapy.
- Corticosteroids have been shown to be detrimental both in experimental animal models as well as clinical trials.
- Adequate pain management is essential.

ALERT

Avoid nonsteroidal anti-inflammatories due to potential for renal impairment,

ONGOING CARE

PROGNOSIS

- Usually complete recovery within 10–14 days **without** scarring if treated
- Prognosis is more guarded in infants and those with underlying illness.
- Childhood mortality approximately 4%, whereas adult mortality reportedly >60%
- Does not tend to recur

COMPLICATIONS

- Occasional shedding of hair and nails
- Fungal or bacterial superinfection following desquamation
- Serious fluid and electrolyte disturbances may occur in cases involving large surface areas, which may lead to poor temperature control, sepsis, shock, and death.
- Neonates are particularly susceptible.

CODES

ICD10

L00 Staphylococcal scalded skin syndrome

FAQ

- Q: Can SSSS recur?
- A: Yes, although it is uncommon.
- Q: Is SSSS contagious?
- A: Yes. The staphylococci are spread primarily from person to person (familial clusters have been reported), even from mother to fetus, most efficiently by someone with lesions, but asymptomatic carriers may also spread infection. Spread of organisms does not necessarily lead to signs of toxin production in those acquiring infection.
- Q: How can one distinguish TEN from SSSS?
- A: TEN is frequently confused with SSSS and may be differentiated by skin biopsy showing cleavage plane at the dermal–epidermal junction. TEN is more common in older children and adults and is usually secondary to drug hypersensitivity (e.g., sulfonamides, barbiturates, pyrazolone derivatives).
- Q: Can *Staphylococcus* be isolated from the bullae?
- A: SSSS bullae are sterile, although organisms may be found in a distant focus, such as the nares or conjunctivae. In bullous impetigo, however, staphylococci may be isolated from the bullae.

STATUS EPILEPTICUS

Heather Olson • Tobias Loddenkemper

BASICS

DESCRIPTION

- Status epilepticus (SE) is defined as continuous seizure activity >30 minutes or recurrent seizures in 30 minutes without return to baseline. In practice, an operational definition of convulsive seizures >5 minutes is treated as presumed SE.
- SE presents in several forms:
 - Generalized SE: continuous or repeated generalized convulsion(s) with persistent loss of consciousness and neurologic function
 - Nonconvulsive SE, myoclonic SE, or absence SE: persistent encephalopathy, often with variable subtle motor signs such as myoclonus or nystagmus
 - Repeated partial seizures with alteration of consciousness (focal SE) or preserved consciousness (epilepsia partialis continua)
- Systemic complications of SE:
 - Hyperthermia, rhabdomyolysis
 - Tachycardia, hypertension early → hypotension late
 - Hypoxia, hypercapnia, aspiration pneumonia
 - Impaired cerebral autoregulation
 - Rare: cardiac arrhythmias, neurogenic pulmonary edema, bone fractures

ALERT

- Neuromuscular blockers used in intubation may obscure ongoing seizures. EEG monitoring is mandatory for all patients who have had any pharmacologic paralysis during SE.
- Continued encephalopathy after convulsions have ended may indicate continued electrographic seizures (nonconvulsive SE).
- Nonepileptic seizures can be mistaken for SE. EEG establishes the diagnosis.

EPIDEMIOLOGY

- Incidence in pediatric patients is 17–23/100,000. In children <1 year old, incidence is 135–156/100,000.
- ~40–70% of children have no history of seizures.

RISK FACTORS

- Known epilepsy
- Remote or acute central nervous system insult
- History of previous SE
- Low anticonvulsant drug levels
- Younger age

GENERAL PREVENTION

- Adherence to the anticonvulsant medication regimen and clinical follow-up in patients with epilepsy
- Refrain from rapid changes in anticonvulsants unless urgently needed.
- Prompt treatment of convulsive seizures

PATHOPHYSIOLOGY

SE may be related to acute or chronic factors or frequently of unknown etiology.

- Common acute factors:
 - Fever
 - Infectious meningoencephalitis
 - Metabolic: electrolyte abnormalities, hypoglycemia
 - Intoxications
 - Trauma or hemorrhage
 - Ischemic stroke, hypoxic–ischemic injury
 - Medications: low anticonvulsant drug levels or abrupt withdrawal of anticonvulsants, inappropriate anticonvulsants (e.g., absence SE with phenytoin or carbamazepine use in generalized epilepsy)
- Subacute or chronic factors:
 - Epilepsy of any cause
 - Brain tumors
 - Brain malformations (e.g., lissencephaly, polymicrogyria, hemimegalencephaly, neurocutaneous syndromes—tuberous sclerosis complex, Sturge-Weber syndrome)

- Other structural brain abnormalities such as strokes hypoxic–ischemic encephalopathy (HIE), or periventricular leukomalacia (PVL)
- Genetic epilepsies: Dravet syndrome (febrile SE), Angelman syndrome (myoclonic SE), progressive myoclonic epilepsy syndromes
- Inflammatory disorders (e.g., Rasmussen encephalitis, N-methyl-D-aspartate [NMDA] receptor antibody syndrome)

DIAGNOSIS

HISTORY

- Ask about prior seizures, treatment with antiepileptic drugs (AEDs), and other neurologic abnormality, including previous neurologic workup such as MRI brain or EEG.
- Ask specifically about precipitating factors: fever, preceding illness, head trauma, change in antiepileptic medication, and family history of seizures

PHYSICAL EXAM

- Vital signs: fever, respiratory rate/O₂ sats (adequacy of air exchange and abnormal breathing patterns), heart rate, BP (hypertension suggests intracranial hypertension)
- Signs of head trauma: retinal hemorrhages, excess bruising, bone fractures, evidence of intracranial hypertension such as bulging fontanelle
- Meningismus signals CNS infection, intracranial hemorrhage, or spine trauma. May be absent in young infants with meningitis
- Signs of systemic infection: fever (also potentiates seizure activity), petechiae, rash, mucosal lesions, lymphadenopathy
- Skin examination: Check for evidence of neurocutaneous disorders (e.g., café au lait spots, ash leaf spots, shagreen patches).
- Observe clinical presentation, specifically focal features or asymmetry.
- Postictal exam: Transient neurologic abnormalities (e.g., pupillary asymmetries, eye deviation, focal motor weakness [Todd paresis],

aphasia) may not correlate with the underlying structural lesion. After seizure has stopped, a neurologic examination should be performed, with attention to mental status, focal weakness, tone, or sensation.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial:

- STAT glucose, electrolytes, calcium, magnesium, and arterial blood gas
- Anticonvulsant levels if indicated
- CBC, liver function tests
- Toxicology screen, urinalysis

Imaging

Neuroimaging, CT, or MRI: indicated for SE, especially with partial-onset seizures (including aura), focally abnormal EEG, focal neurologic signs, or history of head trauma. MRI is the preferred neuroimaging test, but CT may be more appropriate for urgent imaging or if the patient is medically unstable.

Diagnostic Procedures/Other

- EEG: recommended to determine continued electrographic seizures and to identify focal versus generalized abnormalities. Urgent EEG recommended in patients with persistent SE or encephalopathy and in those with concern for nonconvulsive SE and nonepileptic SE.
- Lumbar puncture (LP): indicated to evaluate CNS infection in cases with suspected meningitis or encephalitis. Contraindications include intracranial hypertension known or suspected from exam or CT scan, cerebral mass lesion, and obstructive hydrocephalus. Lumbar puncture may be deferred if suspicion of CNS infection is low, that is, patient is afebrile, and an alternate etiology is present

DIFFERENTIAL DIAGNOSIS

- Nonepileptic SE: clinically suspected with eye closure; asynchronous, thrashing limb movements; pelvic thrusting, fluctuating responsiveness, head side to side movements, purposeful resistance to passive movement; and normal concurrent EEG. Induction of a seizure

by suggestion further supports this diagnosis.

- Movement disorders (including dystonia, chorea, and very frequent tics) can be mistaken for persistent seizure activity.
- Postanoxic myoclonus: status after prolonged cardiopulmonary arrest. These movements are usually nonrhythmic and segmental but can appear rhythmic at times. EEG is recommended for diagnosis.

TREATMENT

INITIAL STABILIZATION

- ABCs (stabilization of airway, supporting respiration, maintaining BP, and gaining intravascular access)
- Assess for hypoxia, hemodynamics, hyperthermia, hypoglycemia, hyponatremia.
- BP, EKG, and respiratory function should be monitored.
- Airway control may be maintained by head positioning, and oral airway placement and oxygen supplementation provided via nasal cannula, mask, or bag–valve–mask ventilation. If the need for respiratory assistance persists, endotracheal intubation may be required.
- For hypoglycemia: 2–4 mL/kg of D25
- Rectal acetaminophen and a cooling blanket for fever

MEDICATION

Anticonvulsant administration should be initiated when continuous seizure activity persists for >5 minutes. The most important modifiable treatment parameter is timing to treatment, and sooner treatment provides better seizure control.

ALERT

- 1st line: benzodiazepines
 - Lorazepam 0.05–0.1 mg/kg IV (max 5 mg over 1–4 minutes)
 - If no IV: diazepam 0.2–0.5 mg/kg/dose PR (max 20 mg/dose) or nasal or buccal midazolam
- 2nd line
 - Fosphenytoin 20 mg PE/kg IV

- If fosphenytoin unavailable: phenytoin 20 mg/kg IV
- 3rd line
 - Phenobarbital 20 mg/kg IV; can give additional 10 mg/kg if needed
 - Alternatives: valproic acid 20–40 mg/kg over 5–10 minutes, levetiracetam, or others
- 4th line: refractory SE
 - Midazolam or pentobarbital continuous infusion to seizure control or burst suppression
 - Alternatives: propofol (beware of propofol infusion syndrome with prolonged use), inhalational anesthetics

GENERAL MEASURES

- Attempt to establish IV access, but do not waste time on IV access. Consider IM midazolam, IN midazolam, or IO access or rectal diazepam immediately. The most important modifiable treatment parameter is timing to treatment.
- Consider bedside EEG monitoring in any patient who needs more than the listed second line treatment.

ONGOING CARE

PATIENT MONITORING

- Cardiorespiratory monitoring, level of care as appropriate for clinical status
- Monitor hydration and creatine kinase (CK) levels in case of convulsive SE.
- Consider need for continued video-EEG monitoring and medication titration.

PATIENT EDUCATION

- Need for long-term anticonvulsant drug therapy after SE depends on the etiology, patient's age, and circumstances in which SE occurred.
 - Chronic anticonvulsant therapy is indicated when SE is caused by structural brain lesions and in other patients with a clear predisposition toward seizures.
 - Chronic anticonvulsant therapy is generally not needed in children

who have SE from transient metabolic disturbances (e.g., hyponatremia, intoxication, fever).

- Educate family members regarding first aid for seizures. Discuss potential risks of seizure recurrence even if the child is taking an anticonvulsant drug. Review risks of climbing, swimming, bathing, and head protection for wheeled toys (bikes, skateboards, scooters).
- Provide caregivers with rectal diazepam with instructions for its use for seizure ≥ 5 minutes in duration.
- For patients with known epilepsy, counsel families regarding importance of medication compliance.

PROGNOSIS

The morbidity and mortality of SE reflect etiology and are lower in children than in adults. Recent mortality estimates in children range from 1 to 3%, with risk of new neurologic sequelae estimated at 15% and subsequent epilepsy at 30%. Refractory SE, however, has a morbidity estimated at 32% and a mortality of 17%. Factors associated with outcome include duration of SE, patient age, and underlying cause.

FAQ

- Q: Does SE cause brain injury?
- A: Research suggests that neuronal loss may occur with prolonged SE. This illness represents a neurologic emergency. Other determinants of outcome are hypoxic brain injury due to hypoventilation during a seizure and brain injury because of an identifiable underlying cause of SE such as encephalitis. Outcome in children with idiopathic SE without hypoxia is usually very good. Outcome of SE due to other brain injury (e.g., hypoxia, encephalitis, trauma) depends on the severity of the inciting process.
- Q: How safe is administration of rectal diazepam for clusters of seizures?
- A: Studies suggest that when dosing guidelines are followed, this agent is safe and effective in terminating clusters of seizures, obviating a trip to the emergency room. Respiratory depression is very rare but can occur.
- Q: How likely is SE to recur?
- A: It is estimated at 17% in the 1st year and predominantly in children with other neurologic conditions.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Lara Wine Lee • James R. Treat

BASICS

DESCRIPTION

- Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe, potentially fatal, mucocutaneous drug reactions characterized by epidermal necrosis involving skin and at least 2 mucous membranes.
- The cutaneous necrosis leads to widespread epidermal detachment and loss of skin barrier function.
- Given the potential risk for infection and fluid and electrolyte imbalances with widespread denudation, SJS and TEN are considered medical emergencies.

EPIDEMIOLOGY

Incidence

- Overall annual risk of 0.5–1.9 per million in the general population
- The precise incidence in children is unknown.
- Patients with HIV have a 1,000-fold increased risk.

RISK FACTORS

- Exposure to inciting medications
- Infection with *Mycoplasma pneumoniae*, HIV
- Genetic background
- Coexistence of cancer
- Concomitant radiotherapy

Genetics

- Recently, strong associations have been made between HLA alleles and SJS/TEN.
- Associations are ethnic population–specific and therefore universal screening of HLA alleles is rarely recommended.

- The FDA recommends checking for HLA-B*1502 in Asian populations where this HLA subtype is highly prevalent before prescribing carbamazepine.

GENERAL PREVENTION

Once SJS/TEN has occurred, the inciting medication and any cross-reacting medications should be avoided.

PATHOPHYSIOLOGY

- Widespread keratinocyte and mucosal cell death occurs secondary to CD8+ T-cell–mediated apoptosis via Fas and Fas ligand pathways and/or direct granulysin secretion. Fas receptors are located on keratinocytes and, when activated with Fas ligand, induce apoptosis and therefore necrosis of epidermal cells. Granulysin is released from cytotoxic T cells and induces apoptosis by creating holes in target cell membranes.
- The exact mechanism by which the implicated drug or infection triggers activation of cytotoxic T cells and the upregulation of the Fas/FasL pathway is unknown.
- Soluble Fas ligand is increased in patients with SJS/TEN.
- IVIG theoretically acts to block the Fas–FasL connection, thereby interrupting keratinocyte death and epidermal necrosis. Trials that show a benefit of IVIG use demonstrate improvement of disease severity but not complete abolition of symptoms; this incomplete effect may be due to IVIG being started too late in the disease progression or due to a potential alternative pathway to keratinocyte destruction.

ETIOLOGY

- <5% of cases have no known cause.
- Medications
 - Over 100 medications have been implicated in causing SJS/TEN.
 - High-risk drugs include aromatic amine anticonvulsants such as carbamazepine, phenobarbital and phenytoin, lamotrigine, β -lactam antibiotics, sulfa medications (including trimethoprim-sulfamethoxazole and sulfasalazine), minocycline, cephalosporins, quinolones, NSAIDs (especially piroxicam and meloxicam), allopurinol, and nevirapine.

- Acetaminophen (very rare)
 - Recently, the FDA issued a warning about the risk of acetaminophen-related SJS/TEN.
 - Although SJS/TEN is a very rare occurrence in patients taking acetaminophen, the ubiquity of acetaminophen in prescription and OTC products prompted the requirement for new labeling.
- A greater risk of developing SJS/TEN is seen in the first 8 weeks of treatment with these medications, with the highest risk being 1–3 weeks after exposure.
- *M. pneumoniae*
 - A well-established nondrug cause of SJS/TEN
 - More commonly implicated in children and adolescents
- There is scant evidence that vaccines, neoplastic syndromes, and autoimmune disease such as SLE may play a role in etiology.
- Herpes simplex virus–associated erythema multiforme (EM) was historically categorized on the spectrum with SJS and TEN, but new classification schemes place it as a separate entity.

DIAGNOSIS

HISTORY

- Prodromal period for 1–7 days of low-grade fever, sore throat or upper respiratory infection or dysphagia, and general malaise; patient may also complain of pain or stinging in the eyes.
- Subsequent development of targetoid red papules and plaques with dusky, blistered, or eroded center as well as mucosal (lip, intraoral, conjunctival, urethral, anal) pain with blistering and erosions
- Recent initiation of high-risk agent (see earlier list) or upper respiratory symptoms such as cough indicative of *Mycoplasma* infection

PHYSICAL EXAM

- Acute phase
 - Early skin lesions are erythematous targetoid macules and patches with a dusky center that then vesiculate.
 - The eruption usually starts on the face, presternal area of chest, and

palms and soles. >90% of patients also have ocular and/or genital mucosa involvement consisting of erythema and erosions as well as hemorrhaging, crusting, and blisters.

- Skin and mucosal lesions are very tender.
- Intraoral lesions may precede the cutaneous findings.
- Ocular involvement at the onset of disease is common. Early ocular disease ranges from acute conjunctivitis, eyelid edema, and ocular discharge to pseudomembrane formation and corneal erosion.
- Secondary phase
 - Over hours to days, necrosis, blistering, and sloughing cause large areas of epidermal detachment.
 - Lesions are characterized by a positive Nikolsky sign (epidermal detachment upon mechanical stress).
- Extensive mucosal involvement may include the esophagus, distal gastrointestinal (GI) tract, and respiratory epithelium.
- Occasionally Mycoplasma-induced SJS can involve only the mucosal surfaces with little or no cutaneous involvement.

ALERT

- The progression of disease to sheets of widespread epidermal necrosis and sloughing may be hours. This is a medical emergency.
- The systemic severity of SJS and TEN is often underestimated based on the severity of skin disease.
- Ocular involvement is often early and severe.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- CBC with differential, metabolic panel, hepatic function test, coagulation studies, urinalysis, mycoplasma serology, or PCR if indicated
- Anemia and lymphocytopenia are common and portend a poor prognosis.

Imaging

Symptom-directed imaging may be indicated depending on the extent of mucosal and systemic involvement.

Clinical Diagnosis

- The diagnosis of SJS and TEN is largely clinical based on history and physical exam.
- By definition, <10% affected body surface area (BSA) is SJS; 10–30% affected BSA is SJS/TEN overlap; >30% affected BSA is TEN.

Diagnostic Procedures/Other

- Skin biopsy with cryosection can be performed to confirm the clinical diagnosis if in doubt.
- Histologic examination with direct immunofluorescence (DIF) can be performed to rule out other autoimmune blistering diseases such as paraneoplastic pemphigus if in doubt.

Pathologic and Diagnostic Findings

- Skin biopsy shows full-thickness epidermal necrosis and few inflammatory cells; the skin biopsy may additionally show separation at the subepidermal level.
- DIF shows no immunoglobulin or complement deposition in the epidermis or in the epidermal–dermal zone.

DIFFERENTIAL DIAGNOSIS

- Staphylococcal scalded skin syndrome (SSSS)
- Linear IgA dermatosis
- Paraneoplastic pemphigus, pemphigus vulgaris, and bullous pemphigoid
- Acute generalized exanthematous pustulosis
- Disseminated fixed bullous drug eruption
- Drug-induced hypersensitivity syndrome (drug reaction with eosinophilia and systemic symptoms [DRESS])

TREATMENT

MEDICATION

First Line

- Stop all potentially offending medications.
- Early admission to burn unit or pediatric intensive care unit for initial stabilization and management of fluid, electrolytes, and nutrition;

airway stability; and eye care

- Prompt ophthalmology and dermatology consultation
- Otolaryngology, urology, or gynecology consultation may be needed based on extent of mucosal involvement.
- Meticulous wound care with bland emollients; avoid silver sulfadiazine as it may cause SJS owing to its sulfa moiety.
- Topical antibiotics should be used in areas of superinfection. The prophylactic use of topical antibiotics is somewhat controversial. Most agree that they should be applied to areas with a higher risk of superinfection, such as the perioral, periocular, and intertriginous areas.
- IVIG: 0.5–1 g/kg/dose given in 2–4 doses for a total of 2–3 g/kg total
- There have been variable results from a limited number of quality studies looking at the effects of IVIG. Multiple studies have demonstrated a beneficial effect especially if started early in the course.
- Adverse effects of IVIG include acute renal failure, DIC, osmotic nephrosis, anaphylaxis, serum sickness, aseptic meningitis, and thrombosis, among others.
- Steroids (prednisolone, dexamethasone, methylprednisolone) were the mainstay of therapy in the 1990s but now are less commonly used because of the increased risk of sepsis, infection, and other complications especially when used in TEN with widespread epidermal loss.
- Thalidomide, cyclosporine, TNF antagonists, plasmapheresis, and cyclophosphamide have been studied in the treatment of SJS/TEN, primarily in adults and some limited data may support their use.
- Prophylactic systemic antibiotics are not recommended, as they place the patient at an increased risk of candidemia and resistant infections.

ADDITIONAL TREATMENT

- Pain control is key to patient comfort.
- Good oral care using agents such as “magic mouthwash” helps debride dead skin and provide oral anesthesia.

SURGERY/OTHER PROCEDURES

- Surgical debridement. Studies have shown that surgical debridement of wounds prior to wound care yielded no additional benefit.
- Lysis of synechiae and vaginal adhesion
- Ocular amniotic membrane transplantation

Discharge Criteria

When afebrile, the loss of skin is clearly done, and reepithelialization has occurred; cleavage of synechiae in the eyes is no longer needed; and the patient can eat and drink appropriately

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Follow-up with a dermatologist and/or wound care specialist.

Reepithelialization often starts within days and may take up to 3 weeks to be completed.

Patient Monitoring

- SCORTEN is a well-validated, widely used scoring system in adults used for its predictive value, which is best at day 3. Variables include age, percentage BSA affected, BUN, serum glucose, HR, serum bicarbonate, and associated malignancy.
- Monitor for skin, urinary tract, and pulmonary infections; synechiae in the eyes; and vaginal and urethral adhesions.

PROGNOSIS

- Mortality is 1–5% in SJS and up to 25–35% in TEN (although most of this data is from the adult literature and likely the mortality is lower in children).
- Prognosis depends on BSA affected, time to cessation of offending medication, and time to initiation of supportive care.

COMPLICATIONS

- Mucosal complications occur in >70% of patients with acute-phase mucosal involvement. Ocular complications occur in 50% of patients with TEN.
- Systemic: sepsis, multiorgan failure, major metabolic dysregulation

- Mucosal: respiratory failure, pneumonia, pulmonary embolus, UTI, GI hemorrhage, obstruction, and perforation
- Cutaneous: skin infections, scarring, hypo-/hyperpigmentation, nail dystrophies
- Ocular: synechiae, dry eyes, bacterial conjunctivitis, suppurative keratitis, endophthalmitis, impaired tear ducts, corneal ulcers, vision loss

- L51.3 Stevens-Johnson synd-tox epdrml necrolysis overlap syndrome
- L51.2 Toxic epidermal necrolysis [Lyell]

STOMATITIS

Cara L. Biddle

BASICS

DESCRIPTION

- Inflammation of the mucous membranes of the mouth including the buccal mucosa, gingiva, tongue, lips, hard palate, and soft palate
- Also called gingivostomatitis when the gums are specifically involved
- Enteroviruses (causing herpangina and hand-foot-and-mouth disease) and herpes simplex virus type 1 are the most common infectious causes of stomatitis.
- Recurrent aphthous stomatitis (or canker sores) is also common in children. Etiology is unknown.

EPIDEMIOLOGY

- Enteroviruses (including coxsackie viruses)
 - More common in the summer and fall months in temperate climates but occur year-round in the tropics
 - Herpangina and hand-foot-and-mouth disease are most common in infants, toddlers, and young children.
- Herpes simplex virus type 1 (HSV-1)
 - Infections occur throughout the year.
 - Most primary HSV infections in childhood after the neonatal period are asymptomatic.
 - Primary herpetic gingivostomatitis is most common in infants, toddlers, and young children.
 - Recurrent HSV-1 infections can occur any time after the primary infection.
 - Seroprevalence of HSV-1 in the United States: more than 25% by age 7 years; more than 40% by age 21 years
- Recurrent aphthous stomatitis is most common in older children and adolescents.

GENERAL PREVENTION

- Wash hands after contact with infected individuals to help prevent spread of viral stomatitis.
- Disinfect surfaces, toys, and other objects used by an infected child to decrease spread. Enteroviruses can survive on surfaces long enough to allow transmission of infection.
- Use contact precautions for hospitalized patients with viral stomatitis.

PATHOPHYSIOLOGY

- Enteroviral infections
 - Spread by fecal–oral and respiratory routes. Can also be passed from mother to infant prenatally, in the peripartum period, and possibly via breast milk
 - Result in viremia which spreads virus to target organs
- HSV-1 infections
 - Spread via contact with mucous membranes or open skin
 - Travel from the skin to the trigeminal sensory ganglion where infection persists for life. Reactivation causes recurrent symptoms.

ETIOLOGY

- Herpangina: most often coxsackie A viruses; also caused by other enteroviruses
- Hand-foot-and-mouth disease: most often coxsackie A viruses; also coxsackie B, enterovirus 71, and echoviruses
- Primary herpetic gingivostomatitis: typically HSV-1; can also be caused by HSV-2
- Recurrent aphthous stomatitis: possible causative factors: physical and chemical trauma, foods, nutrient deficiencies, immunodeficiency, systemic illness, infections, genetic predisposition, smoking, stress, medications

DIAGNOSIS

HISTORY

- History of present illness
 - Onset and duration
 - Mouth pain or sores in mouth

- Drooling
- Fever
- Intake of liquids and food
- Urine output
- Activity level
- Close contact with similar symptoms
- Review of systems
 - Vomiting, diarrhea, abdominal pain
 - Rash on body
 - Headache, mental status changes
 - Respiratory symptoms
 - Previous history of oral lesions
- Chronic health issues and family history: immunodeficiency (including HIV infection), inflammatory bowel disease, gluten enteropathy, anemia, neutropenia, rheumatologic disease
- Include recent medication history to assess risk for Stevens-Johnson syndrome.

PHYSICAL EXAM

- Exam of lips and oral cavity
 - Mucous membranes: Moist? Erythematous? Swollen? Friable?
 - Oral lesions: Color? Location? Number? Ulceration?
- Additional physical exam
 - General appearance
 - Hydration status
 - Respiratory, cardiovascular, and abdominal exam
 - Skin exam for additional rash
 - Lymphadenopathy
- Typical physical findings
 - Herpangina: vesicles and ulcers surrounded by erythematous ring on tonsillar pillars, soft palate, uvula, tonsils, and/or posterior pharynx
 - Hand-foot-and-mouth: inflamed oropharynx with scattered vesicles and ulcers with an erythematous ring on buccal mucosa, tongue, gingiva, hard and soft palate, and/or posterior pharynx.
 - Maculopapular, vesicular, and/or pustular lesions on hands and fingers, feet, and buttocks. Hand and foot lesions most commonly

- on dorsal surface but can also be on palms and soles.
- Primary herpetic gingivostomatitis (herpes labialis): inflamed gingiva with mucosal hemorrhages. Clusters of vesicles throughout the mouth including the lip's mucocutaneous margin and perioral skin
 - Recurrent herpes labialis: cluster of vesicles on lip or mucocutaneous margin
 - Aphthous stomatitis: shallow round or ovoid ulcers with gray base and surrounding erythema
 - Also consider the following:
 - Varicella: grouped vesicles or ulcers on hard palate, buccal mucosa, tongue, or gingiva. Diffuse vesicles in various stages of healing on skin of body
 - Stevens-Johnson syndrome: erythema and edema of lips. Painful intraoral bullae that rupture, leaving erosions. Rash on body includes urticaria, target lesions, and bullae.
 - Behçet syndrome: oral ulcers accompanied by genital ulcers, uveitis, rash, and other systemic symptoms
 - Periodic fever with aphthous stomatitis, pharyngitis, and adenitis (PFAPA syndrome): prodrome of systemic symptoms, sore throat, and aphthous ulcers on lips or buccal mucosa followed by abrupt onset of fever and chills

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Diagnosis of stomatitis is typically made by history, location and characteristics of oral lesions, and additional physical findings.
- Confirmatory lab tests are available if needed:
 - Enterovirus can be identified by polymerase chain reaction (PCR) assay or culture of stool, throat, blood, urine, tracheal aspirate, or conjunctiva or by tissue biopsy.
 - HSV can be detected by viral culture, PCR, direct fluorescent antibody (DFA) staining, or enzyme immunoassay (EIA).
 - For HSV culture: Unroof a vesicle with scalpel or sterile needle, and use swab to soak up fluid and scrape the base. Use appropriate viral transport media.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Enteroviruses (coxsackievirus and others)
 - HSV
 - Varicella
 - HIV infection
 - Syphilis
 - Candida
- Recurrent aphthous stomatitis
- Trauma
- Burn
- Other
 - Chemotherapy-associated stomatitis
 - Stevens-Johnson syndrome
 - Behçet syndrome
 - Reiter syndrome
 - PFAPA syndrome
 - Geographic tongue

TREATMENT

MEDICATION

- Pain control
 - Acetaminophen or ibuprofen
 - Acetaminophen with codeine in severe cases. Use caution due to risk of sedation and constipation. Do not use in combination with regular acetaminophen.
 - Use codeine with caution due to variability in metabolism by cytochrome P450 CYP2D6. Patients who are “ultra-rapid metabolizers” of codeine convert up to 15% (vs. 3%) of the drug to morphine, which can lead to toxicity.
- Antivirals
 - Oral acyclovir can be used for immunocompetent children with herpetic gingivostomatitis if started within the first 72–96 hours of illness. May shorten the duration of symptoms and viral shedding

- Topical acyclovir is not recommended for primary herpetic gingivostomatitis.
- Topical therapy: “magic mouthwash”
 - 1:1 mixture of diphenhydramine and calcium carbonate or bismuth subsalicylate (plus viscous lidocaine in severe cases)
 - Use with caution. Many young children cannot “swish and spit” and will swallow the medication. Applying magic mouthwash to ulcers with a swab may cause additional irritation to friable mucosa. Use of viscous lidocaine can result in systemic toxicity (e.g., arrhythmias), anesthesia of the oral mucosa leading to mechanical trauma, and anesthesia of the posterior pharynx leading to choking or aspiration.

ADDITIONAL TREATMENT

General Measures

- Maintain hydration. Offer small amounts of cool, nonacidic liquids frequently. Use a syringe to continue giving liquids when children are refusing to drink. Try popsicles as another source of liquids.
- Offer soft, cool foods such as ice cream, yogurt, and Jell-O. Avoid foods that are salty, spicy, hard, or acidic, as they are likely to irritate the mouth sores and cause more pain.
- Apply petroleum jelly or other barrier ointment to the lips to limit cracking and prevent adhesions in herpetic gingivostomatitis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Most children with stomatitis can be cared for at home with pain control and maintenance of hydration.
- Providers should ensure that parents and caregivers are familiar with signs and symptoms of dehydration.
- Children with poor oral intake due to pain may be unable to maintain hydration at home and require admission for intravenous fluids.

PROGNOSIS

- Primary herpetic gingivostomatitis results in permanent HSV infection. Recurrent infection can be triggered by stress, fever, trauma, sun exposure, immunosuppression, or extremes in temperature. Children may have tingling, pain, itching, or paresthesias before the appearance of recurrent lesions.
- Recurrent aphthous stomatitis causes significant morbidity due to recurrences of painful oral lesions.

COMPLICATIONS

- Enteroviral infection
 - Respiratory: bronchiolitis, pneumonia, pleurodynia
 - Neurologic: viral meningitis, encephalitis, motor paralysis
 - Gastrointestinal: vomiting, diarrhea, abdominal pain, pancreatitis, hepatitis
 - Genitourinary: orchitis
 - Ophthalmologic: uveitis, acute hemorrhagic conjunctivitis
 - Cardiac: myocarditis, pericarditis
 - Muscular: myositis

ALERT

Enterovirus 71 (EV71) can cause both hand-foot-and-mouth disease and herpangina and can also cause children to develop severe neurologic disease (including brainstem encephalomyelitis and acute paralysis) followed by secondary pulmonary edema/hemorrhage and cardiopulmonary collapse.

- HSV infection
 - Herpetic keratitis: herpetic eye infection due to autoinoculation from mouth lesions
 - Herpetic whitlow: development of herpetic lesions on the extremities (typically fingers) due to direct contact with mouth lesions
 - Eczema herpeticum: extensive herpes infection of the skin in children with atopic dermatitis or other chronic skin disease
 - HSV encephalitis

- B00.2 Herpesviral gingivostomatitis and pharyngotonsillitis
- B08.4 Enteroviral vesicular stomatitis with exanthem

FAQ

- Q: My child is refusing to drink any liquids. How can I keep her hydrated?
- A: Mouth sores can be very painful. Even if your child is not having fever, give regularly scheduled doses of ibuprofen or acetaminophen around the clock for pain control. Offer cool, nonacidic liquids and foods, which will be less likely to irritate the mouth sores. Use a syringe to put small amounts of liquids in her mouth every few minutes if she refuses to drink anything.
- Q: What should I do at home to prevent spread of the infection?
- A: Frequent hand washing is the most important way to prevent the spread of infection. Avoid sharing contaminated toys, utensils, and other objects until they have been cleaned, and wipe down surfaces to

disinfect. For enteroviral infections, it is particularly important to do careful hand washing after diaper changes because the virus is shed in the stool.

- Q: When can my child return to school or daycare?
- A: Viral stomatitis is contagious. Children who drool are the most contagious and should not return to school until the mouth sores heal. Children with aphthous ulcers or recurrent herpes labialis should not be excluded from school.

STRABISMUS

Leah G. Reznick

BASICS

DESCRIPTION

- Strabismus is defined as any form of ocular misalignment. It derives from the Greek word strabismos (to squint).
- Strabismus can be intermittent or constant.
- There are many types of strabismus, which are defined by the direction of misalignment.
 - Exotropia: out-turning of eyes
 - Esotropia: in-turning of eyes
 - Hypertropia: one eye higher than the other eye
- Strabismus can be comitant (amount of misalignment is the same in all directions of gaze) or incomitant (variable angle of deviation, which is dependent on the direction of gaze).
 - Comitant strabismus is the most common form of strabismus. These children are typically developmentally normal.
 - Incomitant strabismus is less common. It is caused by paralytic strabismus such as cranial nerve palsies or restrictive strabismus such as Brown syndrome.
- Strabismus may cause permanent loss of three-dimensional vision, amblyopia (visual acuity loss), and/or ocular torticollis.
- Strabismus can result in significant psychosocial problems for children, which warrant attention.
- Patients with intermittent strabismus can also develop lifelong loss of depth perception and visual acuity. These children should be evaluated and potentially treated for their strabismus.

EPIDEMIOLOGY

Prevalence

For children younger than 6 years of age, the prevalence of strabismus is 4–5%.

RISK FACTORS

- Low birth weight
- Maternal cigarette smoking
- Retinopathy of prematurity
- Refractive errors: high hyperopia and anisometropia
- Congenital or acquired vision loss
- Cerebral palsy
- Craniofacial syndromes
- Seizure disorders
- Developmental delays
- Hydrocephalus

Genetics

- There is a 4-fold increase in the risk of strabismus for a child with an affected family member.
- There is limited knowledge of the genetic inheritance patterns of common strabismus. There appears to be polygenic pattern, but the STBMS1 gene has been isolated as a specific locus for a few individuals.

PATHOPHYSIOLOGY

- There is a limited understanding of the pathophysiology of the most common comitant strabismus. There is no specific pathologic abnormality of the cranial nerves, extraocular muscles, or orbits. Therefore, a “tight” or “weak” muscle is not the cause of the strabismus problem.
- Accommodative esotropia is a common form of strabismus in young children. It is associated with high hyperopia (farsightedness) and anisometropia (see “[Refractive Error](#)”). When a child with high hyperopia attempts to focus at any distance, he or she needs to focus his or her intraocular lens (accommodation). This focusing can trigger overconvergence of the eyes (esotropia).
- Paretic strabismus is caused by weakness of cranial nerves and their associated extraocular muscles. Examples of this type of pathology include cranial nerve palsies—III, IV, and VI; Möbius syndrome; or Duane syndrome.

- Neuromuscular diseases such as myasthenia gravis can cause strabismus with decreased extraocular muscle function.
- Restrictive strabismus is a result of muscle tightness causing a limitation in eye movement. Examples include Graves disease, Brown syndrome, or trauma to extraocular muscles.
- Sensory strabismus results from poor visual acuity in one eye.

COMMONLY ASSOCIATED CONDITIONS

- Strabismus can be a sign of a vision- or life-threatening neurologic problem.
 - A physician needs to consider that retinoblastoma, brain tumor, cataract, and other conditions may initially present with ocular misalignment.
- Other ocular problems often coexist with strabismus including amblyopia, nystagmus, and refractive error.

DIAGNOSIS

- It is normal for infants younger than 2 months of age to have intermittent strabismus but not constant strabismus.
- After 4 months of age, any strabismus is abnormal and warrants an ophthalmologic exam.
- Children do not commonly “grow out” of strabismus.
- A delay in diagnosis and treatment can lead to a worse prognosis for normal visual development.

SIGNS AND SYMPTOMS

- Children are typically asymptomatic. Because the brain suppresses one eye in childhood strabismus, the patient has no diplopia and is not aware of ocular misalignment.
- Strabismus needs to be screened for and identified by primary care providers and family members.

HISTORY

- Onset of misalignment
- Frequency, duration, and direction of deviation

- Torticollis
- History of eye or head trauma
- Birth and developmental history focusing on prematurity, seizure disorder, or neurologic abnormality
- History of glasses, patching, or other vision therapy
- Family history of strabismus, amblyopia, refractive error, or childhood vision problems

PHYSICAL EXAM

- Patient's visual acuity should be evaluated in an age-appropriate manner individually for each eye (see "[Amblyopia](#)" and "[Refractive Error](#)").
- The presence of torticollis may indicate strabismus.
- Ocular alignment
 - Corneal light reflex (Hirschberg test): With a patient looking at a light, look for the location of the corneal light reflex. The light reflex should be focused at the center of each pupil symmetrically. If the reflex is located outside of the pupillary center and asymmetric, the child likely has strabismus. If it is positioned laterally, the child has esotropia, and if it is positioned medially, the child has exotropia.
 - Red reflex test (Brückner): With dimmed room lights, an examiner uses a direct ophthalmoscope to look at the red reflex of both eyes simultaneously from 2–3 feet. Normally, the pupils should be red and the pupils should symmetrically fill with light. If there is asymmetry to the brightness, a dulled reflex, or a black or white area within the reflex, there is likely an ocular problem, which could be strabismus.
 - Alternate cover test: The examiner should get the patient to focus on a single target. While they are holding fixation, the examiner should occlude each eye for a brief period of time. The examiner should watch for movement of the eye to pick up fixation. If the eyes remain still while you alternately occlude each eye, then there is no strabismus. If the eyes move from inward to outward, the child has esotropia. If the eyes move from outward to inward, the child has exotropia.

- Ocular rotations
 - Each eye should be evaluated for full movement in horizontal and vertical directions. If the eye has limited movement in a particular direction, then there may be paralytic or restrictive strabismus. If there is limited movement, a patient should be evaluated by an ophthalmologist urgently.
- Complete ophthalmic examination is indicated whenever there is suspicion of strabismus or abnormal vision based on history, screening tests, or examination.

DIAGNOSTIC TESTS & INTERPRETATION

Serologic or radiologic testing is rarely performed to work up the etiology of routine strabismus.

Lab

In select patients, a physician may order antiacetylcholine receptor antibodies testing to test for myasthenia gravis or thyroid function studies to test for thyroid eye disease.

Imaging

If orbital or neurologic pathology is suspected, an MRI or CT scan may be performed to evaluate for a restrictive or paralytic strabismus.

DIFFERENTIAL DIAGNOSIS

- In the initial evaluation, one needs to differentiate between true strabismus and pseudostrabismus.
 - Children with wide epicanthal folds often give the false appearance of esotropia due to minimal amount of conjunctiva showing in the medial canthal region.
 - Rather than looking at the amount of “whites” showing, a practitioner can use the corneal light reflex (Hirschberg test) to see if the light reflex lies in the central pupil and perform a cover test.
 - If there is any doubt about the presence of strabismus, a referral to an ophthalmologist is warranted.
- In children with abnormal eye movements (incomitant strabismus), the differential diagnosis includes the following:
 - Cranial nerve palsies (III, IV, or VI)

- Craniofacial anomalies
- Orbital fracture
- Systemic or localized motor abnormalities such as myasthenia gravis
- Orbital pseudotumor
- Thyroid eye disease (Graves)
- Strabismus syndromes
- Strabismus syndromes include the following:
 - Duane syndrome: congenital aberrant innervation of cranial nerve III
 - Möbius syndrome: congenital absence of cranial nerve VI and VII
 - Brown syndrome: an abnormality of the trochlear-superior oblique tendon causing a monocular elevation deficit
- Sensory strabismus is caused by any form of vision loss. The strabismus can be either esotropia or exotropia. If a child has sensory strabismus, it is crucial to identify the cause of vision loss because it can be life threatening (such as retinoblastoma or intracranial tumor).

ADDITIONAL TREATMENT

General Measures

- If a child remains strabismic for a prolonged period, it can result in irreversible loss of depth perception and vision loss (amblyopia). Therefore, it is imperative that a child receives prompt evaluation and treatment.
- Treatment options can include glasses, occlusion therapy, orthoptic exercises, surgery, or a combination of these therapies.
- Glasses are primary treatment for a common form of strabismus—accommodative esotropia.
- Occlusion therapy is typically used for amblyopia rather than strabismus. If occlusion therapy improves vision, occasionally, the strabismus may improve, but more importantly, better vision improves prognosis for strabismus treatment.
- Eye exercises (orthoptic exercises) are useful in patients with convergence insufficiency. There is no evidence that they improve typical childhood esotropia and exotropia.

SURGERY/OTHER PROCEDURES

- If patching and glasses do not improve strabismus, then surgery is often recommended to improve binocular vision.
- In strabismus surgery, the eye muscles are either weakened by moving the muscle's insertion or tightened (strengthened) by removing a small piece of muscle tissue.
- For most patients, strabismus surgery is performed in an outpatient setting with minimal risk or morbidity.
- In large-case series, there is ~80% success rate for surgery and a ~20% reoperation risk.

ONGOING CARE

Long-term follow-up is important for children to monitor their vision development until at least 10 years of age. There is a risk for amblyopia and strabismus recurrence even after a successful surgical correction.

- H50.10 Unspecified exotropia
- H50.00 Unspecified esotropia

FAQ

- Q: Will a child's strabismus resolve on its own?
- A: In most cases, children do not outgrow strabismus. Diagnosis and treatment should not be delayed.
- Q: Should a child wait to have surgery until he or she is older?
- A: When a child has strabismus, there are anatomic changes to the brain to prevent diplopia. The longer a child spends strabismic, the more adaptation occurs and the harder it is to regain normal depth perception. Therefore, it is important not to delay diagnosis and treatment. There is improved prognosis with prompt treatment.
- Q: Does strabismus cause learning difficulties?
- A: There is no proven association between strabismus and learning disabilities. If a child has learning difficulties and has strabismus, the learning issues should be evaluated outside of the strabismus.
- Q: How does loss of depth perception affect a child?
- A: A child may demonstrate subtle changes in fine motor skills, visual-spatial tasks, and athletic capabilities.
- Q: Will surgery in older children and adults improve their ocular function?
- A: With surgery, older children and adults may expand their visual fields and restore binocularity. The psychosocial effects of strabismus can significantly affect a person's sense of self and social interaction. For this reason, strabismus surgery can dramatically improve quality of life.
- Q: When is vision therapy prescribed for strabismus?
- A: Vision therapy has limited use for patients with strabismus. Eye exercises have been proven effective for one type of exotropia called convergence insufficiency. For most childhood strabismus, there is no evidence that vision therapy successfully treats ocular misalignment.

STREP INFECTION: INVASIVE GROUP A β -HEMOLYTIC STREPTOCOCCUS

Maribeth Chitkara

BASICS

DESCRIPTION

Infection associated with isolation of group A β -hemolytic streptococci (GABHS) from a normally sterile body site; includes 3 clinical syndromes:

- GABHS toxic shock syndrome (STSS)
- GABHS necrotizing fasciitis (NF)
 - Infection characterized by extensive local necrosis of skin and subcutaneous soft tissues
- Isolation of GABHS from normally sterile sites in patients not meeting criteria for STSS or NF (e.g., meningitis, osteomyelitis, septic arthritis, myositis, surgical wound infections) with or without bacteremia

Diagnostic criteria for STSS:

- (I) Isolation of GABHS
 - A: From a normally sterile site (e.g., blood, CSF, tissue, peritoneal fluid)
 - B: From a nonsterile site (e.g., throat, vagina, sputum, open surgical wound)
- (II) Clinical signs of severity
 - A: Hypotension
 - B: Two or more of the following signs:
 - Renal impairment
 - Coagulopathy
 - Hepatic involvement
 - Adult respiratory distress syndrome
 - A generalized erythematous macular rash that may desquamate
 - Soft tissue necrosis, including NF or myositis, or gangrene
- A definite case fulfills criteria IA and II (A and B). A probable case fulfills criteria IB and II (A and B) and no other identifiable cause.

EPIDEMIOLOGY

- Overall mortality rates for invasive GABHS infections are lower in children (5–15%) than in adults (30–80%).
- Most cases occur in winter and early spring.

Incidence

- It is estimated that the annual incidence in the United States is 1.5–5.9 cases per 100,000 persons.
- Incidence is highest in infants and the elderly.
- 85% of cases are sporadic, 10% hospital-acquired, 4% in chronic care facilities, 1% in cases with a close index contact.

RISK FACTORS

- Risk factors for invasive GABHS infections include injuries resulting in bruising or muscle strain, surgical procedures, and viral infections such as varicella.
- High-risk groups include patients with diabetes mellitus, chronic cardiac or pulmonary disease, HIV infection or AIDS, and those with a history of IV drug use.

GENERAL PREVENTION

- Routine immunization against varicella
- Isolation of hospitalized patients
 - In addition to standard precautions, droplet precautions for children with pneumonia
 - Contact precautions should be used for at least 24 hours after the start of antimicrobial therapy in children with extensive or draining cutaneous infections.
- Several GABHS vaccine candidates are in varying stages of development. A 26-valent recombinant M protein vaccine is the only vaccine to have entered into clinical trials.

PATHOPHYSIOLOGY

- The pathogenic mechanism has not been fully defined; however, an association with streptococcal pyrogenic exotoxins (SPE) has been suggested.
- SPE A, B, and C (responsible for rash of scarlet fever) along with

streptococcal exotoxins, mitogen factor, and superantigen stimulate activation of T lymphocytes and macrophages to produce large quantities of cytokines resulting in shock and tissue damage.

- There may be no identifiable focus of infection.

ETIOLOGY

Streptococcus pyogenes is the only species of β -hemolytic streptococci to be associated with invasive infections.

DIAGNOSIS

HISTORY

- Historic features vary depending on the GABHS syndrome.
- May have preceding soft tissue infection such as cellulitis
- A preceding clinical pharyngitis is not common.
- Consider GABHS infection in any child with varicella who has any of the following:
 - Localized skin findings of erythema, warmth, swelling, or induration
 - Return of fever after having been afebrile
 - A temperature of $\geq 39^{\circ}\text{C}$ (102.7°F) beyond the 3rd day of illness
 - Any fever persisting beyond the 4th day of illness
- In children without varicella, presentation can mimic influenza infection (fever, chills, myalgias). Abrupt onset of localized or severe pain and absence of respiratory symptoms or a contact history are clues to help distinguish STSS from influenza.
- Incubation period for STSS is unknown.

PHYSICAL EXAM

- Vital signs
 - Elevated temperature
 - Tachycardia
 - Hypotension (late sign)
- Toxic appearance is common but may not be present, especially early in the disease course.
- Skin exam varies:

- Often, there are no cutaneous findings.
- With varicella infection, vesicular lesions may have underlying erythema, warmth, or induration but can also appear normal.
- NF should be suspected in child who presents with diffuse swelling of an extremity followed by the development of bullae with fluid that rapidly evolves from clear to violaceous in color.
- Erythroderma, a generalized macular exfoliative and erythematous rash, is sometimes observed with STSS.
- Deep infections will have exam findings consistent with the specific focus (e.g., joint pain and limitation of mobility in septic arthritis, respiratory symptoms in GABHS pneumonia).
- Pain and/or hyperesthesias out of proportion to clinical findings may be noted.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC (leukocytosis with immature neutrophils may be noted but WBC can also be normal)
- Electrolytes, BUN, creatinine, and glucose
- Liver function tests
- Screen for disseminated intravascular coagulation
- Creatine kinase level (may be elevated in NF)
- Blood culture
- Culture of wound and tissue aspirates
- Throat culture
 - If culture negative, a rise in antibody titers to streptolysin O, deoxyribonuclease B, or other streptococcal extracellular products 4–6 weeks after infection may help confirm the diagnosis.
 - These antibodies may remain elevated for several months and indicate an infection in the recent past.

Imaging

In cases of NF: Consider MRI to confirm diagnosis and extent of infection.

DIFFERENTIAL DIAGNOSIS

- Bacterial sepsis
- Toxic shock syndrome from *Staphylococcus aureus*

- Other soft tissue infections
 - Cellulitis
 - Erysipelas
 - Clostridial or mixed anaerobic and aerobic fasciitis/gangrene

ALERT

- Diagnosis is primarily clinical and requires a high degree of suspicion because of the rapid progression of infection.
- Diagnosis should be considered even in suspect cases with absence of rash, cellulitis, or superinfected varicella lesions.
- In cases of NF, extent of involvement in subcutaneous tissues may be underestimated. Infection may be more widespread than what is apparent on physical exam.
- In STSS cases, care should be taken to search for a localized infection as a possible source of toxin production.

TREATMENT

MEDICATION

- Parenteral therapy at maximum doses for both GABHS and *S. aureus* should be instituted promptly with the capacity to do both of the following:
 - Kill organism with bactericidal cell wall inhibitor.
 - Decrease enzyme, toxin, or cytokine production with protein synthesis inhibitor.
- Recommended regimens:
 - Oxacillin (150 mg/kg/24 h divided q6h) or nafcillin (200 mg/kg/24 h divided q4–6h; maximum 12 g/24 h) plus clindamycin (25–40 mg/kg/24 h divided q6h or q8h)
 - In penicillin-allergic patients, consider vancomycin (40 mg/kg/24 h divided q6h) plus clindamycin.
 - In areas with high prevalence of community-acquired methicillin-resistant *S. aureus* vancomycin should be used in place of β -lactamase-resistant penicillins.
- Once GABHS has been identified, antibiotic regimen should be

changed to high-dose penicillin G (200,000–400,000 U/kg/24 h in 4–6 divided doses) plus clindamycin.

- No penicillin G-resistant isolates of GABHS have been reported.
- There are strains resistant to clindamycin, so it should not be used alone until shown to be sensitive.
- Antibiotics should be continued for a minimum of 14 days in patients with bacteremia and for 14 days after last positive culture obtained during surgical debridement for patients with deep soft tissue infections.
- The use of IV immunoglobulin may be considered in cases refractory to aggressive therapy, for infection in an area that precludes drainage, or persistent oliguria with pulmonary edema. Various regimens have been used: 150–400 mg/kg/24 h for 5 days or 1–2 g/kg as single dose.

ADDITIONAL TREATMENT

General Measures

- Volume resuscitation
- Replete electrolytes as indicated
- Inotropes as indicated
- Blood products as indicated for anemia or thrombocytopenia
- Airway support for severe depression of level of consciousness or respiratory insufficiency

SURGERY/OTHER PROCEDURES

Consider surgical consult early in management of NF. Extensive debridement of necrotic tissue is often indicated. Fasciotomy may be required to relieve compartment syndrome.

ONGOING CARE

PROGNOSIS

- Fulminant course with rapid deterioration is characteristic of invasive GABHS infections.
- Prognosis is improved with early recognition and aggressive management.
- Case fatality rate for invasive GABHS infections is 13.7% (36% for

STSS and 24% for NF).

- Increased morbidity and mortality reported in cases of coinfection with H1N1 influenza
- Poor prognostic factors:
 - Emm/M strain types 1, 3, or 12
 - Increased age
 - Occurrence in winter/early spring
 - Development of GI symptoms

COMPLICATIONS

- From deep and systemic infections:
 - Sepsis syndrome
 - Hematologic seeding and development of focal infection
 - Infection site–specific complications (e.g., meningitis, neurologic impairment; septic arthritis, joint destruction)
- From NF:
 - Severe tissue necrosis usually requires extensive surgical debridement and may require amputation of involved extremities.
 - Compartment syndrome
 - Functional disabilities
 - Cosmetic sequelae
- From STSS:
 - Multiorgan system failure
 - Acute respiratory distress syndrome
 - Disseminated intravascular coagulation
 - Acute tubular necrosis and renal failure
 - Hepatic failure
 - Cardiac insufficiency
 - Cerebral ischemia and edema
 - Metabolic derangements

- B95.1 *Streptococcus*, group B, causing diseases classd elswhr
- A48.3 Toxic shock syndrome

FAQ

- Q: For whom should the diagnosis of invasive GABHS be entertained?
- A: Consider GABHS in any child with varicella who experiences recrudescence of fever, fever $\geq 39^{\circ}\text{C}$ (102.2°F) beyond the 3rd day of illness, or any fever beyond the 4th day of illness. A high index of suspicion should be maintained in patients with septicemia and in febrile patients with pain and hyperesthesia out of proportion to the clinical findings.

- Q: Is NSAID use in patients with varicella associated with GABHS?
- A: There are reports suggesting an association between the use of NSAIDs and the development of invasive GABHS diseases, but a causal relationship has not been established. There is evidence that NSAIDs impair granulocyte function and enhance production of cytokines. Additionally, they may mask signs of disease by suppressing the pain and fever that might encourage a patient with invasive GABHS infection to seek medical attention. No formal recommendations for restricting the use of NSAIDs are being made at this time.
- Q: Should close contacts of patients with invasive GABHS infections receive chemoprophylaxis?
- A: Although the risk of developing disease for household contacts is elevated in comparison to the general population, the risk is not sufficiently high to warrant routine testing or treatment for GABHS colonization. No clearly effective chemoprophylactic regimen has been identified. However, in high-risk populations (people >65 years or those with HIV, varicella, or diabetes mellitus), targeted chemoprophylaxis may be considered. Chemoprophylaxis is not recommended in schools or child care facilities.

STROKE

Melissa G. Chung • Warren Lo

BASICS

DESCRIPTION

Acute CNS insult that causes objective evidence (e.g., radiographic, pathologic) of neurologic damage in a vascular territory and clinical symptoms lasting more than 24 hours. A stroke can be ischemic due to decreased arterial blood flow (acute ischemic stroke [AIS]), venous thrombotic (cerebral sinovenous thrombosis [CSVT]), or hemorrhagic. Acute neurologic dysfunction lasting less than 24 hours and not causing evidence of brain injury is a transient ischemic attack (TIA). Acute neurologic dysfunction lasting less than 24 hours with diffusion changes on MRI is an ischemic stroke. Acute hemiparesis, sensory loss, aphasia, cranial nerve deficits, or altered consciousness (especially if occurring together) should prompt rapid evaluation for possible stroke to prevent delays in diagnosis.

EPIDEMIOLOGY

Incidence

- The neonatal period is the highest risk period for pediatric stroke. Neonatal stroke occurs in approximately 1 in 4,000 live births.
- Incidence of AIS is 1.2–7.9 per 100,000 per year in children over a month of age.
- Hemorrhagic stroke incidence is estimated to be 0.5–5.1 per 100,000 children per year.
- CSVT occurs in 0.67 per 100,000 children per year.

RISK FACTORS

Genetics

Pediatric stroke occurs secondary to a plethora of etiologies as noted below. Some risk factors are genetic:

- Hemoglobin SS (Hgb SS, sickle cell disease): autosomal recessive (AR)

- Factor V Leiden mutation
- Prothrombin G20210A gene mutation
- Classic homocystinuria: CBS gene, AR
- Mitochondrial encephalomyopathy, lactic acidosis and stroke-like symptoms (MELAS): maternal inheritance
- Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL): NOTCH-3, autosomal dominant (AD)
- Fabry disease: GLA gene, X-linked
- Ehlers-Danlos type IV: COL3A1 gene, AD
- Marfan syndrome: FBN1 gene, AD

ETIOLOGY

- Cardiac
 - Congenital heart defects
 - Cardiac rhabdomyoma or myxoma
 - Infectious endocarditis
 - Rheumatic heart disease
 - Prosthetic heart valves
 - Cardiomyopathy/myocarditis
- Vascular
 - Congenital/genetic vasculopathies including Ehlers-Danlos type 4, Marfan syndrome, Sturge-Weber syndrome, PHACES, neurofibromatosis type I
 - Fibromuscular dysplasia, moyamoya disease, postradiation vasculopathy, intracranial aneurysm, arterial agenesis or hypoplasia, traumatic dissection, transient cerebral arteriopathy, focal arteriopathy, arteriovenous malformation
- Vasculitis, inflammatory
 - Systemic: systemic infections, varicella, lupus, hemolytic uremic syndrome, AIDS, Takayasu arteritis, drug abuse, Behçet disease
 - Primary angiitis of the CNS
 - Cranial or cervical infections
- Hematologic/coagulation disorders
 - Severe anemia, polycythemia, or thrombocytosis
 - Hemoglobinopathies especially Hgb SS

- Primary thrombophilia: antithrombin III deficiency, factor V Leiden homozygous mutation, protein S and C deficiencies, prothrombin G20210A homozygous mutation, hemophilia A and B
- Acquired thrombophilia: disseminated intravascular coagulation, leukemia or other neoplasm, L-asparaginase treatment, anticardiolipin/antiphospholipid syndrome, oral contraceptives, nephrotic syndrome, pregnancy/postpartum period, inflammatory bowel disease, thrombotic thrombocytopenic purpura, warfarin/heparin use
- Trauma
 - Blunt cervical or intraoral trauma
 - Carotid ligation (e.g., with extracorporeal membrane oxygenation [ECMO])
 - Fat, air, foreign body, amniotic fluid embolism
 - Catheter angiography
 - Chiropractic manipulation
- Metabolic disorders
 - Hyperhomocysteinemia
 - Mitochondrial disorders
 - Fabry disease
- Miscellaneous
 - Migraine
 - Severe hypotension or hypertension
 - Reversible vasoconstriction syndrome
 - Cervical vessel compression

DIAGNOSIS

HISTORY

- Timing and progression of symptoms, including last known time when patient was normal.
- Analysis of risk factors/etiology: Inquire about history of trauma, recent medication/drug use, cardiac history, infectious history, skin lesions (acute and chronic), other symptoms/signs of inflammatory disorders, and personal and family history of excessive bleeding or

clotting.

ALERT

Acute stroke may present with stuttering symptoms rather than abrupt onset of maximal deficits.

PHYSICAL EXAM

- Note level of alertness, vital signs, presence of cough/gag and respiratory pattern as signs of possible increased intracranial pressure (ICP), and/or need for respiratory support/intubation.
- Age-appropriate neurologic examination including special attention to mental status, funduscopic exam for papilledema, cranial nerve abnormalities, and focal motor deficits. Pediatric National Institutes of Health (NIH) stroke scale use is encouraged.
- General examination: careful cardiac exam for murmurs or dysrhythmias; evaluate for neurocutaneous syndromes or connective tissue disorders

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood chemistry, particularly glucose
- CBC, prothrombin (PT), partial thromboplastin time (PTT), and fibrinogen
- Fasting lipid panel
- Thrombophilia screening (best to consult hematology): antithrombin III, protein C and S levels, factor V Leiden mutation, prothrombin G20210A mutation, and antiphospholipid screen
- More extensive testing in unexplained cases should be tailored to the individual patient and may include the following:
 - Homocysteine
 - Mitochondrial disorder: blood +/- CSF lactate, genetic testing, muscle biopsy
 - Connective tissue disorder gene testing
 - Testing for systemic inflammatory disease (best done in consultation with rheumatology) such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), antiphospholipid antibodies, antinuclear antibody, etc.

- Intracranial infection: lumbar puncture (after imaging) with opening pressure, cell counts, glucose and protein, viral studies, and cultures; blood cultures
- Consider drug screen.

Imaging

- After stabilization, prompt neuroimaging:
 - Non-contrast-enhanced images to look for possible hemorrhage
 - Gold standard for diagnosis of AIS is MRI with diffusion-weighted imaging.
 - Contrast images (CT or MR) should be obtained if there is concern for infection.
 - Consider vascular imaging (MR or CT) of the head and neck to evaluate for focal stenosis/thrombosis, dissection, vasculopathy, or congenital malformation.
 - Perfusion imaging (CT or MRI) may be helpful in defining the penumbra to evaluate the possible benefit of endovascular procedures.
- More extensive testing in undiagnosed cases may include the following:
 - ECG to assess for rhythm dysfunction
 - Echocardiography with bubble study
 - Conventional catheter angiography

ALERT

CT scan may be normal in the first 24 hours after nonhemorrhagic stroke.

DIFFERENTIAL DIAGNOSIS

Several disorders may mimic an acute stroke:

- Hypoglycemia
- Complicated migraine (hemiplegic, basilar)
- Postepileptic paralysis (Todd paralysis)
- Alternating hemiplegia of childhood
- Posterior reversible encephalopathy syndrome
- Brain tumor
- Conversion disorder
- Metabolic encephalopathies

- Intoxication/toxins
- Syncope
- Acute vestibular disease

TREATMENT

Recommendations are extrapolated from adult stroke literature and expert opinion, as randomized control trials in pediatric stroke have only been conducted in sickle cell patients.

MEDICATION

- Hyperacute treatment with tissue plasminogen activator (tPA) is recommended only in the setting of a clinical trial per American Heart Association (AHA) guidelines.
- Consider low-molecular-weight heparin or unfractionated heparin for CSVT, craniocervical dissection, or cardioembolic stroke.
 - Avoid anticoagulation for intracranial dissection due to increased risk of subarachnoid hemorrhage.
 - Avoid anticoagulation in large hemispheric strokes due to risk of hemorrhagic conversion.
- Antiplatelet therapy, such as aspirin 3–5 mg/kg/day, is reasonable in children whose strokes are not secondary to sickle cell disease, dissection, or cardioembolism.

ADDITIONAL TREATMENT

General Measures

- Admit patients with acute stroke to the hospital for close monitoring for clinical deterioration and for workup for underlying etiology.
- Patients with diminished or fluctuating level of alertness, large hemispheric strokes, or posterior fossa strokes may require monitoring in an intensive care unit for respiratory deterioration or signs of increased ICP.
- Consultation with neurology, hematology, and other pediatric subspecialists as clinically indicated (e.g., rheumatology, genetics)

ALERT

- Obtain urgent hematology consult for children with sickle cell disease and AIS for exchange transfusion.
- Urgent neurosurgical evaluation is indicated for large hemispheric stroke, intracranial hemorrhage, or posterior fossa stroke for possible surgical decompression.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Immediately attend to airway, breathing, and circulation to avoid hypoxia and hypotension, which may cause secondary brain injury.
- Start empiric antibiotics if there is clinical concern for acute CNS infection.
- Maintain adequate hydration particularly in patients with CSVT.
- Avoid hypoglycemia.
- Aggressively treat fevers to avoid increased cerebral metabolic demand.
- Up to 25% of children have seizures with an acute stroke (may be the presenting sign). Treat seizures aggressively.
- Bedrest for at least the first 24 hours is recommended for patients with large territory strokes, stuttering symptoms, or increased ICP.

IV Fluids

Isotonic-based fluids, preferably 0.9 NS, should be used to avoid hyponatremia and brain edema.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Follow serial neurologic examinations.
- Initiate rehabilitation (physical, occupational, speech therapies) early.
- For patients with significant neurologic deficits, consider discharge to inpatient rehabilitation.

DIET

Strongly consider a swallow study in patients with facial weakness or

cranial nerve involvement before allowing oral intake.

PROGNOSIS

- More than half of children with AIS have residual neurologic deficits.
- Predictors of poor outcome after hemorrhagic stroke include Glasgow Coma Scale score ≤ 7 at admission, infratentorial hemorrhage, age < 3 years, or large hemorrhage volume (Appendix, [Tables 5](#) and [6](#)).

COMPLICATIONS

- Acute complications include increased ICP/cerebral edema, seizures, dysphagia resulting in aspiration, and respiratory failure.
- Mortality from AIS is estimated to be 5–18% and from hemorrhagic stroke 7–54%.

CODES

ICD10

- I63.9 Cerebral infarction, unspecified
- I63.50 Cereb infrc due to unsp occls or stenosis of unsp cerebr artery
- I61.9 Nontraumatic intracerebral hemorrhage, unspecified

FAQ

- Q: Will my child have another stroke?
- A: Overall risk of recurrence is estimated to be about 6.6–25%, but the

risk primarily depends on the cause of the stroke. Children with Hgb SS and congenital heart defects have a higher risk for recurrence. Children with neonatal strokes without an identified risk factor are unlikely to have a second stroke.

- Q: Which therapies will help my child the most?
- A: Significant research is being conducted in rehabilitation after pediatric stroke, but there is no consensus on the best approach. Constraint-induced therapy has shown promising results. Therapies should not focus on just motor deficits but include cognitive and behavioral difficulties as well.

STUTTERING

Gary A. Emmett

BASICS

DESCRIPTION

Stuttering (also referred to as stammering or dysfluency) is an involuntary disturbance in the normal fluency and timing of speech that is not appropriate for the age of the speaker. Various patterns are seen:

- Prolongation of sounds or syllables
- Repetition of sounds, syllables, or even whole words
- Pauses in the middle of words
- Blocking—either silence or pauses filled with nonsense sounds in the middle of words as if considering what to say next
- Avoidance—word substitutions that are used to skip known problem words; also called circumlocution
- Overemphasis of some syllables or words; also called tension
- Stuttering is significant when it interferes with the patient's life in academic, occupational, or social arenas. Many children with developmental delays have dysfluencies of speech, but it is not considered stuttering unless the dysfluencies are present more frequently than expected for the level of disability.

EPIDEMIOLOGY

- At least 1% of all studied populations affected
- Males stutter 3 times more often than females.
- Stuttering is found in every culture and language. The language spoken in the home does not increase or decrease the amount of stuttering.
- Stuttering begins between 2 and 7 years of age, with 98% of cases presenting by age 10 years.
- Girls start stuttering several months earlier on average than boys; however, they also speak, in general, earlier than boys do.

RISK FACTORS

Genetics

Stuttering does cluster in families:

- Monozygotic twins have a higher concordance for stuttering than dizygotic twins.
- The more closely related one is to a stutterer, the more likely one is to stutter.
- Identical twins have a concordance for stuttering of $\geq 30\%$.
- In specific families with a high propensity for stuttering, Lee et al. (and others) have shown single gene defects that correlate highly with dysfluency.

GENERAL PREVENTION

There is no known prevention strategy for stuttering.

PATHOPHYSIOLOGY

Stuttering appears to be associated with an excessive amount of dopamine, or closely related vasoactive compounds, in the brain:

- Patients with Parkinson disease often develop adult-onset stuttering.
- PET scans show increased vasoactive substances in the brains of those who stutter.
- Medications that increase brain dopamine (antidepressants) or are dopaminergic (major tranquilizers) can induce stuttering in nonstutterers; medications that lower dopamine (e.g., clomipramine) may stop stuttering.
- Many differences exist between the brains of stutterers and nonstutterers in glucose uptake, dopamine release, and metabolic activity of the basal ganglia, but no single physiologic process has been well defined as the cause of stuttering.

ETIOLOGY

- Specific etiology is not known, but many factors contribute. Stuttering may be more pronounced when a child is fatigued, excited, upset, rushed, or exposed to some other stressor.
- Environmental factors are thought to have a role. Children adopted by a parent who stutters are more likely to stutter than children adopted by a parent who does not stutter.

COMMONLY ASSOCIATED CONDITIONS

- Other language problems: articulation disorders, phonologic disorders, learning disabilities, dyslexia, ADHD
- Students with developmental delay or intellectual impairment are found to stutter up to 25% of the time.

DIAGNOSIS

HISTORY

- Stuttering runs in families by both nature and nurture.
- Age of onset and length of persistence
 - Onset is insidious, with the child often unaware of the problem.
 - If stuttering starts after the 10th birthday, suspect an intracranial mass or brain ischemia.
- Physiologic stuttering is rarely present during oral reading, singing, acting, and reciting in rhythm or while talking to pets or inanimate objects.
- Medications, especially those that increase dopamine, may activate stuttering.
- Increased intracranial pressure from disease or trauma may lead to stuttering.

PHYSICAL EXAM

- There are no specific physical exam findings of stuttering. Observations of children improve the ability to make this diagnosis. Stuttering is 2 or more repetitions of a speech unit.
- Stutterers often improve in one-to-one situations with familiar people, so ask the parents to bring in a video recording of the child in a variety of situations: when talking in public, singing, and talking to a pet or infant.
- Observations that may be made in the office and correlate strongly with the diagnosis of stuttering include the following:
 - Multiple repetitions and/or prolongations
 - Rising pitch with difficult words
 - Grimacing or other physical tension such as taking deep breaths or jerking the head back when speaking

- Inappropriate emphasis of words not normally emphasized, extremely slow speech, or speech without intonation
- Although unwillingness to speak to the examiner is normal, unwillingness to speak to the parent is not.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- None currently available, but PET scan may be a useful modality in the future
- If stuttering begins after the age of 10 years, or if the patient has additional neurologic or developmental problems, a workup for brain abnormalities should be considered.

DIFFERENTIAL DIAGNOSIS

- Developmental
 - Normal development: dysfluencies associated with rapid onset of full speech capabilities that will usually resolve very quickly
 - Transitory dysfluency is an ill-defined term but generally means stuttering in preschool-aged children that lasts <1 year.
 - Cluttering: Patients with extremely rapid speech will have dysfluencies that resolve with slowing down of speech.
 - Pervasive developmental disorder (autism spectrum disorder): may also have echolalia, tonelessness, and poor eye contact
- Neurologic
 - Tics/Tourette syndrome: similar time of onset, initially somewhat similar symptoms. Stuttering is usually not associated with simultaneous physical movement.
 - Trauma, tumor, or major CNS disease, such as Parkinson disease, may cause late-onset stuttering.
- Medications
 - Any medication that increases the presence of dopamine may worsen (or cause) stuttering. Examples are SSRI-type antidepressants or major tranquilizers.

TREATMENT

GENERAL MEASURES

- Therapy must work on improving the child's fluency and increasing acceptance and tolerance of this problem by the patient and his or her family.
- In a multicultural learning atmosphere, sensitivity to the learning styles of each social group is paramount in achieving successful results.
- Current evidence-based analysis suggests that early intervention by a certified speech pathologist is always indicated.

ADDITIONAL THERAPIES

- Speech therapy
 - Stuttering in young children can be resolved with very short courses of therapy, often ≤ 3 months. Stuttering remains resolved in $\geq 95\%$ of these early treatment cases. The younger the patient is at the time of referral to speech therapy, the shorter the course of therapy needed, and the more likely that the therapy will be successful.
 - Many experts in dysfluency believe that early intervention is more likely to be successful than waiting to start therapy if the stuttering has not spontaneously resolved by the 7th birthday.
 - Among the more successful new programs for young children who stutter is the Lidcombe Program of Early Stuttering Intervention, an intense behavioral therapy program that centers on the belief that stuttering is physical in nature. The program teaches parents and caregivers to praise the child for speaking fluently and to correct them occasionally when they stutter. Parents are supported throughout the process by the clinician. The therapy ultimately enables the child to speak fluently and to monitor his or her own speech.
- Other therapies
 - A successful new therapy for adolescents and adults is a hearing-aid type device (SpeechEasy, www.speecheasy.com) that feeds the individual's speech directly back into an earpiece.
 - Devices that make hearing monaural or provide a white noise background in the ear also improve stuttering.
 - Information for families is available through organizations such as The Stuttering Foundation, a nonprofit organization

(www.stutteringhelp.org).

ALERT

- Because stuttering waxes and wanes with time, temporary improvement does not equal cure.
- Any behavioral therapy must be done under the guidance of a well-trained professional because inappropriate criticism may worsen stuttering.
- Waiting to see if stuttering goes away by age 7 years is not the best strategy for young children, as was often taught in the past.
- The literature does not give a clear time frame for how long stuttering in preschool children should last before requiring evaluation and treatment, but a significant stutter that lasts for >1 year should be referred to a speech therapist.
- No medications are known to reduce stuttering safely. Acupuncture, hypnosis, and yoga have been used with some success but not in controlled studies.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

If stuttering is reported by the parents in a preschool-aged child, follow up in 1–2 months to see if it was only a transitory dysfluency that has resolved. If not, obtain a speech therapy consult for evaluation.

Patient Monitoring

- Periodic follow-up to ensure that speech therapy is in place and that progress is being made
- Reassessment to ensure that child is adapting to social situations and interacting with others

PATIENT EDUCATION

- The following suggestions, although helpful to parents, should be recommended in conjunction with, but not in place of, speech therapy. Parents may be too critical of their own children.
 - Take time out of each day to speak with the child one-on-one.

- Model slow speech.
- Wait for the child to speak. Take turns speaking.
- Allow for transition time between activities and tasks.
- Keep a notebook of things that help make speech better and things that elicit stuttering.

PROGNOSIS

- Up to 80% of stuttering cases spontaneously regress by age 16 years.
- Severity of stuttering does not relate to persistence of stuttering.
- The longer stuttering exists, the more likely it will persist.

COMPLICATIONS

- Anxiety and depression, often far out of proportion to the degree of dysfluency
- Blocking and hesitation, giving an impression of delayed intellectual development
- Voluntary withdrawal from social interaction to avoid embarrassment

CODES

ICD10

F80.81 Childhood onset fluency disorder

FAQ

- Q: Are some children more prone to stuttering?
- A: Yes. “Sensitive” children (many different definitions in many different studies) are more likely to stutter as are the children of highly critical parents.
- Q: Should family and friends complete the sentences of children who stutter?
- A: No. Children who cannot complete a thought should be gently asked to slow down and try again with no time limit set; others should simply wait until the child has completed his or her sentence. Children with a stuttering problem should also be praised when they do not stutter.

SUBDURAL HEMATOMA

Daphne M. Hasbani • Sabrina E. Smith

BASICS

DESCRIPTION

A subdural hematoma (SDH) is a collection of blood between the outer pial and inner dural meningeal layers. The bleeding is usually venous in origin, although either cortical arteries or bridging veins may be torn.

EPIDEMIOLOGY

- Heterogeneous causes; occur in all age groups
- Incidence in infants <1 year old estimated at 20–25/100,000.

RISK FACTORS

- In infants and young children, SDHs are frequently the result of abusive head trauma.
- In older children, SDHs are often the result of motor vehicle collisions.
- Neonatal SDHs occur with spontaneous deliveries but may be more frequent following deliveries with forceps or vacuum extraction. SDHs related to birth usually resolve.
- Risk factors for abusive head trauma include disability or prematurity of the child, unstable family situations, parents of young age, and low socioeconomic status.
- 1 study found that fathers were the most frequent perpetrators, followed by boyfriends, female babysitters, and mothers, in descending order of frequency.
- Accidental trauma

Genetics

There is no clear genetic predisposition except when hereditary coagulopathy or metabolic disease is implicated.

GENERAL PREVENTION

- Parents should be counseled about appropriate methods to channel frustration and anger toward infants and children. Shaking an infant

when the parent is angry is never appropriate.

- Bicycle helmets, car seats, and seat belts are all valuable in preventing head injuries in children.

PATHOPHYSIOLOGY

- SDHs may be acute or chronic:
 - Arterial SDHs grow quickly, whereas venous SDHs may accumulate slowly, remaining undetected for weeks or months.
 - Acute SDHs contain blood, whereas chronic SDHs contain proteinaceous exudate and blood-breakdown products.
 - Rebleeding may be the underlying cause of many chronic SDHs.
- Significant force is usually required for SDH unless there are predisposing circumstances; SDH is only rarely due to trivial or minor trauma. However, SDH can occur with relatively minor trauma in individuals with bleeding disorders, children on chronic dialysis, and those with enlarged extracerebral spaces or cortical atrophy.
- SDHs in abusive head trauma may be due to the striking of the infant's head against a surface (such as a mattress):
 - The sudden deceleration associated with the impact may tear bridging veins traveling in the subdural space.
- The term shaking-impact syndrome may be more accurate than shaken baby syndrome.

ETIOLOGY

- See “[Risk Factors](#).”
- SDHs can also occur after ventricular shunting and extracorporeal membrane oxygenation (ECMO).

COMMONLY ASSOCIATED CONDITIONS

- Some metabolic disorders, such as glutaric aciduria type I and Menkes disease, can be associated with both acute and chronic SDHs.
- Victims of motor vehicle collisions with SDH may have other intracranial injuries such as diffuse axonal injury.
- Traumatic SDHs are often associated with cerebral contusions. Other associated injuries include skull fractures, diffuse axonal injury, and penetrating injuries.
- Sequelae: epilepsy, developmental delay, cerebral palsy

DIAGNOSIS

A careful history and detailed physical exam are essential to explore possible causes of the SDH, assess the child's neurologic status, and look for evidence of other injuries. Prompt neuroimaging is critical.

HISTORY

- Newborns: SDHs due to birth trauma may present with lethargy, pallor, poor feeding, apnea, and seizures. However, many term newborns with small SDHs are asymptomatic.
- Infants and young children: SDHs may also present with a nonspecific history of lethargy, irritability, vomiting, poor feeding, apnea, and seizures.
- Older children: present with a history of trauma and alteration of consciousness
- Caution
 - Be suspicious if the stated history does not fit with the pattern or severity of the injury.
 - Physicians and other health care professionals with experience in child abuse should be consulted early if abuse is suspected.

PHYSICAL EXAM

- Newborns may present with decreased responsiveness, a bulging fontanelle, hypotonia, or hypertonia. Retinal hemorrhages are not specific at this age because they are seen in up to 40% of newborns following a vaginal delivery.
- Infants and young children may also present with nonspecific physical signs, but focal neurologic signs may be present. Retinal hemorrhages are most often associated with abusive head trauma, but they have been reported after accidental trauma leading to SDH. Bilateral retinal hemorrhages with retinal folds or detachments are particularly associated with abusive head trauma.
- Other signs of child abuse include burns, lacerations, and bruises in various stages of healing and belt marks, choke marks, and multiple fractures of different ages.
- Older children present with signs of external head trauma, decreased

responsiveness, and focal neurologic signs.

- SDHs present with nonspecific signs such as vomiting, irritability, lethargy, failure to thrive, anemia, and seizures.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- CT scan is the imaging study of choice in acute head trauma with neurologic signs:
 - SDH appears as an extra-axial area of increased density, crescentic in shape, and often associated with cerebral contusion or mass effect.
 - CT also may show evidence of cerebral edema, with loss of gray matter/white matter differentiation and small ventricles.
 - Subacute SDHs may be difficult to distinguish from adjacent gray matter on CT scan.
 - Loss of gray/white matter differentiation may occur.
 - Chronic SDHs appear as areas of low density on CT scan, often bilateral.
- MRI is helpful to clarify subacute and chronic SDHs and to identify small SDHs missed by CT.
- Ultrasound is less helpful because it may be difficult to distinguish the subdural space from the subarachnoid space.
- If child abuse is suspected, a skeletal survey or bone scan is useful to look for fractures of different ages.
- Incidental SDH may be found on neuroimaging studies in newborns; frequently, no intervention is required other than close follow-up.

DIFFERENTIAL DIAGNOSIS

- SDHs are usually traumatic, but separating accidental from abusive head trauma may be difficult: Falls in infants may cause linear skull fractures but rarely SDHs. On noncontrast head CT, homogeneous hyperdense SDH is more common following accidental trauma, whereas mixed-density SDH is more common following abusive head trauma.
- Macrocephaly or other signs/symptoms since birth may help to date the origin of the SDH to the perinatal or neonatal period.

- Epidural hematomas, subarachnoid hemorrhages, and acute SDHs cannot be distinguished clinically:
 - The lucid interval sometimes seen with epidural hematomas in adults is not a reliable sign.
 - A head CT should differentiate the different entities.
- Chronic SDHs must be differentiated from benign enlargement of the subarachnoid spaces, a self-limited condition characterized by progressive macrocrania and extra-axial fluid collections with the density of spinal fluid:
 - MRI can differentiate benign enlargement of the subarachnoid spaces from SDH.
 - Rarely, SDH can also occur in children with benign enlargement of the subarachnoid spaces.

TREATMENT

MEDICATION

Seizures

- Phenytoin and levetiracetam are good choices if IV medication is needed, with phenobarbital as a reasonable alternative, especially in neonates.
- Prophylactic anticonvulsants given for a few weeks are effective in reducing early posttraumatic seizures but may not affect long-term risk of epilepsy.

ADDITIONAL TREATMENT

General Measures

- The treatment of choice for large, acute SDHs is surgical evacuation. Smaller SDHs may be managed conservatively, with careful monitoring for signs of neurologic deterioration.
- While awaiting surgery, attention to airway, breathing, and circulation (ABCs) is critical. Tracheal intubation should be performed if the child's Glasgow Coma Scale score is <8 or if airway protective reflexes are impaired.
- Measures to control intracranial pressure (ICP) include elevating the

head of the bed 30 degrees to promote venous drainage and osmotic therapy with mannitol:

- ICP monitoring should be considered.
- Mild hyperventilation (PCO₂ 30–35 mm Hg) may be helpful but should not be instituted prophylactically.
- The efficacy of these measures in improving long-term outcome following large SDHs has not been established. Mild hypothermia and hypertonic saline have been used in some cases of traumatic brain injury in adults, but these are not proven therapies in children.
- Seizures should be treated promptly.
- Treatment of chronic SDHs is more controversial:
 - If there are no signs of elevated ICP, conservative treatment is reasonable, and most collections will resolve.
 - Subdural taps are indicated if ICP rises.
 - If taps are not successful, a subdural peritoneal shunt may be placed.
- Treatment of SDHs that develop after ventricular shunting is particularly challenging.

ISSUES FOR REFERRAL

Social work services should be consulted in cases of known or suspected child abuse.

SURGERY/OTHER PROCEDURES

The treatment of choice for large, acute SDHs is surgical evacuation.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Children with SDHs may be critically ill on presentation.
- The aggressiveness of acute therapy depends on the child's clinical condition.
- Neuroimaging studies and, if necessary, prompt neurosurgical consultation should be performed.

IV Fluids

Isotonic fluids should be given because hypotonic fluids may worsen cerebral edema.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Children with neurologic sequelae from head injury may benefit from admission to a rehabilitation hospital.

PROGNOSIS

- In general, long-term outcome is related to the condition of the child at time of presentation. Prolonged elevation of ICP, concomitant ischemic brain injury, or significant cerebral edema before treatment is worrisome and indicates a poor prognosis.
- Children typically have a better outcome from head injury than do adults, but children <7 years of age often do worse than older children, especially if the SDH is the result of abusive head trauma.

COMPLICATIONS

- SDHs may result in mass effect, focal neurologic signs, and coma.
- Increased ICP and seizures are other serious complications.
- Neurologic sequelae of SDHs are more severe than epidural hematomas because of associated cerebral contusions.
- Long-term problems include headache, seizures, hydrocephalus, cerebral palsy, difficulty concentrating, poor school performance, fixed neurologic deficits, and neurobehavioral problems.
- Epilepsy eventually develops in ~10–15% of patients after severe head injury: This risk generally does not warrant the use of prophylactic anticonvulsants.

CODES

ICD10

- S06.5X0A Traum subdr hem w/o loss of consciousness, init
- P52.8 Other intracranial (nontraumatic) hemorrhages of newborn
- P10.0 Subdural hemorrhage due to birth injury

FAQ

- Q: When did the bleed occur?
- A: With chronic SDHs, the time and type of injury may be difficult to establish because no trauma may be reported and the trauma may have occurred weeks or months before. Neuroimaging can give some indication of the injury's timing.
- Q: What limitations should be imposed after an acute SDH?
- A: Because SDH may recur with minor trauma, it is prudent to avoid any activities that have significant risk of fall or a blow to the head for weeks to months or until neuroradiologic resolution of the hematoma.
- Q: Why are anticonvulsants not used to prevent seizures following SDHs?
- A: Seizure medications may be given for a few weeks to prevent early seizures following an SDH. After a few weeks, the risks and side effects of the medications outweigh the risk of developing seizures. If seizures begin at a time remote from the injury, then seizure medications can be restarted.
- Q: My baby twisted out of my arms, fell head first onto a tile floor, and

suffered a head injury. Will I be reported for child abuse?

- A: Not if the injuries fit with the stated history. In this case, the most likely injury would be a linear skull fracture. If more serious intracranial injuries occur, they will probably not be associated with retinal hemorrhages or other injuries such as older fractures in multiple stages of healing.

SUBSTANCE USE DISORDERS

Sara M. Buckelew

BASICS

DESCRIPTION

- In adolescence, substance use tends to occur along a continuum from abstinence to experimentation to nonproblematic use to problematic use to substance use disorder.
- DSM-5 defines substance use disorder as a maladaptive pattern of use leading to clinical impairment or distress, which is based on presence of specific criterion including the following:
 - Substance use resulting in failure to fulfill obligations (such as school or work)
 - Substance use in situations that are hazardous (such as driving)
 - Continued use despite interpersonal problems exacerbated by use
 - Development of tolerance
 - Development of withdrawal
 - Craving for the substance
 - Persistent desire or unsuccessful efforts to curb/cut down usage
 - Significant time and energy spent obtaining substances
 - Continued use despite recognition of associated psychological or physical consequences of continued use (with or without physiologic dependence)
- Substance use disorder combines the previous diagnoses of substance abuse and substance dependence from the DSM-IV.
- Substance use disorder exists along a continuum from mild to severe depending on the number of criterion met.

EPIDEMIOLOGY

- Substance use estimates vary by substance, age of youth, and geographical location. Up to date, epidemiologic data can be found online at www.monitoringthefuture.org which includes data for cigarette, alcohol, and other illicit drug use among 8th, 10th, and 12th graders. Another source of substance abuse data includes the Youth

Risk Behavior Survey (YRBS) conducted by the Centers for Disease Control and Prevention.

- Although rates of overall use over time have remained relatively stable, rates for each individual substance have varied.
- Adolescent substance use has been associated with increased morbidity and mortality including depression, suicide, motor vehicle accidents, unintentional injuries, teenage pregnancy, high-risk sexual activity, and sexually transmitted infections (STIs).

RISK FACTORS

- Early initiation: Adolescents who begin using alcohol or drugs at an early age have an increased risk of developing an addictive disorder later in life. Later initiation of use may be a protective factor.
- Individual factors such as low self-esteem and impulsivity
- Social factors such as peer use
- Family factors such as a negative parent–child/adolescent relationship, permissive or authoritarian parenting style, parental divorce during adolescence
- Other environmental factors such as school failure and availability of substances within the community
- Individual and family factors may be protective as well such as positive self-esteem and positive, open and supportive relationships with family.

GENETICS

Research demonstrates a genetic predisposition to alcohol dependence. Children of alcoholic parents are 4–6 times more prone to developing alcohol dependence.

COMMONLY ASSOCIATED CONDITIONS

- Mood disorders
- Anxiety disorders, including posttraumatic stress disorder
- Eating disorders (specifically bulimia nervosa)
- Attention deficit disorder
- Learning disorders
- Conduct disorders
- Psychotic disorders

DIAGNOSIS

HISTORY

- Adolescent-appropriate screening using a validated measure should be administered at least annually at every adolescent preventive care visit and appropriate urgent/acute care visits.
- Screening should be performed confidentially and with the adolescent alone (without parents).
- SBIRT Model recommended for adolescents. Includes the following steps: Screening, Brief Intervention, and Referral to Treatment. The Brief Intervention is based in principles of motivational interviewing in addressing behavior change.
- The CRAFFT (an acronym for key components in the questions: car, relax, alone, forget, family/friends, trouble) screen is one of several tools validated for adolescent.
- All patients who screen positive warrant a more complete assessment including more in-depth substance use history. Questions should include what substances are used, frequency of use, mode of use (nasal, ingestions, smoking, intravenous), how they are obtaining the substances, and peer group usage.
- The 5 A's was developed to address smoking cessation and includes Asking about use; Advising all smokers to quit; Assessing a patient's willingness to quit; Assisting the patient with smoking cessation; and Arranging follow-up.

PHYSICAL EXAM

- Vital signs: increased blood pressure and increased pulse seen in stimulants (such as cocaine, amphetamines), cannabis, phencyclidine (PCP)
- General: odor of alcohol, marijuana, or tobacco; poor personal hygiene; slurred speech; intoxicated appearance
- HEENT: rhinitis and/or nasal mucosa irritation if snorting substances
- Eyes: injected conjunctiva with cannabis; nystagmus with PCP; pupillary constriction with opiates; pupillary dilatation with cocaine, PCP, and opiate withdrawal

- Respiratory depression with opiates, overdose on depressants (such as alcohol and benzodiazepines)
- Respiratory: wheezing/abnormal breath sounds due to smoking substances (tobacco, cannabis, other substances)
- Skin: needle marks in injection users

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urine drug screens are most commonly used. Their use in the emergency situation is critical when overdose or acute intoxication is suspected. They can be used effectively as part of a drug treatment program. With limited exceptions, random and routine drug screening is not recommended by the American Academy of Pediatrics and is of limited value.
- Urine drug screens typically include
 - Cannabinoids
 - Cocaine
 - Amphetamines
 - Opiates
 - PCP

Diagnostic Procedures/Other

Screening for STIs including HIV (particularly in IV drug users) and hepatitis B and C is recommended as part of a risk reduction program.

DIFFERENTIAL DIAGNOSIS

- Mood disorders
- Attention deficit disorder
- Psychotic disorders

TREATMENT

MEDICATION

- Cigarette/nicotine dependence
 - Nicotine replacement available in number of different forms including nicotine replacement patch, lozenge, inhaler, and gum

- Bupropion may be recommended in those who have failed with nicotine replacement alone.
- Varenicline is not approved in those <18 years of age.
- Alcohol dependence
 - Medications available for adults such as naltrexone, disulfiram, and acamprosate are not approved for adolescents.
- Buprenorphine (partial agonist of the mu opioid receptor) for treatment of opioid dependence. Approved in those aged 16 years and older and may be used for maintenance. Methadone has been used for short-term detoxification but not typically used for maintenance due to poor adherence.
- Comorbid and associated psychiatric illnesses such as mood disorders, anxiety disorders, and ADHD should be medicated appropriately.

ADDITIONAL TREATMENT

General Measures

- Treatment can be provided in a number of different settings both outpatient and inpatient with varying intensity, including the following:
 - Outpatient treatment: typically 1 hour weekly, may be individual therapy or family therapy
 - Intensive outpatient program or partial hospitalization program: more intensive outpatient program where teen lives at home but may be participating in individual and group therapy multiple hours per day and multiple days per week
 - Residential treatment/therapeutic boarding school: where teen is no longer living at home and receiving more intensive services

ISSUES FOR REFERRAL

- Rates of treatment are low, with only 6–10% of those adolescents with substance use disorders receiving treatment.
- All youth with a concern for substance abuse or comorbid disease should be referred to an experienced mental health professional or addiction specialist.

ADDITIONAL THERAPIES

Strongest body of evidence in the treatment of adolescent substance use

disorders is therapy.

- Cognitive behavioral therapy: structured and goal-oriented therapy designed to assist teen in identifying behavioral strategies to address distorted thoughts and subsequent emotions
- Family therapy: Some research demonstrates that family treatments are superior to individual therapy.
- 12-step programs such as Alcoholics Anonymous (AA) and Narcotics Anonymous (NA): typically small group format where participants may provide support for each other
- Brief intervention/brief advice/motivational interviewing: a counseling style that is patient-focused, aimed at exploring benefits and cons of usage in order to direct the patient toward behavior change

INPATIENT CONSIDERATIONS

- Detoxification should be considered for youth when there is concern for withdrawal. Includes medical management of withdrawal symptoms.
- Residential treatment is an intensive, structured program for adolescents who may require this particularly acutely. For those who require 24-hour care and support

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients should be screened annually at all preventive visits.
- When an action plan is created or in those receiving brief advice or brief interventions, patients should be followed closely.
- The pediatrician may play an important role in monitoring for relapse in those who have undergone treatment.

PATIENT EDUCATION

All youth who have not initiated substance use should be given positive reinforcement about their behaviors and encouraged to discuss the topic in the future.

PROGNOSIS

- Youth who receive treatment do better than those who do not.
- Approximately 1/3–1/2 of youth who receive treatment will relapse within 12 months following treatment completion.
- Factors associated with relapse include psychiatric comorbidity, poor coping skills, poor familial relationships, and return to prior peer groups.
- Continued involvement in therapy and ongoing support helps to protect against relapse.

COMPLICATIONS

Acute intoxication/overdose can have significant associated morbidity and mortality.

- F10.10 Alcohol abuse, uncomplicated

- F12.10 Cannabis abuse, uncomplicated

FAQ

- Q: Should I screen adolescents who use substances for suicide risk?
- A: Yes. All adolescents with a history of substance misuse should be screened for suicide risk and suicidal ideations. Adolescents who use substances have a higher percentage of psychiatric comorbidity and a higher risk of suicide.
- Q: What do I tell parents about their teen's substance use?
- A: The laws about confidentiality pertaining to adolescent substance use and disclosure to parents depend on the state. It is important to know the laws in your state.
- Q: What symptoms would you expect to see based on a patient's blood alcohol level?
- A: Blood alcohol levels (BAL) can be indicative of the severity and may vary due to metabolism and body weight. A BAL of 0.05% is associated with slowing reaction time and altered cognition; 0.1–0.2%: intoxication, drowsiness, and loss of balance; 0.2–0.3% may lead to vomiting and stupor; 0.3–0.4% may lead to hypothermia and coma; and >0.4% may lead to death.

SUDDEN INFANT DEATH SYNDROME

Katherine Deye • Rachel Moon

BASICS

DESCRIPTION

- Sudden infant death syndrome (SIDS) is the sudden and unexpected death of an infant younger than 1 year of age, with onset of the lethal episode apparently occurring during sleep, which remains unexplained after a thorough investigation, including the performance of a complete autopsy, review of the circumstances of death, and review of the clinical history.
- SIDS is a subcategory of deaths described as “sudden unexpected deaths in infancy” (SUDI) or “sudden unexpected infant deaths” (SUID). SUID can include both explained deaths, including suffocation, asphyxia, entrapment, trauma (accidental or nonaccidental), cardiac arrhythmia, infection, and metabolic disorders, and unexplained deaths, including SIDS and those with an undetermined/ill-defined cause of death.

EPIDEMIOLOGY

- Most common cause of death in postneonatal (>1 month old) infants
- Peak age of incidence: 2–4 months; uncommon before 2 weeks or after 6 months
- Incidence has been decreasing:
 - 1970s: ~2.5 SIDS deaths per 1,000 live births: SIDS defined somewhat loosely
 - 1980s: ~1.4 per 1,000 live births
 - 1990s: ~1.2 per 1,000 (1992)–0.7 per 1,000 live births (1999): “Back to Sleep” campaign encouraging supine positioning during sleep in 1994 is associated with steady decline in deaths.
 - 2000s: Since 2001, SIDS rate has remained constant (~0.5/1000 live births).
- The rate of SUID (suffocation, asphyxia) or other undetermined or unspecified causes of death has risen.

- For example, the death rate from accidental suffocation and strangulation in bed (ASSB) has more than quadrupled in recent years.
- Largely because of improved death scene investigations, many deaths that previously would have been classified as SIDS are now being classified as having resulted from these other causes of death.

RISK FACTORS

- Male sex
- Premature birth or low birth weight
- Inadequate prenatal care
- Poverty
- Lower maternal educational level
- Exposure to prenatal, gestational, and postnatal tobacco smoke
- Alcohol and illicit drug use in utero and after infant's birth
- Maternal substance abuse
- Young maternal age
- Prone and side sleeping position
- Overheating and overbundling
- African American or American Indian/Alaska Native heritage
- Soft sleep surface
- Soft and loose bedding
- Bed sharing, particularly if sharing bed with one or more smokers; if the infant is <11 weeks of age (even if neither parent is a smoker); if sleeping on a surface with soft bedding; if bed sharing adults have consumed alcohol or drugs; if bed sharing with people who are not the infant's parents; and if the sleep surface is very soft (couches, armchairs, waterbeds)

Potential protective factors include the following:

- Breastfeeding
- Pacifier use at bedtime and naptime
- Regular prenatal care
- Immunizations
- Room sharing without bed sharing

Genetics

- Most likely represents a heterogeneous group of causes of death
- Genetic factors may play a role in some of these deaths. Candidate genes include those encoding ion channel proteins, serotonin transporters, nicotine-metabolizing enzymes and those regulating autonomic nervous system development, inflammation, energy production, hypoglycemia, and thermal regulation.
- There appears to be a complex gene and environment interaction.
- Parents should be reassured that the chance of recurrence in future siblings is small and will be examined during the investigation of the SIDS death.

GENERAL PREVENTION

- Place infants on their backs for every sleep until 1 year of life.
- Use a firm sleep surface.
- Do not use blankets, pillows, bumper pads, sheepskins, or comforters in the infant's sleep area.
- Avoid tobacco smoke exposure during pregnancy and after birth.
- Room sharing without bed sharing is recommended.
- Breastfeed as much and as long as possible.
- Consider offering a pacifier at naptime and bedtime. If breastfeeding, wait until breastfeeding is well established (3–4 weeks) before introducing a pacifier.
- Do not use alcohol or illicit drugs during pregnancy or after birth.
- Avoid overheating.
- Do not cover infant's head during sleep.
- Immunize your infant.
- Do not use home cardiorespiratory monitors as a strategy to reduce the risk of SIDS.

PATHOPHYSIOLOGY

- The “triple risk” model of SIDS describes the interplay of three factors thought to contribute to these deaths: a vulnerable infant, a critical period of development, and stressful environmental challenges.
 - Individual traits that influence an infant's vulnerability to SIDS are characterized as intrinsic risk factors. Examples include serotonin receptor abnormalities noted in the ventral medulla of SIDS infants

at autopsy, suggesting derangements in the neural circuits responsible for arousal and cardiorespiratory functioning. Autopsy studies have also revealed changes in the serotonin transporter gene (5-HTT) that ultimately reduce serotonin concentration at these nerve synapses.

- The period from birth to age 6 months is one of rapid brain growth and maturation, as well as motor skill acquisition, such as the ability to lift and turn the head in the event of life-threatening rebreathing or asphyxia.
- Exogenous risk factors such as soft bedding, tobacco smoke, side or prone positioning, and overheating place these vulnerable infants at risk for asphyxia or other physiologic disturbances.
- Failure of arousal in the face of asphyxia or other physiologic disturbances likely contributes to the final pathway leading to these infants' deaths. Known risk factors for SIDS have been linked to arousal and cardiorespiratory responses. For example:
 - Prematurely born infants have immature central respiratory responses.
 - When compared with supine-sleeping infants, prone-sleeping infants have increased arousal thresholds.
 - Prenatal and postnatal nicotine exposure blunts arousal responses to hypoxia.

DIAGNOSIS

HISTORY

- SIDS is a diagnosis of exclusion.
 - A thorough postmortem evaluation, including death scene investigation, complete autopsy, and review of the infant's clinical history, should be done.
 - Standardized forms developed by the Centers for Disease Control and Prevention for the collection of the circumstances and factors contributing to these deaths and reporting of cases of SUID are available online at www.cdc.gov/sids/SUIDRFdownload.htm.
- Parents and other caregivers should be interviewed in a sensitive

manner so as not to imply that parents or caregivers are blamed for the death. Specifically, the following should be ascertained:

- Signs and symptoms (such as fever, cough, irritability, easy fatigability, and lethargy) that may be suggestive of an acute or chronic medical condition that may have caused or contributed to the death
- Family history of sudden death, condition associated with cardiac arrhythmia, epilepsy, metabolic or genetic disease
- Known risk factors for SIDS and other SUID, including sleep position when placed and found, sleep environment, bed sharing, prematurity, parental smoking history, and history of maternal substance abuse
- Evidence suggestive of accidental suffocation, strangulation, or entrapment
- Evidence suggestive of nonaccidental traumatic injury and other forms of abuse (including medical child abuse, also known as “Munchausen syndrome by proxy”)

PHYSICAL EXAM

- Normal-appearing infant without obvious reason for death
- May have postmortem lividity and/or a pink, frothy discharge from the mouth or nose
- May have signs of terminal motor activity (clenched fists, trismus, or anal dilation)
- Lack of signs of injury or neglect (malnourishment, dehydration, wasting)
- Care must be taken with the deceased body; only medical examiners and coroners have legal authority to establish the cause of death.

Manipulation or examination of body after the declaration of death may violate applicable laws. All medical paraphernalia used during resuscitation must be left in place.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- A full autopsy, including the cranium and cranial contents, must be performed on all infants who die suddenly and unexpectedly.

- A toxicology screen; microbiologic evaluation for bacterial, viral, and fungal infections; and urine and serum chemistries to evaluate for metabolic disease should be performed—whether these are performed at the hospital or by the medical examiner is dictated by local resources and protocols.

Imaging

- Skeletal survey
 - Whether this is performed at the hospital or by the medical examiner is dictated by local resources and protocols.

Pathologic Findings

- After a review of a thorough death scene investigation, clinical history, and complete autopsy, pathologists are able to make the diagnosis of SIDS when no other specific cause of death has been identified.
- There are no pathologic findings that are pathognomonic. Approximately 80–85% of SIDS infants are noted to have intrathoracic petechiae on examination. Additional common autopsy findings include pulmonary congestion and edema as well as minor airway inflammation.

DIFFERENTIAL DIAGNOSIS

- In approximately 10–15% of cases of suspected SIDS, an alternate cause of death is identified. These include the following:
 - Environmental: asphyxia (due to such causes as overlaying, wedging, choking, obstruction of nose or mouth, rebreathing, neck compression, immersion in water); hyperthermia, hypothermia, toxic exposures
 - Infectious: sepsis (bacterial, viral), pneumonia, bronchiolitis, meningitis, myocarditis, pertussis
 - Trauma: accidental and nonaccidental trauma (cranial injuries, abdominal trauma, nonaccidental suffocation, and drowning)
 - Metabolic: electrolyte disturbances, inborn errors of metabolism, especially involving energy production or toxic metabolites (e.g., medium chain acyl-CoA dehydrogenase deficiency, defects in glycogenolysis, defects in oxidative phosphorylation, urea cycle defects, aminoacidopathies, glycogen storage disease)

- Congenital/anatomic: congenital heart disease, Arnold-Chiari malformation, malrotation, volvulus
- Miscellaneous: adrenal insufficiency, cardiac arrhythmias (channelopathies)

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Prevention rather than treatment is the goal. All caregivers of infants should be educated about SIDS risk reduction strategies, ideally before the infant's birth.
- For families who have experienced a SIDS death, grief counseling may be helpful.
- Families who are contemplating a subsequent pregnancy should be offered genetic and metabolic screening to rule out any hereditary conditions that may mimic SIDS. Avoidance of risk factors should be stressed. However, this discussion should be done with sensitivity, as discussion of risk factors may incur feelings of guilt, particularly if risk factors were associated with the infant's death.

CODES

ICD10

R99 III-defined and unknown cause of mortality

FAQ

- Q. What is the difference between SIDS and an undetermined cause of death?
- A. SIDS, which is a subcategory of SUID, is most commonly defined as “the sudden death of an infant under 1 year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and a review of the clinical history” (Willinger et al, 1991). When the cause of death cannot be clearly established (e.g., appears to be SIDS, but death occurred in a sleep environment where accidental suffocation cannot be ruled out), cause of death may be “ill-defined” or “undetermined.”
- Q. Won’t giving a baby a pacifier interfere with breastfeeding?
- A: If a baby is breastfed, there is a theoretical risk of “nipple confusion.” A recent Cochrane Collaboration review on the topic (2012) concluded that “for mothers who are motivated to breastfeed

their infants, pacifier use before or after breastfeeding was established did not significantly affect the prevalence or duration of exclusive and partial breastfeeding up to 4 months of age.” However, long-term data beyond 4 months of age are lacking. If concerned, parents can wait until breastfeeding is well established, usually about 3–4 weeks, before introducing a pacifier.

- Q: Is it okay for a baby to take a nap while lying prone on the parent’s chest?
- A. No. Parents often fall asleep unintentionally, which can result in a hazardous situation. Falling asleep with the baby while on a couch or sofa is particularly dangerous.

SUICIDE

Leonard J. Levine • Jonathan R. Pletcher

BASICS

DESCRIPTION

- Suicidal behavior is a voluntary self-harming act with the intent of ending one's own life.
- Attempted suicide occurs when the act does not result in death (also, failed or near-suicide).
- Suicidal ideation is any thought, with or without a specific plan, to end one's life.
- Suicidality can include suicidal ideation, preparatory acts, and/or attempts.

EPIDEMIOLOGY

- Suicide is the 3rd leading cause of death for adolescents and emerging young adults (10–26 years), whereas it is the 10th overall cause of death for Americans.
- Adolescent mortality from suicide tripled between the 1950s and the 1990s and has remained overall stable since, after declining in 1990s then rising over the past decade.
- Females attempt suicide at a rate 2–4 times that of males and are most likely to attempt suicide through ingestion.
- Males 15–24 years old are 5 times as likely to die by suicide as females and are most likely to use more lethal methods.
- Completed suicide rates are highest in non-Hispanic white (13.9/100,000) and Native American (10.6/100,000) adolescents. Suicide rates for black males 10–19 years old doubled between the years 1980 and 1995.
- Gay, lesbian, bisexual, transgender, and questioning youth report significantly higher rates of suicide thoughts and attempts than their heterosexual peers.
- More than half of all deaths by suicide in the United States involve a firearm.

Incidence

- Annually in the United States, ~2,000 adolescents die from suicide and over a million suicide attempts come to medical attention; there were as many as 11 times the number of attempts as completed suicides.
- Overall, suicide accounted for 10.9 deaths per 100,000 persons aged 15–24 years in 2011.
- In 2013, 17% of youth surveyed in grades 9–12 reported seriously considering suicide at some point in the preceding year: >8% reported attempting suicide in the previous year.

RISK FACTORS

- Previous suicide attempt(s)
- Social isolation
- Substance/alcohol abuse
- Family history of suicide
- Family history of severe mental illness or substance abuse
- Past or present sexual or physical abuse
- Family conflict or disruption
- Presence of firearms in the home

GENERAL PREVENTION

- Universal screening of all adolescents for suicidality should occur in primary and acute care settings.
- Brief, validated screening tools are available for medical settings.
- There is ample evidence that direct inquiry, paper-and-pencil questionnaires, and computer-assisted screening enhance identification.
- Warning signs, aside from obvious emotional distress, can include the following:
 - Chronic physical symptoms, with or without discrete physiologic etiology (e.g., chronic headache, abdominal pain)
 - Change in level of functioning in school, work, or home
 - Changes in mood or affect
- If suicidal ideation is reported, components of risk assessment include the following:
 - Frequency and timing of suicidal thoughts

- Active planning
- Access to lethal means such as firearms
- History of past suicide attempt(s)
- History of mental health problems, including substance abuse, and treatment
- Acute or anticipated psychosocial stressor
- Family history of suicide
- Family violence
- Exploration of coping strategies and social support systems
- Referral or consultation with a psychiatrist or mental health professional is indicated with any question or risk for suicide attempt.

PATHOPHYSIOLOGY

- Decreased central serotonergic activity may result in aggressive or impulsive behaviors, which may be aimed at oneself.
- An underlying psychiatric or personality disorder acutely worsened by a stressful life event may trigger a suicidal act.
- Feelings of isolation and lack of external support can result in hopelessness and limit opportunities for care.
- Suicide may be an impulsive act to express frustration or rage.

ETIOLOGY

Suicidal behavior in adolescents results from the interaction of long-standing individual and family factors, social environment, and acute stressors:

- Diagnostic criteria for psychiatric disorders such as major depressive episode and borderline personality disorder include suicidality (DSM-5).
- Intense emotional state, in particular shame or humiliation, can be “trigger events” for a suicidal act.
- Personality and social factors, such as antisocial behavior, aggressive or impulsive proclivities, and social isolation, can also contribute.

DIAGNOSIS

HISTORY

- The provider should establish a quiet environment with clear discussion of confidentiality and limitations before inquiring about suicidal ideation or attempt.
- If positive, a comprehensive history should always be obtained or reviewed by a trained mental health worker. Components include the following:
 - Sensitively ascertain any planning, including method and timing.
 - Ask factors that could increase lethality of attempt (e.g., number of pills ingested).
 - Circumstances of attempt (e.g., remote site, public display)
 - History of prior attempts
 - Current psychological status (e.g., feelings and/or level of depression, hopelessness, impulsivity, self-esteem)
 - Family consistency and dynamics
 - Pharmaceuticals available at home; what is missing
 - History of interpersonal conflict or loss
 - Family history of suicide
 - History of substance use
 - History of psychological disorder
 - History of abuse, neglect, or incest
 - Social supports and coping strategies
 - Feelings of regret or continued desire for self-harm

PHYSICAL EXAM

- Regardless of ingestion history, closely observe vital signs, skin, mucous membranes, and pupils for evidence of toxidrome.
- Examine skin for signs of physical abuse or self-mutilation, including extremities and torso.
- A complete neurologic examination is essential for the evaluation of intracranial processes, acute mental status changes, and ingestions.

DIAGNOSTIC TESTS & INTERPRETATION

Different laboratories offer different spectra and sensitivities in their toxicology screens.

Lab

- Serum and urine toxicology screens

- Urine pregnancy test: Pregnancy status could be a precipitating factor and, if positive, could affect treatment options.
- Acetaminophen level, as it is highly hepatotoxic and is used frequently by teenagers
- EKG is indicated for ingestions, including antidepressants and benzodiazepines.

Imaging

Abdominal plain film: if history of iron or vitamin ingestion or severe trauma

TREATMENT

MEDICATION

- For recent ingestions, GI decontamination with activated charcoal may be appropriate, as is the administration of pertinent antidotes (e.g., naloxone for opioids, N-acetylcysteine for acetaminophen).
- Although psychotherapy is an essential component to the care of the suicidal ideation, pharmacotherapy with antidepressants can also play a role.
- SSRIs (fluoxetine, sertraline, and citalopram) have been shown to be effective in treating depressive disorders in adolescents. Use of SSRIs in patients with the potential for suicidal behavior requires close monitoring. In general, SSRIs may cause a short-term increase from 1 to 2% in the risk of suicidality in depressed teens.
- Tricyclic antidepressants (TCAs) have high lethality potential. TCAs are not indicated in treating depression in children and adolescents.

ADDITIONAL TREATMENT

General Measures

- Parents and professionals should avoid minimizing attempts as “not serious” or as “just seeking attention.”
- Psychiatric disposition should be determined by, or in conjunction with, a mental health professional. Considerations for admission:
 - Historical factors indicating high risk for repeated attempt
 - Ongoing suicidal ideation and/or planning

- Family instability and lack of support
- Altered mental status
- Lack of alternative interventions (e.g., intensive psychiatric follow-up, day treatment program)
- Medication initiation that has risk for increasing suicidal thoughts (e.g., SSRIs)
- When discharge to a caregiver is being considered, the following minimal criteria should be in place at the time of discharge:
 - The patient reliably expresses regret and denies ongoing suicidal thoughts.
 - The patient is medically stable.
 - The patient’s adult caregiver reports understanding of the seriousness of the attempt and importance of follow-up.
 - The patient and parents agree to contact a health professional or go to the emergency department if suicidal intent recurs. The patient and family should have 24-hour access to mental health or physical health professionals.
 - The patient must not have impaired mental status (e.g., psychoses, delirium).
 - Lethal methods of self-harm are not immediately available to the patient.
 - Follow-up for underlying mental health disorders have been arranged, including a transfer of key information and clear communication of follow-up locations and times with a behavioral health provider accessible to the patient.
 - Acute precipitants and crises have been addressed.
 - Caregivers and patients are in agreement with the discharge plan.
 - Barriers to obtaining follow-up treatment, in particular insurance and social stigma, have been addressed and will not preclude the next step toward ongoing treatment.

ADDITIONAL THERAPIES

In addition to medication, important psychiatric interventions include acute, short-term, inpatient psychiatric hospitalization, partial hospitalization (with intensive treatment and support), and outpatient therapy.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Airway, breathing, circulation (ABCs)
- One-to-one monitoring is typically indicated until formal mental health evaluation is obtained.
- Decontamination of GI tract and circulation is rarely indicated.
- When available, a poison control center or toxicologist will be helpful with evaluation and treatment of most drug ingestions.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Long-term psychotherapy (individual and family therapy) is often needed for adolescents who attempt suicide. Improvement may be slow and punctuated by setbacks.

PROGNOSIS

- 20–50% of those attempting suicide will try again.
- Multiple reports show that a majority of adolescents and young adults who attempt suicide disengage with treatment after a few visits due to a multitude of systemic and societal factors.

COMPLICATIONS

- Long-term organ damage or physical disability, depending on the method used
- Long-lasting emotional sequelae in survivors, resulting from frustration, anger, and guilt
- Repeat suicide attempt or completion

CODES

ICD10

- R45.851 Suicidal ideations
- T14.91 Suicide attempt
- Z91.5 Personal history of self-harm

FAQ

- Q: Should I ever keep suicide attempts or plans confidential?
- A: No. The limits of confidentiality should be clearly outlined to patients and families at the first visit or early in the patient's adolescence. These limits include anything that will directly place the patient's life in danger such as suicidal intent, ongoing or recent abuse, or homicidal intentions.
- Q: If I directly question my patients about suicide, won't that put the idea in their head?
- A: No. In the majority of cases, patients will be relieved by having a professional who wants to talk about suicide. There is only risk in asking if nothing is done with the answer. Appropriate referral to mental health services or counseling will save patients' lives.
- Q: Is a patient who is engaging in self-injurious behavior but denies

suicidal ideation actually suicidal?

- A: Any adolescent who is practicing self-mutilation to cope with emotional distress is at risk of developing additional unhealthy coping behaviors. Furthermore, they are likely suffering from a mood disorder that places them at risk for developing suicidality. There is no evidence to support management of self-injurious behavior as if the patient has a secret agenda.

SUPERIOR MESENTERIC ARTERY SYNDROME

Eric H. Chiou • Kristin L. Van Buren

BASICS

DESCRIPTION

- Superior mesenteric artery (SMA) syndrome is extrinsic compression of the third portion of the duodenum between the SMA and aorta.
- It is also called Wilkie syndrome, cast syndrome, or aortomesenteric duodenal compression syndrome.
- The diagnosis is somewhat controversial because symptoms do not always correlate with radiologic findings and do not always improve following treatment.

EPIDEMIOLOGY

- Rare
- More common in adolescents
- Also seen following corrective scoliosis surgery with a rate of 0.5–2.4%

ETIOLOGY

- The SMA arises from the aorta at the L1 vertebral body level and forms an acute downward aortomesenteric angle that is normally between 35–65 degrees, due in part to the mesenteric fat pad.
- The third portion of the duodenum lies within the aortomesenteric angle, and narrowing of the angle (<25 degrees) can lead to duodenal compression by the SMA anteriorly and the L3 vertebral body posteriorly.
- Any factor that narrows the aortomesenteric angle can cause duodenal compression. Common conditions that predispose to narrowing of this angle are as follows:
 - Illnesses associated with significant weight loss leading to loss of the mesenteric fat pad:
 - Anorexia nervosa, malignancy, spinal cord injury, trauma, or

burns

- Rapid linear growth in children
- Increase in lordosis of the back such as from immobilization by body cast, scoliosis surgery, or prolonged bed rest in a supine position
 - Weight percentile for height of <5% is a risk factor for development of SMA syndrome following scoliosis surgery.
- Variations of the ligament of Treitz: A short ligament lifts the third or fourth part of the duodenum into the narrower segment in the aortomesenteric angle.
- If the left renal vein is also compressed, this can lead to microscopic hematuria, also known as nutcracker syndrome.

DIAGNOSIS

HISTORY

- Clinical presentation can be acute or chronic with gradual, progressive symptoms.
- Symptoms are generally consistent with proximal small bowel obstruction, including the following:
 - Nausea
 - Vomiting (bilious and nonbilious, postprandial)
 - Gastroesophageal reflux
 - Epigastric abdominal pain
 - Eructation
 - Weight loss
 - Early satiety
 - Dehydration
 - Bloating
 - Failure to thrive
- Symptoms may be relieved when patient is lying prone, in left lateral decubitus, or in knee-chest positions.

PHYSICAL EXAM

- Nonspecific findings of small bowel obstruction include the following:

- Abdominal distension
- Succussion splash
- High-pitched bowel sounds
- No pathognomonic signs or symptoms, but a history of weight loss, immobilization, or back surgery followed by symptoms of early satiety, bloating, and vomiting after meals would suggest the diagnosis.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Imaging should show duodenal obstruction with dilated stomach and proximal duodenum, active peristalsis, and a narrow angle between the aorta and the SMA.
- Abdominal radiograph is usually the initial diagnostic imaging test.
 - Findings can be nonspecific but may also reveal suggestive findings of obstruction, including a distended stomach or a dilated proximal duodenum with a sharp cutoff of the third portion of the duodenum where the SMA crosses the duodenum.
- Additional evaluation with upper gastrointestinal (GI) series:
 - Passage of contrast is typically delayed and often stops at the third portion of the duodenum. Contrast passes when the patient is moved to a prone position, where gravity will increase the aortomesenteric angle.
 - Similar findings can be seen with CT.
- Additional imaging may be required if the diagnosis remains unclear.
 - Superior mesenteric arteriography with simultaneous barium contrast radiography to show SMA superimposed on duodenum
 - CT and MR angiography have now replaced superior mesenteric arteriography.
- An aortomesenteric angle <25 degrees is the most useful diagnostic marker, especially if the aortomesenteric distance is <8 mm.
- Determination of the aortomesenteric angle in severe cases may help with decision for surgery.

DIFFERENTIAL DIAGNOSIS

- Causes of small bowel obstruction:
 - Luminal obstruction: foreign body

- Intramural obstruction: duplication cyst, web, tumor, bezoar, stricture
- Extramural obstruction: tumor, annular pancreas, bands, adhesions, volvulus, intussusception
- Duodenal dysmotility
 - Intrinsic neuronal disorder
 - Muscular weakness (holovisceral myopathy, diabetes)
 - Fibrosis (scleroderma, lupus retroperitoneal fibrosis)
 - Collagen vascular diseases
 - Chronic idiopathic intestinal pseudo-obstruction
- Anorexia nervosa/bulimia

TREATMENT

GENERAL MEASURES

- Correct fluid and electrolyte imbalances.
- Decompress obstruction.
 - Insert nasogastric tube to decompress stomach and proximal duodenum.
- Definitive treatment is aimed at correcting the precipitating factor.
- Feed to improve nutrition and weight gain.
 - Feeding in a prone or left lateral decubitus position can help relieve pain but may require a jejunal tube to bypass the obstruction.
 - Total parenteral nutrition may be needed if cannot tolerate enteral nutrition.
- If a patient had recent spinal surgery:
 - Frequent repositioning of patients in body casts
 - Reversal of back surgery may be necessary in some patients.
- Surgery is typically unnecessary.
 - Surgery is indicated only if supportive care is ineffective.
 - Usually performed in patients with a prolonged history of weight loss or pronounced duodenal dilation
 - Surgical options include duodenojejunostomy, gastrojejunostomy, or Strong procedure (mobilization of duodenum by dividing the ligament of Treitz).

- Consider psychiatric evaluation if eating disorder suspected.

ONGOING CARE

PROGNOSIS

- Delay in diagnosis of SMA syndrome can result in the following:
 - Electrolyte disturbances
 - Dehydration and malnutrition
 - In severe cases, possible GI pneumatosis, perforation, formation of a duodenal bezoar, or death
- Most patients do not require surgery and improve with supportive care alone.

K55.1 Chronic vascular disorders of intestine

FAQ

- Q: When the diagnosis of SMA syndrome is suspected, what are the next steps in management?
- A: The general sequence is to confirm the diagnosis with an imaging study such as an upper GI contrast study and also to initiate supportive care of refeeding and mobilization.
- Q: The following treatment modalities are known to be useful in treatment of SMA syndrome: do nothing, or feed with a jejunal tube, a liquid diet, prone feeding, or total parenteral nutrition. Which program works?
- A: All of the above have been used in SMA syndrome. Weight gain has also been accomplished with total parenteral nutrition.
- Q: Does radiographic testing or a feeding clinical trial help in confirming the diagnosis?
- A: Yes. It may be helpful to confirm the diagnosis and look at the aortomesenteric angle with a CT or MR angiography. In addition, a clinical trial of feeding and weight gain often becomes the criterion for confirmation of the diagnosis.

SUPRAVENTRICULAR TACHYCARDIA

Francesca A. Byrne

BASICS

DESCRIPTION

- The term supraventricular tachycardia (SVT) is generally used to refer to atrioventricular nodal reentry tachycardia (AVNRT), atrioventricular reciprocating tachycardia (AVRT), and atrial tachycardia (AT) but includes any tachycardia originating at or above the atrioventricular (AV) node.
- The heart rate in SVT in infants generally ranges from 220 to 320 beats per minute (bpm) and in older children from 150 to 250 bpm.

EPIDEMIOLOGY

- SVT is the most common arrhythmia in childhood.
- Incidence of SVT is 35 per 100,000 per year.
- Incidence of SVT among patients with Wolff-Parkinson-White syndrome (WPW) is about 1% per year.
- Prevalence of SVT is 1 in 250–25,000 children.
- AVRT is the most common type of SVT in children, occurring in ~75% of cases.
- AVNRT rarely occurs before age 2 years.
- 50–60% of pediatric patients with SVT present in the 1st year of life.

RISK FACTORS

- Most children with SVT have structurally normal hearts; however, children with congenital heart disease (CHD) have an increased risk of SVT.
- SVT is commonly observed in patients who have undergone surgery for CHD, for example, after the Mustard/Senning procedure, the Fontan operation, and repair of an atrial septal defect.

Genetics

- WPW syndrome has been noted in several families, and an autosomal dominant (AD) mode of inheritance has been demonstrated:

- ~20% of cases of WPW have associated CHD, such as Ebstein anomaly, L-looped transposition of the great arteries, and hypertrophic cardiomyopathy.
- Many patients with the WPW pattern on electrocardiogram (ECG) do not develop SVT; when episodes of SVT do occur, the patient has WPW syndrome.
- ~50% of the cases of junctional ectopic tachycardia (JET) occur in a familial setting with an AD mode of inheritance.

PATHOPHYSIOLOGY

There are 2 major mechanisms for SVT:

- Reentry tachycardia: This is the most common mechanism for SVT. It involves a circuit rhythm within the atria (atrial flutter), within the AV node (AVNRT), or using an accessory pathway (AVRT); characterized by sudden onset and termination, regular rate, and responsiveness to pacing maneuvers and DC cardioversion
- Automatic tachycardia: Automaticity refers to a group of cell's enhanced ability to spontaneously depolarize, which can overdrive suppress the sinus node. Examples are ectopic atrial tachycardia, multifocal atrial tachycardia, and JET; characterized by warm-up and cool-down phases, an irregular rate that is sensitive to catecholamine states, and lack of responsiveness to pacing and cardioversion

ETIOLOGY

SVT can frequently be precipitated by exercise, infection, fever, or drug exposure.

DIAGNOSIS

HISTORY

- Infants manifest signs and symptoms of low cardiac output and congestive heart failure (CHF) with prolonged SVT (>48 hours): tachypnea, retractions, irritability, decreased feeding, excessive sweating, hypotension, poor perfusion, and decreased urine output.
- A toddler or older child may experience palpitations, shortness of breath, chest pain, anxiety, and dizziness or syncope:

- It is important to know what the child was doing at the time the arrhythmia started and whether there is an abrupt onset and termination.
- Older children often report being able to terminate episodes of tachycardia by performing a vagal maneuver.

PHYSICAL EXAM

The following need to be assessed in all patients presenting with SVT:

- Heart rate and regularity
- Respiratory rate
- Blood pressure
- Hydration status
- Peripheral perfusion
- Liver size
- Mental status
- Presence of gallop rhythm

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

Initial approach

- Chest radiograph to assess for pulmonary edema and cardiomegaly
- Echocardiogram to assess underlying cardiac anatomy and ventricular function

Follow-Up Tests & Special Considerations

Repeat imaging may be warranted if there are initial abnormalities.

Diagnostic Procedures/Other

- Outpatient: Diagnosis can be made with a 24-hour or transtelephonic event monitor.
- Inpatient
 - 15-lead ECG during SVT if patient is hemodynamically stable
 - Continuous ECG monitoring during therapeutic maneuvers can aid in diagnosis.
- Patients with WPW pattern have ventricular preexcitation (short PR interval and a delta wave) on the ECG during sinus rhythm.
- An exercise stress test may be indicated in older patients with exercise-induced SVT or those with WPW syndrome to help determine the risk

of rapid conduction through the accessory pathway.

- Electrophysiologic study is often performed to evaluate drug effect or to map in conjunction with catheter ablation.
- Nonpharmacologic maneuvers (ice, vagal) and pharmacologic maneuvers (IV adenosine) may distinguish tachycardias that involve the AV node from other types of SVT.

DIFFERENTIAL DIAGNOSIS

- Narrow-complex SVT needs to be distinguished from sinus rhythm and sick sinus syndrome with tachyarrhythmia.
- Structural heart disease should be excluded in all cases of newly diagnosed SVT.
- Wide-complex tachycardia can occur in the setting of SVT with bundle branch block or aberrant conduction, antegrade conduction down an accessory pathway, or preexcited atrial flutter/fibrillation in WPW. This can be difficult to distinguish from ventricular tachycardia. Unless it is known that the patient has SVT, wide-complex tachycardia should always be interpreted as ventricular tachycardia until proven otherwise.
- Differentiating between types of SVT can be accomplished by evaluating the regularity of the rate, modes of onset/termination, and the responsiveness to pacing and cardioversion.

TREATMENT

GENERAL MEASURES

- Short-term treatment goals are to terminate the tachycardia.
 - Nonpharmacologic vagal maneuvers; for example, ice to the face for 15–30 seconds, rectal stimulation, Valsalva, gag, and headstand may be helpful. In younger children, Valsalva can be achieved by having the child blow into an obstructed straw or thumb. Pacing maneuvers via an esophageal catheter may also be used. Carotid massage and orbital pressure should not be performed in children.
 - In a stable child, adenosine (rapid IV bolus, 0.1 mg/kg and increase by 0.1 mg/kg to a maximum of 0.3 mg/kg up to 12 mg) may be used to block the AV node for reentrant SVT that requires the AV node.

The half-life of the drug is <10 seconds. Because of the risk of atrial fibrillation, DC cardioversion should be available. Use adenosine with caution in asthmatic patients, as it can cause acute bronchospasm.

- IV verapamil is an effective therapy in older children with SVT but should be avoided in children <12 months of age because of its vasodilatory and negative inotropic effect.
- Unstable patients with hemodynamic compromise warrant termination with synchronized DC cardioversion (0.5–2.0 J/kg).
- Long-term treatment goals are to reduce the frequency of episodes of SVT. Long-term treatment may not be necessary when the episodes are infrequent, self-terminating, or produce minimal symptoms.
- Catheter ablation using radiofrequency energy or cryoenergy is an alternative to long-term drug therapy and is 1st-line therapy in the following scenarios:
 - SVT refractory to medical therapy
 - Side effects from the medical regimen
 - Patient choice due to frequency, duration, or poor quality of life
 - Life-threatening arrhythmias (syncope)
 - Rapid conduction properties of an accessory pathway (e.g., WPW)
 - Congenital or acquired heart disease

MEDICATION

- Long-term preventive pharmacotherapy is an alternative approach in some patients
- Reentrant SVT
 - β -Blockers (propranolol or atenolol) are 1st-line treatment in individuals with WPW and patients with exercise-induced SVT.
 - Procainamide and amiodarone may be used in cases that are more resistant.
 - Oral digoxin is an option in patients with hemodynamically stable SVT. Digoxin is contraindicated in patients with WPW.
 - Atrial flutter may be treated with digoxin, procainamide, sotalol, or amiodarone as a single agent or in combination.
- Automatic SVT: Automatic tachycardias may be responsive to antiarrhythmics such as procainamide, flecainide (avoid if the patient

has structural heart disease), amiodarone, or β -blockers either alone or in different combinations.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Always assess the child's ABCs (airway, breathing, and circulation).
- Initial management of SVT depends on the child's hemodynamic condition.

Admission Criteria

- Hemodynamically unstable SVT requiring electrical cardioversion
- Tachycardia-induced cardiomyopathy

ONGOING CARE

PROGNOSIS

- Of patients who present in infancy, 30–70% will be asymptomatic by 1 year of age. However, ~1/3 of these patients may experience a reappearance of their tachycardia at an average age of 8 years.
- Most older children who present with SVT will have persistent recurrence of SVT.

FOLLOW-UP RECOMMENDATIONS

- As SVT may recur, neonates and infants have historically received maintenance therapy for the 1st year of life and then been observed off medications if they are not having breakthrough episodes of SVT. This approach has recently been challenged, and studies evaluating the ideal duration for maintenance therapy in the neonate and infant are being proposed.
- In children who present beyond infancy, spontaneous resolution of the tachycardia substrate is less likely, and treatment may need to be continued into adulthood. These patients may be considered for catheter ablation therapy.
- Over-the-counter sympathomimetic cold medications and caffeine should be avoided, as they may increase the likelihood of SVT.

COMPLICATIONS

Complications from SVT can arise from 1 of 3 causes:

- Persistent tachycardia can lead to CHF, tachycardia-induced cardiomyopathy, and cardiovascular collapse. This is especially true of the infant whose symptoms go unrecognized for 24–48 hours.
- Some patients with WPW syndrome (<5%) can have rapid conduction through the accessory pathway. A rapid ventricular response to atrial flutter/fibrillation can potentially cause ventricular fibrillation and sudden death. Therefore, digoxin and verapamil should not be used in patients with WPW syndrome.
- Side effects of pharmacologic agents used to treat SVT include bradycardia, other arrhythmias due to proarrhythmic effects (digoxin, procainamide, amiodarone, flecainide), and noncardiac side effects (GI, liver, pulmonary, and thyroid dysfunction).

I47.1 Supraventricular tachycardia

FAQ

- Q: How should infants on chronic therapy be monitored?
- A: Parents with infants on chronic therapy for SVT should be educated about counting the heart rate by palpation or auscultation at least 1 or 2 times daily. This method of surveillance is just as effective as apnea/bradycardia monitors. Because alarm monitors can increase parental anxiety with frequent false alarms, they are generally not recommended. Patients on amiodarone should be monitored with liver function tests and thyroid function tests at baseline and every 3–6 months.
- Q: What is the concern with verapamil?
- A: Verapamil is an L-type calcium channel blocker that blocks conduction in the AV node and is very effective in treating SVT in adults. Because myocardial contractility in infants depends mostly on the trans-sarcolemmal L-type calcium channels, hypotension and cardiovascular collapse have been reported in children <1 year of age.
- Q: What are success rates and risks of catheter ablation?
- A: The success rate of radiofrequency catheter ablation varies from 80 to 97%, depending on the location of the bypass tract or ectopic focus. The incidence of major complications is <2%, with the most common being heart block requiring a pacemaker, cardiac perforation, brachial plexus injury, and embolization. The risk of complete heart block is greater in patients whose accessory pathway is located close to the AV node. In such patients, cryoablation is a safer ablation technique because of its potentially reversible electrical and thermal effect.

SYMPATHOMIMETIC POISONING

Robert J. Hoffman • Richard Loffhagen

BASICS

DESCRIPTION

- Excess autonomic stimulation by adrenergic agents produces the clinical syndrome typically described as “sympathomimetic.”
- Overdose from sympathomimetic agents occurs secondary to the use of prescription drugs, nonprescription drugs such as OTC cold medicine (e.g., pseudoephedrine), dietary supplements (e.g., ephedra, synephrine), and illicit drugs such as cocaine, amphetamine, and methamphetamine.
- A more recent trend is the use of mephedrone and methylenedioxypyrovalerone (MDPV) among others are sold legally under the guise of “bath salts.”
- The sequelae of sympathomimetic overdose are generally related to the neurologic and cardiovascular systems.
- Severe problems may include agitation-induced hyperthermia, cardiac dysrhythmia, hypertension, myocardial ischemia, and infarction; CVA; seizure; and cardiovascular collapse.
- Bath salts appear to be associated with a much higher incidence of psychotic events than other sympathomimetics.
- A number of potent amphetamine analogs, such as paramethoxymethamphetamine (PMA), which have a high incidence of morbidity and mortality, are increasingly common components of tablets sold as MDMA.

EPIDEMIOLOGY

- Cocaine, methamphetamine, and MDMA (commonly called “Molly” or “ecstasy”) are the 3 most common illicit stimulant drugs causing emergency visits in the United States.
- Prescription stimulants such as methylphenidate and albuterol are often frequent causes of intentional as well as unintentional poisoning.

PATHOPHYSIOLOGY

- Relevant pathophysiology is based on the adrenergic receptor type stimulated by the drug in question. The adrenergic receptors of relevance include α_1 , β_1 , and β_2 receptors.
- Ephedrine and pseudoephedrine stimulate both α and β receptors:
 - Excessive cardiovascular stimulation results in symptoms qualitatively similar to those that occur with catecholamines.
 - Ephedrine and pseudoephedrine have weaker penetration of the CNS relative to drugs of abuse.
 - As a result, users may suffer from systemic complications of the relatively larger doses necessary to achieve the CNS “high” of other stimulants.
- Nonelective β -adrenergic agonists
- Isoproterenol, rarely used, is the prototypical nonselective β -agonist causing the following:
 - Tachycardia, hypotension, tachydysrhythmia, myocardial ischemia, and flushing due to its cardiostimulatory and vasodilatory properties
 - Commonly, CNS effects of anxiety, fear, and headache occur.
- Selective β_2 -adrenergic agonists are commonly used, and these include albuterol, levalbuterol, salmeterol, terbutaline, and others.
- Common adverse effects include the following:
 - Tachycardia, palpitations, and tremor
 - Hypotension, often with widened pulse pressure
 - Nausea, vomiting, and sometimes diarrhea
 - Hyperglycemia and hypokalemia
 - Elevation of CPK as well as troponin, although myocardial infarction is never expected to occur in otherwise healthy children with selective β_2 agonist exposure
 - Anxiety, fear, and headache also may occur.
- α_1 Selective agonists include phenylephrine and phenylpropanolamine, although the latter is no longer commercially produced in any meaningful quantity in the United States.
 - Hypertension due to direct vasoconstrictive effects is the most common effect.
 - Reflex bradycardia may occur, particularly with

phenylpropanolamine.

- Headache due to elevated BP and even CVA may occur.

ETIOLOGY

Causative agents:

- Agents with combined α - and β -adrenergic activity: epinephrine, norepinephrine, dopamine, ephedrine, and pseudoephedrine
- α 1-Adrenergic agonists: phenylephrine, phenylpropanolamine
- β -adrenergic agonists: nonselective β -agonist isoproterenol
- Selective β 1 agonists: dobutamine
- Selective β 2 agonists: albuterol, salmeterol, terbutaline, ritodrine
- OTC agents: ephedrine-containing cold medicine, ephedra, Ma Huang
- Illicit drugs: cocaine, amphetamine, methamphetamine, MDMA (ecstasy), MDPV (bath salts)
- Theophylline and caffeine may cause a clinical syndrome of sympathomimetic poisoning.

COMMONLY ASSOCIATED CONDITIONS

- Many sympathomimetic agents are capable of producing psychiatric symptoms, particularly psychosis.
- This psychosis is similar to or indistinguishable from schizophrenia.
- 2 rare results of MDMA use include serotonin syndrome and SIADH with symptomatic hyponatremia.

DIAGNOSIS

SIGNS AND SYMPTOMS

- The clinical effects of these agents' overdose vary based on their receptor selectivity.
- Most agents have some degree of combined α - and β -adrenergic activity (ephedrine, pseudoephedrine).
 - Hypertension, tachycardia, dysrhythmia, acute coronary syndromes, pulmonary edema and cerebrovascular injury, anxiety, a sense of impending doom, apprehension, fear, and headache may occur.
 - At very high doses, agents cross the blood–brain barrier, which results in CNS symptoms, such as headache, seizures, and

intracranial hemorrhage.

HISTORY

- History of exposure may be helpful but is often unavailable or deliberately concealed, particularly use of illicit drugs such as cocaine, methamphetamine, and ecstasy.
- Use of OTC medicines, such as multisymptom cold preparations or dietary supplements
- High suspicion of sympathomimetic overdose especially in patients with the sympathomimetic toxidrome
- The onset of symptoms usually occurs within 1 hour.
 - Typically, prescription and OTC sympathomimetic agents are inhaled or orally administered.
 - Inhalation or injection results in immediate symptoms.
 - Cocaine, amphetamine, and methamphetamine or the sympathomimetics are most commonly used in this manner.
 - Sympathomimetic toxicity following ingestion typically peaks 1–4 hours and last 4–8 hours, but sustained-release preparations may alter this time course.
- Chest pain due to dysrhythmia, myocardial ischemia, infarction, etc. may be a complaint.
- Headache, visual changes, epistaxis

PHYSICAL EXAM

Sympathomimetic toxicity is a clinical diagnosis.

- Vital sign derangement is the most common and most reliable indicator of toxicity.
- Mental status changes are also common although less reliable as they do not occur with the same regularity and may be the result of toxicologic or psychiatric phenomenon.
- The patient's general appearance (e.g., agitation, diaphoretic, delirium, psychotic) is often suggestive of toxicity.
- HEENT: mydriasis, visual changes, epistaxis, poor dentition
- Tachycardia and hypertension are the most common vital sign abnormalities.
- Skin: diaphoresis, flushing, the track marks associated with IV drug

use

- CNS: Focal neurologic findings may occur. Focal cranial nerve abnormalities are particularly concerning for the possibility of CVA. CNS stimulation or agitation is very common.

DIAGNOSTIC TESTS & INTERPRETATION

- Sympathomimetic overdose is a clinical diagnosis and assays are only adjunctive.
- Unless there are specific forensic indications, such as malicious poisoning or child abuse, drugs of abuse screening is not recommended and is not useful.
- Serum acetaminophen level should be considered in patients with ingestion with intent of self-harm.
- The measurement of electrolytes, BUN, creatinine, and blood sugar may be useful.
- Cardiac markers (e.g., CPK-MB, troponin) are appropriate to screen for cardiac injury.
- An EKG should be obtained to assess for ischemia as well as dysrhythmias.

Imaging

A noncontrast head CT should be obtained in unresponsive patients or those with focal neurologic deficits.

DIFFERENTIAL DIAGNOSIS

- Hyperthyroidism/thyroid storm
- Anticholinergic syndrome
- Pheochromocytoma
- Withdrawal syndromes
- Mania
- Subarachnoid hemorrhage
- Serotonin syndrome
- Neuroleptic malignant syndrome
- Other situations of increased endogenous catecholamine release

TREATMENT

INITIAL STABILIZATION

Managing ABCs should be addressed first, but sympathomimetic toxicity usually does not result in illness requiring any specific airway, breathing, or circulation issues.

GENERAL MEASURES

Maintaining vital signs within acceptable limits and controlling patient agitation are commonly required.

- Managing ABCs is paramount.
- If protocol permits, sedation of agitated patients with a benzodiazepine may be appropriate.
- Use of benzodiazepines is helpful to address both cardiovascular stimulation as well as psychomotor agitation.
- Use of specific cardiovascular medications may be needed.
- Use of antipsychotics, such as haloperidol or droperidol, is relatively contraindicated both because these medications may lower seizure threshold, impair heat dissipation, and increase risk of cardiac dysrhythmia.

SPECIAL THERAPY

- Severe hyperthermia should be treated with active cooling.
- Patients with core temperature of $\geq 107^{\circ}\text{F}$ should be placed in an ice bath and have core temperature monitored.

IV Fluids

- Unless there is a contraindication, at least maintenance IV fluid should be administered.
- IV fluids may protect against rhabdomyolysis as well as potential dehydration that may occur with stimulant exposure.

MEDICATION

Agitation, vasoconstrictive effects, chronotropic and inotropic effects, and psychomotor agitation are the most common issues requiring medication therapy for sympathomimetic toxicity.

First Line

- Psychomotor agitation may be managed with benzodiazepines.
- The quantity of benzodiazepine required will directly depend on degree

of adrenergic stimulation.

- In some cases, large doses may be required for sedation.
 - Lorazepam in doses of 0.1 mg/kg IV q15min titrated to effect is preferred due to predictable duration of action.
 - Diazepam 0.1 mg/kg IV q15min titrated to effect may also be used.
- Vasoconstrictive effects may be managed with a variety of medications.
 - Phentolamine 0.1 mg/kg/dose (up to 5 mg/dose) IV repeated q10min PRN
 - A dihydropyridine calcium channel blocker, such as nifedipine or amlodipine, may be used.
 - Sodium nitroprusside 0.3–10 mcg/kg/min IV, titrated to effect
- Chronotropic and inotropic effects may be managed with conduction-modulating calcium channel blockers such as diltiazem or verapamil.

Second Line

- A β -blocker may be used only if an α -adrenergic antagonist is concomitantly administered.
- Use of a β -blocker without α -adrenergic blockade may result in paradoxical increase in BP and death.
 - Labetalol has some α -adrenergic blockade and may be used alone as a 2nd-line agent: 0.2–0.5 mg/kg/dose IV, maximal dose 20 mg, followed by infusion of 0.25–1 mg/kg/h
 - Esmolol 500 mcg/kg IV bolus over 1 minute followed by infusion 50 mcg/kg/min titrated to effect up to 500 mcg/kg/min
- Severe cardiovascular symptoms resulting from β -agonists or methylxanthines such as theophylline or caffeine may be treated with a β -blocker.
 - This treatment may seem counterintuitive in the management of hypotension.
 - Severe β_2 agonist effects resulting in hypotension may be counteracted by using a β -blocker.
 - Such therapy should only be undertaken under the direction of a medical toxicologist, intensivist, or other clinician familiar with and experienced with use of such cardiovascular medications.

ONGOING CARE

Admission Criteria

Any patient with severely deranged vital signs, end organ manifestations such as chest pain, severe headache, focal neurologic deficit, or agitation should be admitted.

Discharge Criteria

Any patient with vital signs within safe limits, normal mental status, and no evidence of end organ damage or manifestations may be discharged from the emergency department or inpatient unit.

PROGNOSIS

If end organ damage such as myocardial infarction or CVA are prevented, prognosis for full recovery to premorbid status is excellent.

COMPLICATIONS

The most common catastrophic complications are cardiovascular, including dysrhythmia, myocardial infarction, and CVA.

SYNCOPE

Nancy Drucker

BASICS

DESCRIPTION

Transient loss of consciousness, typically lasting no longer than 1–2 minutes, due to a transient drop in cerebral perfusion pressure

GENERAL PREVENTION

- Avoiding circumstances predisposing to the most common form of syncope (vasovagal)
- Sitting or lying down when warning signs occur
- Maintaining adequate hydration, especially during illness/exertion

PATHOPHYSIOLOGY

Most common mechanism is vasovagal or neurocardiogenic, in which a variety of stimuli and conditions—pain, dehydrated state, emotional upset, carotid pressure—trigger increased vagal tone, leading to slowed heart rate, peripheral vasodilatation, and decreased cerebral perfusion.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cardiac
 - Congenital heart defect, myocarditis, cardiomyopathy, coronary artery anomaly, heart block (congenital or acquired complete heart block, status post cardiac surgery), arrhythmia secondary to long QT syndrome, Brugada syndrome, arrhythmogenic right ventricular dysplasia, catecholaminergic polymorphic ventricular tachycardia, Wolff-Parkinson-White syndrome. Syncope due to an arrhythmia may be familial and may occur as unprovoked syncope or as exercise-induced syncope that may resemble an epileptic convulsion.
- Neurologic

- Migraines (predisposed to orthostatic intolerance); arteriovenous malformation; pulmonary hypertension; intracranial hypertension due to hydrocephalus, mass, pseudotumor
- Pulmonary
 - Pulmonary hypertension
- Other
 - Medications/toxins
- Other causes of syncope by age group include the following:
 - Toddlers
 - Pallid or cyanotic breath-holding spells; these occur in response to pain, fear, excitement, or frustration, begin with a deep inspiration or exhalation, although the precipitating “gasp” may not be apparent (iron deficiency may be associated). A history of pallid breath-holding spells is not uncommon in adolescents with vasovagal syncope.
 - Older children
 - Situational syncope: venipuncture, defecation, hair brushing, stretching
 - Dysautonomia, orthostatic hypotension
 - Dehydration
 - Adrenal insufficiency
- Syncopal spells in children may be accompanied by a convulsion (nonepileptic) that usually lasts <1 minute (EEG shows normal findings or slowing, not epileptiform activity).
- Alternative causes of loss of consciousness not due to syncope include the following:
 - Head trauma
 - Epilepsy (“temporal lobe syncope”)
 - Psychogenic
 - Stroke
 - Hypoglycemia (rare except in certain metabolic disorders)

HISTORY

- **Question:** Detailed history of the spell (focus on signs/symptoms prior to the event)?
- **Significance:** Most important information used to distinguish syncope

from seizure or head trauma

- **Question:** The child or observers may recall “presyncopal” signs?
- **Significance:** Often present in patients with benign syncope—such as warmth, diaphoresis, light-headedness, nausea, palpitations, auditory, or visual changes—all lasting only a few seconds before loss of consciousness
- **Question:** Family history?
- **Significance:** Obtaining a careful history is essential. Family history of sudden unexpected death, seizures, syncope, cardiomyopathy, or arrhythmias especially at younger ages or requiring pacemaker/implantable defibrillator should trigger further testing and investigation.
- **Question:** Syncope during exercise or without warning?
- **Significance:** May indicate an underlying arrhythmia
- **Question:** Generalized tonic–clonic movements?
- **Significance:** May occur with syncope—presyncopal signs point to the nonepileptic nature of the event
- **Question:** Increasing duration of unconsciousness?
- **Significance:** Suggests increasing probability that the event is epileptic rather than syncope
 - Caution: Syncope may be associated with a convulsion in a patient with epilepsy.
 - Epilepsy may rarely mimic a syncopal episode or recurrent presyncopal symptoms; temporal lobe syncope seems to occur principally in adults or adolescents.
- **Question:** Details of body position, eye movements, and respiratory pattern?
- **Significance:** May help determine etiology
- **Question:** Carbon monoxide poisoning?
- **Significance:** May cause syncope-like spells; ask about potential exposure

PHYSICAL EXAM

Key findings to document include the following:

- Vital signs with orthostatic pulse and BP changes
- 4-extremity BP

- Pulses in arm and leg
- Funduscopy: possible papilledema
- Cranial bruits
- Precordial thrill
- Heart sounds (gallop, click, rub, significant murmur)

DIAGNOSTIC TESTS & INTERPRETATION

Often, only a thorough physical exam, detailed history, and family history are needed if findings are consistent with vasovagal syncope.

- **Test:** EKG and cardiac consultation
- **Significance:** If the event is suspected to be symptomatic of a heart condition or there is a concerning history/family history, an EKG and cardiac consultation may be indicated.
- **Test:** Treadmill EKG, Holter monitoring, echocardiogram, EEG, MRI (Chiari malformation)
- **Significance:** Children with unexplained syncope may undergo more extensive testing.
- **Test:** Glucose, CBC, blood gases, spinal tap
- **Significance:** Laboratory testing may be appropriate based on clinical suspicion of underlying causes.

ALERT

Pitfall: Recurrent syncope due to prolonged QT interval may be missed on routine EKG; prolongation of QT interval may only be noted on treadmill testing or cardiac monitoring.

TREATMENT

MEDICATION

- Medications are not usually necessary; however, in more extreme clinical presentation, patients may benefit from:
- Midodrine (midodrine hydrochloride): Adult dosing is 10 mg orally, 3 times daily. Dosing should take place during the daytime hours when the patient needs to be upright, pursuing the activities of daily living. A suggested dosing schedule of approximately 4-hour intervals is as follows: shortly before or upon arising in the morning, midday, and

late afternoon (not later than 6 p.m.).

ADDITIONAL TREATMENT

General Measures

- Clinical intervention is aimed primarily at training the patient in prevention/anticipation:
 - Avoiding circumstances predisposing to the most common form of syncope (vasovagal)
 - Sitting or lying down when warning signs occur
 - Maintaining adequate hydration, especially during illness/exertion
 - Support stockings may be beneficial.
- Therapy is otherwise addressed to underlying causes, in the unusual circumstance that one is found.
- Syncope during exercise always warrants a cardiovascular evaluation, with EKG as initial step.

ONGOING CARE

- Many children experience a developmental stage in which for unknown reasons they have frequent vasovagal episodes. Most common age group is adolescents; however, syncopal spells may continue through adulthood.
- Persistent and frequent spells may prompt more extensive laboratory testing, as described earlier.

CODES

ICD10

R55 Syncope and collapse

FAQ

- Q: What limitations in activity are appropriate for children with recurrent syncope who have normal heart structure and function?
- A: Precautions should be taken similar to those for children of similar age who have epilepsy—closely monitored water recreation and restrictions on climbing; however, most children with recurrent syncope do not experience spells in the midst of vigorous activity and do warrant activity restrictions.
- Q: Do breath-holding spells cause brain damage?
- A: Pallid breath-holding spells appear to be uniformly benign; in rare cases, older children with cyanotic breath-holding spells have had

neurologic sequelae of recurrent hypoxemia.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Todd D. Nebesio

BASICS

DESCRIPTION

Inappropriate secretion of antidiuretic hormone (ADH) or ADH-like peptide in the presence of low serum sodium, low serum osmolality, and high urine osmolality and in the absence of renal, adrenal, or thyroid pathology

EPIDEMIOLOGY

Incidence

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) can occur at any age. Its incidence depends on the various possible etiologies.

RISK FACTORS

Genetics

Genetic causes of SIADH are exceedingly rare. However, rare cases have been described with gain-of-function mutations in the vasopressin-2 receptor contributing to SIADH and undetectable serum ADH levels.

PATHOPHYSIOLOGY

- ADH is synthesized within the neurons of the hypothalamus, transported in conjunction with neurophysin down the supraopticohypophyseal tract, and stored in the posterior pituitary.
- ADH acts on the renal collecting ducts.
- Interaction of ADH with its receptors forms intracellular cyclic AMP (cAMP), which increases water permeability through insertion of aquaporins (water channels) in renal collecting ducts and consequently enhances reabsorption of free water.
- SIADH results when elevated concentrations of ADH or ADH-like peptides cause free water retention and hypervolemia, leading to

hyponatremia. Three possible mechanisms include

- Increased hypothalamic production of ADH (e.g., CNS disorders such as stroke or meningitis)
- Independent production of ADH or ADH-like substances from ectopic sources (e.g., lung oat cell carcinoma or olfactory neuroblastoma)
- Decreased venous return that stimulates atrial volume receptors and thereby leads to ADH release (e.g., heart failure, cirrhosis, pulmonary and intrathoracic diseases, such as tuberculosis).

ETIOLOGY

- Idiopathic
- CNS pathology, causing increased secretion of ADH or ADH-like peptides: meningitis, head trauma, neurosurgical procedures, encephalitis, brain tumor, brain abscess, hydrocephalus, hypoxia, subarachnoid hemorrhage, cerebral venous thrombosis
- Ectopic production of ADH or ADH-like peptides: oat cell carcinoma of the lung, bronchogenic carcinoma, olfactory neuroblastoma, and pancreatic carcinoma
- Pulmonary disease (leading to secondary elevation in ADH secretion or ADH-like peptides): tuberculosis, viral or bacterial pneumonia, asthma, cystic fibrosis, pneumothorax, positive pressure ventilation
- Drugs (which mimic ADH or stimulate its release): vincristine, cyclophosphamide, carbamazepine, chlorpropamide, phenothiazines, clofibrate, nicotine, SSRIs
- Iatrogenic exogenous administration of ADH: vasopressin infusion for treatment of diabetes insipidus, excess desmopressin (DDAVP) in conjunction with fluid intake
- Severe, prolonged nausea
- Postoperative patient (e.g., as part of triple-phase response after hypothalamic-pituitary surgery, after transsphenoidal pituitary surgery)
- Rocky Mountain spotted fever

DIAGNOSIS

HISTORY

- Unusual water intake (suspicious for psychogenic polydipsia)
- Review of intake and output for inpatients
- Decreased urine output
- Anorexia, lethargy
- Weight gain or weight loss
- Renal disease
- Vomiting
- Diarrhea
- Use of diuretics
- Burns
- Heart disease
- Liver disease
- Brain injury: trauma, surgery, hypoxia, toxin

PHYSICAL EXAM

- A complete neurologic and physical exam must be performed. Classically, patients with SIADH manifest subtle signs of hypervolemia but without increased urine output.
- With or without edema
- No signs of dehydration
- Signs of fluid overload
- Absent hyperpigmentation of skin creases/gums (presence suggests Addison disease)
- Hyponatremia; may cause lethargy or irritability and muscle cramps. In severe cases, patients may lose deep tendon reflexes, seize, or be comatose.

ALERT

- Pitfall: Failure to distinguish SIADH from other causes of hyponatremia such as adrenal insufficiency, hypothyroidism, or cerebral salt wasting (CSW) can result in erroneous medical management and lead to worsening hyponatremia.
- Patients with SIADH are still capable of producing urine; basing the diagnosis on urine volume alone can be misleading.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Specific tests
 - Simultaneous urinary osmolality, serum osmolality, and serum sodium (order a basic metabolic panel)
 - Urine sodium: usually >30 mmol/L (but not usually >100 mmol/L)
 - Serum uric acid: sometimes low in SIADH
 - Presence of hyponatremia (serum sodium <130 mEq/L), decreased serum osmolality (<260 mOsm/kg), with an inappropriately elevated urinary osmolality (>260 mOsm/L)
 - Plasma ADH concentration: diagnostic but not helpful for rapid diagnosis
- Nonspecific tests
 - Fractional renal excretion of sodium: Net sodium loss is normal or elevated and depends on sodium intake.
 - Urinary specific gravity: helpful but not as specific as urine osmolality
 - Blood glucose: Hyperglycemia results in hypertonic hypernatremia (benign).
 - Triglycerides: Hyperlipidemia causes hypertonic hypernatremia (benign).

Imaging

Head MRI with special cuts of the pituitary and hypothalamus if concern of CNS etiology.

DIFFERENTIAL DIAGNOSIS

- Hypovolemic hyponatremia (e.g., hyponatremic dehydration, seen after running a marathon)
- Euvolemic hyponatremia (e.g., hypothyroidism, adrenal insufficiency)
- Hypervolemic hyponatremia (e.g., CHF, cirrhosis, nephrotic syndrome)
- Diuretics
- Total body sodium loss through vomiting, nasogastric suction, diarrhea, or increased intestinal secretions
- Renal failure
- Severe potassium depletion
- Water intoxication

- CSW: excess production or effects of atrial and/or brain natriuretic peptide hormones
- Reset hypothalamic osmostat
- Rocky Mountain spotted fever
- Hypertonic hyponatremia (sometimes called “pseudohyponatremia,” although blood sodium is low with normal total body sodium stores) with hyperglycemia (diabetic ketoacidosis), severe hyperlipidemia, or after administration of mannitol

TREATMENT

MEDICATION

- For emergency use only: hypertonic saline (1.5–3% NaCl)
- Diuretics should be avoided because they worsen hyponatremia.
- ADH antagonists, such as tolvaptan, have been shown to be effective for treatment of SIADH in research trials for adults.
- Demeclocycline (for chronic SIADH)
- Oral urea (for chronic SIADH)

ADDITIONAL TREATMENT

General Measures

- The most important aspects of therapy for SIADH are diagnosis and treatment of the underlying cause.
- If hyponatremic and $\text{Na} > 120 \text{ mEq/L}$ and no neurologic signs, first step in management is fluid restriction.
- Hyponatremia may result in seizure, which requires immediate treatment with 3% hypertonic saline until the seizure activity stabilizes. Despite the urgent need for correction of hyponatremia to address the severe neurologic symptoms, the rate of sodium correction should not exceed 12 mEq/L in 24 hours.

INPATIENT CONSIDERATIONS

Admission Criteria

Patients with severe hyponatremia and/or neurologic manifestations will need to be admitted for correction of hyponatremia under close medical supervision.

IV Fluids

- Fluid restriction is essential to treat and prevent worsening hyponatremia. Thus, IV fluids, in general, are not recommended for patients with SIADH. If IV fluids are clinically necessary, a rate comparable to insensible losses (1/3 daily maintenance) is recommended with close attention to serum sodium levels.
- The hyponatremia in SIADH is due to free water retention and not due to decreased total body sodium content. For this reason, changing IV fluids from hypotonic solutions to hypertonic (normal saline) without restriction of the IV fluid rate will still result in worsening hyponatremia.

Discharge Criteria

- Depends on the primary etiology causing SIADH
- Generally, when the serum sodium is stabilized and the patient is neurologically stable

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- When to expect improvement: usually during the first 48–72 hours
- Signs to watch for: changes in neurologic status

DIET

Fluid restriction is the most important aspect in the treatment of SIADH. Generally, only fluids for insensible losses (1/3 daily maintenance) are recommended.

PROGNOSIS

Based on the primary cause

COMPLICATIONS

- Severe hyponatremia can cause seizures and, rarely, brain damage. Correcting hyponatremia too quickly can lead to central pontine myelinolysis (CPM), a devastating demyelinating disease that impairs vital functions such as breathing.

- Susceptibility to CPM due to correction of hyponatremia is strongly influenced by the severity and preexisting duration of hyponatremia in the patient.
- Serum sodium should not be increased >12 mEq/L in 24 hours.

CODES

ICD10

E22.2 Syndrome of inappropriate secretion of antidiuretic hormone

FAQ

- Q: Is the use of diuretics beneficial in treating SIADH?
- A: No. Although diuretics may relieve the effects of volume overload, they can also worsen hyponatremia. Overall, diuretics usually cause more detriment than benefit.
- Q: What distinguishes SIADH from CSW?
- A: CSW occurs because of increased natriuresis from increased plasma and CSF levels of atrial natriuretic peptide (ANP) after neurologic

insults (e.g., subarachnoid hemorrhage). Owing to the natriuresis, these patients become dehydrated with notable decreased plasma volume and elevated BUN. In contrast, patients with SIADH have free water overload, causing hyponatremia. CSW is associated with high urine output, in contrast to SIADH, which has low urine output. However, patients with SIADH who are treated with excess solute (3% saline) may exhibit a natural natriuresis and high urine output. Thus, polyuria alone should never be used to distinguish between CSW and SIADH. Net sodium loss is very high in CSW (>100 mmol/L), but SIADH has normal to slightly elevated net sodium loss; thus, urinary sodium levels are often not specific in distinguishing CSW from SIADH. Laboratory features of CSW include suppressed plasma aldosterone and often normal serum uric acid concentration. Note that plasma ADH concentration is high in SIADH and initially in CSW as well. However, in CSW, after the intravascular volume has been restored, ADH will decrease again, and patients may not exhibit elevated urine osmolality. In these patients, persistent hyponatremia with elevated urine osmolality is more suggestive of SIADH, which is far more common than CSW.

- Q: Why is it important to distinguish SIADH from CSW?
- A: Therapies differ dramatically for these conditions. Unlike the water restriction used to treat SIADH, treatment of dehydration in CSW requires replacement of ongoing salt and water losses. However, CSW is much less common than SIADH and appropriate diagnosis of each condition is necessary to avoid worsening of the hyponatremia by the treatment regimen.

SYNOVITIS—TRANSIENT

David D. Sherry

BASICS

DESCRIPTION

Transient inflammatory process resulting in arthralgia and arthritis (especially affecting the hip) and occasionally rash precipitated by an exposure to an infectious agent

EPIDEMIOLOGY

- Any age at risk
- Common in ages 3–10 years
- Males affected 1.5 times more commonly

RISK FACTORS

Genetics

No specific associations

PATHOPHYSIOLOGY

A type III hypersensitivity reaction mediated by immune complex deposition within the skin and joint spaces

ETIOLOGY

Usually viral (especially upper respiratory but also enterovirus)

DIAGNOSIS

HISTORY

- Preceding viral syndromes
- Day care
- Relatively rapid onset of symptoms, with refusal to bear weight, in a non-toxic-appearing child
- Recent nonspecific upper respiratory or GI infection

PHYSICAL EXAM

- General examination usually benign
- Occasional low-grade fever
- Child refuses to bear weight but may tolerate limited ranging of joint.
- Effusions in peripheral joints are rare and usually small and evanescent.
- Pitfalls
 - Distinctions between transient synovitis and a septic joint may be impossible.
 - Extreme pain and guarding on passive ranging raises suspicion for septic joint.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Usually mild leukocytosis
- Erythrocyte sedimentation rate (ESR)
 - Usually midrange elevation (35–50 mm/h)

Imaging

- Radiography
 - Usually normal findings or demonstrates small effusion
 - No evidence of periosteal changes
- Ultrasound
 - Affected hip joints may have demonstrable effusions.
- MRI
 - Normal signal intensity may help differentiate transient synovitis from septic hip.

Diagnostic Procedures/Other

- Joint aspirate culture is usually not needed.
- Be wary of contaminated joint aspiration cultures.
- Up to 50% of infected joints are negative on culture.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Lyme disease
 - Septic arthritis

- Tuberculosis
- Gonorrhea
- Environment
- Trauma (fracture or soft tissue injury)
 - Slipped capital femoral epiphysis
 - Avascular necrosis
- Tumors
 - Osteoid osteoma
- Immunologic
 - Juvenile idiopathic arthritis
 - Spondyloarthropathy
- Psychological
 - Psychogenic limp
 - Imitative limp
- Miscellaneous
 - Hypothyroidism

TREATMENT

MEDICATION

- Usually responsive to NSAIDs such as ibuprofen (up to 10 mg/kg/dose q.i.d.)
- Very rarely, a short course of oral steroids is necessary.
 - Usually, 1–3 weeks of a tapering course of NSAIDs are effective.

ADDITIONAL TREATMENT

General Measures

Pitfalls

- Missing a septic hip or, alternatively, overinvestigating transient synovitis with invasive procedures
- Avoid initiation of therapy until septic joint has been ruled out.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Usually significant improvement in 24–48 hours

Patient Monitoring

Ongoing synovitis despite therapeutic levels of NSAIDs or any bony change indicates need to change diagnosis.

PROGNOSIS

Excellent, although on occasion, patients will experience recurrence of symptoms with subsequent viral syndromes or if there is an underlying spondyloarthropathy.

COMPLICATIONS

Questionably associated with subsequent avascular necrosis of femoral head and coxa magna

CODES

ICD10

- M67.30 Transient synovitis, unspecified site
- M67.359 Transient synovitis, unspecified hip
- M67.351 Transient synovitis, right hip

FAQ

- Q: Are there any chronic sequelae from transient synovitis?
- A: Not usually. This is generally a benign disease, but there is a questionable association with avascular necrosis of the femoral head.
- Q: Is there an association with chronic arthritis?
- A: No. There is no known increased risk for chronic arthritis in affected children unless this is the first manifestation of a spondyloarthropathy.

SYPHILIS

Joseph B. Cantey • Pablo J. Sanchez

BASICS

DESCRIPTION

- Systemic infection caused by the spirochete, *Treponema pallidum*
- Can be congenital or acquired
- Consider sexual abuse when syphilis is diagnosed in young children.

EPIDEMIOLOGY

- Congenital syphilis is defined as transmission from an infected mother to her unborn or newborn baby.
- Infection transmitted to the fetus at any stage of disease; during primary and secondary syphilis, rate of transmission is 60–100%.
- ~10.8 cases per 100,000 live births in 2008
- Acquired syphilis is sexually transmitted from an infected to an uninfected individual.
- Nasal secretions are highly infectious in congenital syphilis, and open, moist skin lesions are infectious in congenital and acquired syphilis.

RISK FACTORS

- Lack of prenatal care
- Maternal use of illicit drugs
- Sexual abuse
- Infection with HIV

DIAGNOSIS

SIGNS AND SYMPTOMS

- Congenital syphilis
 - Clinical manifestations range from clinically inapparent to stillbirth.
 - Clinical signs include hepatosplenomegaly, periostitis, osteochondritis, persistent rhinorrhea, or maculopapular rash.
- Acquired syphilis

- Primary stage: painless, indurated ulcers (chancres), single or multiple, at the site of inoculation ~3 weeks after exposure (range 10–90 days); lesions usually resolve without treatment in 3–6 weeks.
- Secondary stage: generalized rash, which is often maculopapular and involves the palms and soles; condyloma lata, hypertrophic papular lesions; fever, malaise, lymphadenopathy; signs appear 3–6 weeks after initial chancre and may last 2–10 weeks.
- Relapse: Symptoms of secondary syphilis may recur 1 or more times before the latent period.
- Latent period: Untreated, illness may enter a latent stage; patients are asymptomatic, not contagious; lasts 1–40 years or more; patients seroreactive but without other evidence of disease.
 - Early latent period: 1st year of latent period
 - Late latent period: subsequent years
- Tertiary stage: Up to 1/3 of untreated secondary syphilis cases progress to tertiary or late disease; can occur many years after the primary infection; may see gummatous changes of the skin, bone, and/or viscera or cardiovascular syphilis
- Neurosyphilis: CNS involvement in 3–7% of untreated cases; can develop at any stage of disease; signs include changes in mood/behavior, hyperactive reflexes, impaired memory and/or judgment, and Argyll-Robertson pupils

HISTORY

- Newborn/infants
 - Obtain a detailed prenatal history; inquire about all syphilis testing done on the mother; if mother has a history of syphilis, ensure documented treatment. The local department of health should have detailed records that include titers and treatment on all cases of syphilis.
 - Newborns should be evaluated for congenital syphilis if the mother is not adequately treated for syphilis (treated with nonpenicillin regimen, such as erythromycin), mother treated adequately but less than 4 weeks before delivery, maternal syphilis treated prior to pregnancy with insufficient follow-up to assess serologic response

to treatment, if the infant's titer is 4-fold greater than the mother's titer, or if the infant has clinical signs of infection.

- Older children/adolescents
 - Ask about possible sexual abuse in children.
 - Ask about sexual activity in adolescents, including experience, number of lifetime partners, ages of partners, history of other STDs, and use of barrier contraception.
 - Ask about other risk behaviors.
 - Ask about risk factors for HIV exposure.

PHYSICAL EXAM

- Early congenital syphilis
 - Intrauterine growth restriction; irritability, bulging fontanel, if neurosyphilis is present
 - Alopecia (scalp and eyebrows)
 - Fissures in the lips, nares, anus (rhagades); mucocutaneous lesions
 - Rhinitis (“snuffles”) may occur at one to several weeks of age and may be blood-tinged and purulent.
 - Lymphadenopathy
 - Pneumonia alba: Check for tachypnea and/or respiratory distress.
 - Myocarditis
 - Hepatosplenomegaly with or without jaundice
 - Pseudoparalysis of an extremity
 - Rash: bullous (“syphilitic pemphigus”) and/or maculopapular (“blueberry muffin”) lesions symmetrically distributed on palms, soles, and other parts of the body
 - Condyloma lata: flat, wartlike, moist lesions around the anus/vagina; chancres
- Late congenital syphilis
 - Bony deformities, such as short maxilla, high-arched palate, saddle nose, mulberry molars, Higoumenakis sign (enlargement of the sternoclavicular portion of the clavicle), protuberance of the mandible, saber shins, scaphoid scapulae
 - Rhagades, neurologic involvement
- Acquired syphilis
 - Primary syphilis

- Chancre (painless ulcer), single, most commonly located on the genitalia, and/or
- Painless inguinal adenopathy
- Secondary syphilis: flulike illness with fever, headache, sore throat, nasal discharge, generalized arthralgias and myalgias, malaise, generalized painless and mobile lymphadenopathy; hepatosplenomegaly; maculopapular rash involving the palms and soles that may involve mucous membranes; condyloma lata (moist, papular lesions); alopecia; signs of meningitis, hepatitis, nephropathy, ocular involvement

DIAGNOSTIC TESTS & INTERPRETATION

- Pitfalls:
 - False-positive nontreponemal test (e.g., rapid plasma reagin [RPR]) results may be seen with lab error, autoimmune disease, tuberculosis, lymphoma, viral infections (including Epstein-Barr, hepatitis, varicella, HIV, and measles viruses), endocarditis, malaria, and IV drug abuse.
 - False-positive treponemal tests may be seen in other spirochetal diseases (i.e., Lyme disease, leptospirosis) and rarely in autoimmune disease (i.e., systemic lupus erythematosus) and viral infections.
 - False-negative nontreponemal test (e.g., RPR) results may be seen with prozone phenomenon if titers are high.
 - Mothers of infants with congenital syphilis should also be tested for gonorrhea, chlamydia, HIV, and hepatitis B virus infection.
 - In newborns, cord blood testing may result in false-positive and false-negative results; therefore, serum from the infant is the preferred source of testing.
 - Infants should not be discharged from the nursery until the results of maternal syphilis tests are known.
 - “Reverse screening” algorithm refers to using treponemal test first, then confirming a positive result with nontreponemal test.
 - Discordant results should be confirmed with a second, different treponemal test
 - Unclear how to manage well-appearing infants born to mothers identified by reverse screening who have positive treponemal tests

but nonreactive RPR (most experts recommend single IM dose of penicillin G, 50,000 U/kg)

Lab

- Nontreponemal tests
 - VDRL (Venereal Disease Research Laboratory) or RPR test to measure nontreponemal antibodies
 - Used for routine screening; quantitative serum titers generally correlate with disease activity; need to confirm positive results with a treponemal antibody test. 4-fold titer change (e.g., from 1:8 to 1:32) necessary to document clinically significant change. Titers for different nontreponemal tests are not equivalent; therefore, use same test (and preferably same lab) when following serial titers.
 - VDRL (not RPR) is used on CSF to evaluate for neurosyphilis.
- Treponemal antibody tests
 - Used for confirmation of positive nontreponemal test
 - FTA-ABS (fluorescent treponemal antibody-absorption), TPPA (T. pallidum particle agglutination), MHA-TP (microhemagglutination assay for T. pallidum antibodies), or EIA (enzyme immunoassay for antitreponemal IgG)
 - Treponemal tests usually remain positive for life once infected; not useful for measuring treatment effectiveness
- Dark-field microscopy
- CSF analysis
 - Findings include mononuclear pleocytosis, moderately elevated protein, and normal glucose.
 - Should be performed in all patients with acquired syphilis of >1 year's duration
 - Perform on infants when congenital syphilis suspected, if the physical examination is consistent with syphilis, if infant's titer is 4-fold greater than that of mother, or if dark-field or fluorescent antibody test positive on body fluids
 - Remember that CSF protein levels in normal newborns are higher than in older children; some are as high as 150–200 mg/dL.

Imaging

Long bone plain films: Rule out metaphyseal osteochondritis and/or

diaphyseal periostitis.

DIFFERENTIAL DIAGNOSIS

- Congenital syphilis
 - Herpes simplex virus (HSV)
 - Toxoplasmosis
 - Cytomegalovirus
 - Rubella
 - Neonatal hepatitis
 - Osteomyelitis
- Acquired syphilis
 - Chancroid (*Haemophilus ducreyi*)
 - Granuloma inguinale
 - *Calymmatobacterium granulomatis*
 - Lymphogranuloma venereum (*Chlamydia trachomatis*)
 - Scabies
 - Mycotic infections
 - Genital herpes (HSV)
 - Venereal warts (human papillomavirus [HPV])
 - Viral exanthem (e.g., enteroviruses may cause a maculopapular rash involving the palms and soles)

TREATMENT

MEDICATION

- Infants <28 days of age
 - Aqueous crystalline penicillin G (50,000 U/kg/dose) IV q12h for first 7 days of life, then q8h for a total of 10 days or procaine penicillin G (50,000 U/kg/dose) IM daily for 10 days
 - If >1 day of treatment is missed, restart 10-day course.
- Infants >28 days of age
 - Aqueous crystalline penicillin G (50,000 U/kg/dose) IV q4–6h for 10 days
- Primary, secondary, and early latent (<1 year duration) syphilis
 - Infant/child: penicillin G benzathine 50,000 U/kg IM (maximum,

- 2.4 million units), single dose
- Adolescent/adult: doxycycline 100 mg PO b.i.d. or tetracycline 500 mg PO q.i.d. for 14 days for nonpregnant, penicillin-allergic patients
- Late latent syphilis (>1 year duration) or disease of unknown duration
 - Infant/child: penicillin G benzathine, 50,000 U/kg IM (maximum 2.4 million U) weekly for 3 consecutive weeks
 - Adolescent/adult: doxycycline 100 mg PO b.i.d. or tetracycline 500 mg PO q.i.d. for 4 weeks for nonpregnant, penicillin-allergic patients
- Pregnant women with penicillin allergy who require therapy for syphilis should be desensitized
- Alternative therapy can be found at www.cdc.gov/nchstp/dstd/penicillinG.htm.

ONGOING CARE

ISSUES FOR REFERRAL

All cases should be reported to the local department of (public) health.

PROGNOSIS

- The prognosis is better the earlier syphilis is detected and treated.
- Following appropriate therapy, the disease usually is totally arrested.
- With late findings of syphilis involving the nervous and/or cardiovascular systems, there may not be clinical improvement.
- Untreated infection in the neonate progresses to neurosyphilis within 1 year.
- Osteochondritis and periostitis in the newborn are usually self-limited and heal in the first 3–6 months of life.
- Hemolytic anemia seen in congenital syphilis may persist for weeks.

COMPLICATIONS

- Stillbirth or spontaneous abortion
- Perinatal death in 40% of pregnancies in mothers with untreated early syphilis
- Prematurity
- Hydrops fetalis

- Nephrosis
- Pneumonia alba
- Intrauterine growth restriction and failure to thrive
- Disseminated intravascular coagulation
- Pseudoparalysis of Parrot: paralysis of one of the limbs of an infant affected by congenital syphilis; usually unilateral
- Acute syphilitic leptomeningitis
- Cranial nerve palsies
- Interstitial keratitis: 5–20 years after birth
- Cerebral infarction
- Seizure disorder, mental retardation
- Rhagades: cluster of scars radiating around the mouth
- Mulberry molars: maldevelopment of the cusps in the first molars
- Clutton joints: painless arthritis of the knees and, rarely, other joints
- Hutchinson triad: Hutchinson teeth (notched upper central incisors), interstitial keratitis, 8th-nerve deafness
- Saber shins: anterior bowing of the midportion of the tibia

PATIENT MONITORING

- Congenital syphilis:
 - Clinical follow-up and serial nontreponemal serologic testing every 2–3 months until titer decreases 4-fold or test is nonreactive
 - After adequate treatment, nontreponemal tests should be nonreactive after 6 months; infants with a history of abnormal CSF findings need serial CSF analyses every 6 months until CSF is normal.
 - Treated infants, follow-up at 1, 2, 4, 6, and 12 months of age; serologic tests should be performed 2, 4, 6, and 12 months after therapy until they become nonreactive or the titer has decreased 4-fold.
 - If titers have not shown a decline by 6–12 months, require reevaluation and treatment.
- Primary and secondary syphilis
 - Clinical follow-up and serial nontreponemal titers at 6 and 12 months after treatment (more often, if at high risk for reinfection or treatment failure): Nontreponemal titers should drop 4-fold within 6

months of treatment of primary or secondary syphilis and within 12–24 months after treatment of latent or tertiary syphilis.

CODES

ICD10

- A53.9 Syphilis, unspecified
- A50.9 Congenital syphilis, unspecified
- A51.5 Early syphilis, latent

FAQ

- Q: Can an infant have congenital syphilis if the mother had a negative RPR during pregnancy?
- A: A mother with a negative RPR during pregnancy may have acquired syphilis late in pregnancy and transmitted it to her fetus. If the mother was not tested at delivery, then the diagnosis may have been missed.
- Q: What is the prozone phenomenon?
- A: When a nontreponemal test is falsely negative due to high concentrations of antibody to *T. pallidum*; diluting the serum will result in positive test results.

TAPEWORM

Karen E. Jerardi • Samir S. Shah

BASICS

DESCRIPTION

- Tapeworms cause 2 major types of zoonotic disease syndromes, depending on whether humans are the definitive or intermediate host.
- When humans serve as definitive hosts, adult tapeworms infect the GI tract and interfere with nutrition; patients may be asymptomatic.
- When humans serve as intermediate hosts for the larval cestode, serious pathology results.
- Causative organisms include the following:
 - *Taenia saginata* (beef tapeworm)
 - *Taenia solium* (pork tapeworm)
 - *Diphyllobothrium latum* (fish tapeworm)
 - *Dipylidium caninum* (dog tapeworm)
 - *Echinococcus granulosus*

EPIDEMIOLOGY

- Beef tapeworm
 - Estimated 77 million people infested worldwide
 - Widespread in cattle-breeding areas of the world, endemic in Asia, Latin America, Eastern Europe
- Pork tapeworm
 - Estimated >50 million people infested worldwide
 - Taeniasis: typically asymptomatic infection with adult tapeworm (from undercooked pork)
 - Cysticercosis: infection with larval parasite (fecal–oral transmission from carriers).
 - High prevalence in developing areas of Asia, Central and South America
 - 1,000 new cases of neurocysticercosis in United States annually
- Fish tapeworm
 - Infection is most prevalent in temperate climates of Europe

(Finland, Estonia, Sweden most common), and Canada.

- Persons who prepare or eat raw freshwater fish are most at risk.
- In the United States, infected salmon have been implicated in most cases.
- Dog tapeworm
 - Found in dogs and cats worldwide
- Echinococcosis
 - Associated with the practice of feeding sheep viscera to dogs
 - It is hyperendemic in sheep-raising areas of South America, Australia, areas of Africa, China, Central Asia, and the Western United States.

GENERAL PREVENTION

- Adult tapeworms
 - Proper cooking prevents transmission of beef, pork, and fish tapeworms.
- Pork tapeworm
 - Refrigeration of pork infested with cysticerci at temperatures $>0^{\circ}\text{C}$ (32°F) does not affect parasite survival. However, storage of pork for 4 days at -5°C (21.2°F) or 1 day at -24°C (-11.2°F) kills most cysticerci.
- Fish tapeworm
 - Brief cooking (at $>56^{\circ}\text{C}$ [132.8°F] for 5 minutes) or freezing (-18°C [-0.4°F] for 24–48 hours) renders the fish safe to consume.
- Dog tapeworm
 - Periodic deworming of pets
- Echinococcosis
 - Careful disposal of sheep viscera and mass chemotherapy of dogs can interrupt the life cycle of *E. granulosus* as the cestode moves between sheep and carnivore hosts.

PATHOPHYSIOLOGY

- Beef tapeworm
 - Cattle (intermediate host) ingest the eggs of *T. saginata* in contaminated feeds. The eggs hatch, releasing embryos which penetrate intestinal mucosa, enter the bloodstream, and settle in

skeletal muscle, where they develop into larvae. Larvae in undercooked meat are consumed by humans and mature into adult tapeworms within the human (definitive host) GI tract. They grow up to 25-m long.

- Pork tapeworm: Humans are the only definitive host for the adult pork tapeworm. Both humans and pigs are intermediate hosts for its embryonic form, cysticercosis.
 - Pigs ingest *T. solium* eggs. In the intestine, the eggs release embryos that penetrate the mucosa, enter the bloodstream, and settle in various tissues to differentiate into cysticerci (infective larvae). Cysticerci are ingested by humans (definitive host) who consume undercooked pork.
 - Humans ingest food contaminated with human feces containing *T. solium* eggs. The eggs hatch, liberating embryos which penetrate the intestinal mucosa leading to blood-borne distribution to the brain, subcutaneous tissues, muscle, and eye, where they develop into cysticerci.
- Fish tapeworm
 - When sewage containing *D. latum* eggs contaminates freshwater lakes and streams, eggs hatch into the water becoming embryos. Embryos are eaten by crustaceans and then passed on to fresh water fish. Humans are infected when they consume these undercooked fish. The larvae mature into adult tapeworms in the intestines of humans in 3–5 weeks' time and can survive up to 10 years. Rarely, the tapeworm migrates thru intestinal wall to other tissues (sparganosis).
- Dog tapeworm
 - Larvae develop in fleas (intermediate host) after ingestion of the eggs; humans are infected through accidental ingestion of infected fleas.
- Echinococcosis (hydatid disease)
 - Humans ingest eggs of *E. granulosus* through contaminated dog feces. After ingestion, the eggs hatch and release embryos (oncospheres) in the small intestine. Penetration through the mucosa leads to blood-borne distribution to the liver, lungs, and other sites,

where development of cysts begins. Within the cysts, new larvae (scolices) develop, accumulate fluid, and encroach on surrounding structures.

DIAGNOSIS

HISTORY

- Recent travel or immigration
- GI tract
 - Nausea, weight loss, diarrhea, abdominal tenderness or distention
 - Fish and, rarely, dog tapeworm infections can be complicated by intestinal obstruction.
 - May observe proglottids that resemble rice or seeds in stool from dog tapeworm
- Jaundice
 - Hepatic cysts from echinococcosis may be palpable in the right upper quadrant.
 - Biliary tree extension can lead to obstructive jaundice and cholangitis.
- Respiratory tract
 - Pulmonary hydatid cyst due to *E. granulosus* causes cough, dyspnea, and hemoptysis; rupture of a cyst can cause anaphylaxis.
- Hematologic
 - Anemia from vitamin B₁₂ deficiency occurs in 2% of fish tapeworm infections due to competition for absorption in ileum. Other signs of pernicious anemia include glossitis, peripheral neuropathy, decreased vibration sense, and ataxia.
- CNS
 - New-onset seizures (partial or generalized) occur with neurocysticercosis and some species of *Echinococcus*.
 - Neurocysticercosis may present with alteration in mental status, signs of elevated intracranial pressure (headache, vomiting, visual changes), or meningitis.
 - Neurocysticercosis and vitamin B₁₂ deficiency due to fish tapeworm can mimic psychotic illness with delirium or hallucinations.

- CNS symptoms in neurocysticercosis typically appear 5–7 years after initial infection (range: 6 months to 30 years).
- Note: For echinococcosis, a presymptomatic stage may last for years before the enlarging cysts cause symptoms. The variability of signs and symptoms depends on the target organ.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Beef tapeworm
 - Ziehl–Neelsen stain of stool identifies eggs.
 - Proglottids or eggs in stool with microscopic examination (62% sensitivity)
 - ELISA test detects *Taenia* antigens in stool (85% sensitivity, 95% specificity).
- Pork tapeworm
 - Serum enzyme-linked immunoelectrotransfer blot (most sensitive) and ELISA of serum and/or CSF
 - Stool samples for intestinal worms
- Fish tapeworm
 - Stool samples for eggs and proglottids are diagnostic, collect multiple specimens.
 - Mild eosinophilia (5–15%)
 - Low vitamin B₁₂ levels (50%)
 - Megaloblastic anemia 2%
- Dog tapeworm
 - Characteristic egg packets (loose membrane containing up to 20 eggs) or proglottids may be identified in stool.
- Echinococcosis
 - IgE levels are elevated. Eosinophilia is present in <25% of infected persons.
 - Polymerase chain reaction (PCR) of stool
 - Mild elevation of hepatic enzymes may be present with hepatic hydatid cysts.
 - The Casoni skin test (injection of hydatid fluid into the dermis) yields an erythematous papule in <60 minutes in 50–80% of infected patients. False-positive rate is 30% in uninfected patients.

- Serologic testing is falsely negative in 10–50% of cases. False-negative results are more likely in patients with pulmonary hydatid cysts and in children. No serologic test excludes the diagnosis of hydatid cysts.

Imaging

- Pork tapeworm
 - Contrast-enhanced CT or MRI of the brain may reveal cysticerci; ring-enhancing lesions with surrounding edema represent a dying parasite; calcification represents a resolved infection.
 - Imaging is usually diagnostic.
- Echinococcosis
 - On x-ray, pulmonary cysts demonstrate a sharply demarcated, smooth-bordered cyst; there is a crescent-shaped air level after cyst rupture. Liver and spleen lesions may calcify over time.
 - Hydatid cysts: Internal septa or daughter cysts after cyst rupture are detected by CT, MRI, or ultrasound; present in ~50% of patients with unilocular liver cysts

Diagnostic Procedures/Other

Echinococcosis: In seronegative persons, a presumptive diagnosis can be confirmed by demonstrating protoscolices or hydatid membranes in liquid obtained by ultrasound-guided percutaneous cyst aspiration. This procedure is controversial because anaphylaxis may occur with cyst rupture.

DIFFERENTIAL DIAGNOSIS

- Non–tapeworm gastroenteritis
- Inflammatory bowel disease
- Cholecystitis or biliary obstruction (i.e., gallstones, neoplasms, or liver disease)
- B₁₂ deficiency from dietary deficiency or pancreatic insufficiency
- Idiopathic epilepsy
- Echinococcal cysts must be differentiated from benign cysts, cavitory tuberculosis, abscesses, and neoplasms.

TREATMENT

MEDICATION

- Beef, pork, fish, and dog tapeworm (and most other intestinal cestodes)
 - Praziquantel: 5–10 mg/kg as a single dose; no safety profile exists for children <4 years of age.
 - Niclosamide (second line for beef tapeworm): children 11–34 kg, 1 g as a single dose; children >34 kg, 1.5 g as a single dose (not available in the United States)
 - Supplement with vitamin B₁₂ for fish tapeworm.
- Neurocysticercosis
 - Treatment should be individualized based on number, location, and viability of cysticerci on MRI or CT scan.
 - Treatment may not be indicated for single degenerating cysts, calcifications, or encephalitis. Most experts recommend therapy for patients with nonenhancing or multiple cysticerci.
 - Albendazole: 15 mg/kg/24 h (maximum, 800 mg/24 h) in 2 divided doses for 8–30 days or praziquantel 50–100 mg/kg/24 h in 3 divided doses for 30 days
 - Steroids (1 mg/kg/day of prednisone or 0.5 mg/kg/day of dexamethasone), in combination with albendazole, decrease seizure frequency and number of CNS cysts.
 - Antiepileptic drugs are recommended and shunt placement, and/or mannitol should be considered for treatment of hydrocephalus.
 - Antiparasitic therapy is contraindicated in patients with diffuse cerebral edema (“cysticercal encephalitis”) because the inflammatory response that follows treatment may worsen cerebral edema.
 - No definite recommendations exist regarding the use of corticosteroids alone.
- Echinococcosis
 - Albendazole 15 mg/kg/24 h (max 800 mg/24 h) in 2 divided doses for 1–6 months
 - May require 3 courses of therapy with drug-free intervals of 14 days between courses

- Note: The benzimidazoles, including albendazole, are contraindicated in patients with blood dyscrasia, leukopenia, and liver disease. Prolonged courses require monitoring of liver function and hematopoiesis.

SURGERY/OTHER PROCEDURES

- Echinococcosis: surgical resection of intact hydatid cysts, especially if >10 cm, secondarily infected, or causing symptoms
- Subcutaneous sparganosis: surgical resection or ethanol injection

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Beef tapeworm
 - Stool should be checked for eggs and proglottids 1 month after therapy.
- Pork tapeworm
 - Repeat CNS imaging studies at 2-month intervals (with continued therapy) until successful elimination of parenchymal brain cysticerci.
- Fish tapeworm
 - Perform stool examination 12 weeks after therapy to test for cure.
- Dog tapeworm
 - No follow-up stool examination required, but the appearance of proglottids >1 week after therapy indicates treatment failure.
- Echinococcosis
 - Requires prolonged follow-up with ultrasound or other imaging procedures

COMPLICATIONS

- Cysticercosis
 - Cysticerci can develop in the brain, muscle, eye, or other organs. Ophthalmologic exam is warranted in cases of neurocysticercosis.
- Echinococcosis
 - Cysts grow slowly, causing symptoms only when relatively large.

- They frequently develop in the liver (50–70%) and lung (20–30%); 5–10% of cysts involve other organs, including the eye, brain, spleen, heart, bone, and kidneys.
- Rupture of cysts can cause anaphylaxis.
- Bone involvement can cause pathologic fractures, and renal involvement can cause pain or hematuria.

CODES

ICD10

- B71.9 Cestode infection, unspecified
- B68.1 *Taenia saginata* taeniasis
- B68.0 *Taenia solium* taeniasis

FAQ

- Q: Can vegetarians develop neurocysticercosis?
- A: Yes, because neurocysticercosis results from ingestion of *T. solium* eggs in products contaminated with infected fecal matter. GI symptoms result from eating infected pork.
- Q: Is treatment for neurocysticercosis always indicated?
- A: The findings are controversial. In many children, the lesion disappears spontaneously within 2–3 months. Guidelines for treatment depend on the number and location of lesions, as well as the viability

of the parasites within the nervous system. A growing parasite deserves active management, either with antiparasitic drugs or surgical excision.

TEETHING

Karen R. Fratantoni • Anupama R. Tate

BASICS

DESCRIPTION

Teething is the normal developmental process of primary tooth eruption whereby the tooth moves from its position in the alveolar bone through the mucosa into the mouth. Parents/caregivers, physicians, and dentists often associate many localized and systemic symptoms with the teething process, including mouthing/biting, drooling, changes in appetite, and fever.

DIAGNOSIS

Consider the following diagnostic approach when evaluating an infant or toddler who presents with chief complaint of teething:

- Careful history and physical exam
- Evaluation of signs/symptoms inconsistent with teething (fever $>102^{\circ}\text{F}/38.8^{\circ}\text{C}$, irritability, diarrhea) and treatment of possible illness
- If teething is suspected or confirmed and serious illness ruled out, offer education and advice for parents/caregivers around the management of teething symptoms.

HISTORY

Teething is a normal developmental process for which anticipatory guidance should be offered at appropriate well visits. The following questions will be helpful for providers in determining if teething should be considered in the differential diagnosis.

- Is teething likely to be occurring at the child's age?
 - First tooth appears by 6 months of age; however, 1% of children will get their first tooth before 4 months old and 1% after 12 months old.
 - Completion of a set of 20 deciduous/primary teeth by 30 months of

age

- Teeth emerge in pairs, with lower central incisors usually appearing first.
- Rule of thumb: age (in months) – 6 = average number of teeth (until 24 months old)
- Has the child had fever?
 - General consensus is that temperature $>102^{\circ}\text{F}$ or 38.8°C should not be attributed to teething.
 - One prospective longitudinal study showed an association between mild tympanic temperature elevations (with maximum 36.8°F) and day of tooth eruption.
 - Another study showed mild temperature elevation in the 8-day teething period.
- Does the child have one or more symptoms often attributed to teething?
 - Common symptoms parents often attributed to teething include biting, drooling, gum rubbing, irritability, sucking, wakefulness, ear rubbing, facial rash, and decrease in appetite for solids.
 - One prospective study showed an increase of the above symptoms in the period from 4 days prior to 3 days after tooth eruption, considered to be the 8-day window of teething.
 - There is no consensus in the medical literature about the association of teething and these minor symptoms.
- Is the child irritable?
 - Irritability with an inability to console is concerning and must not be attributed to teething.

ALERT

Fever $>38.8^{\circ}\text{C}/102^{\circ}\text{F}$, irritability, or diarrhea should NOT be attributed to teething and should prompt a careful history, physical exam, and investigation for possible etiology, including otitis media, meningitis, serious bacterial illness, or viral infection.

- Is the child exhibiting changes in sleep pattern?
 - Teething should not cause significant sleep disturbances.
 - Further history should be obtained regarding the nature of the sleep changes, some of which are common in children between 6 and 12

months old.

- Are there changes in the mouth which make the parent think the child may be teething?
 - Swelling of the gums may be noted prior to tooth eruption.
 - An area of gum swelling with discoloration may represent an eruption cyst for which no treatment is required.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Gingivostomatitis causing pain or drooling
 - Viral or bacterial illnesses causing pain, fever, fussiness, or change in behavior
- Toxic ingestion causing drooling
- Trauma or burn to the mouth
- Normal developmental behaviors: Drooling, gum rubbing, and finger sucking may be consistent with typical development.

PHYSICAL EXAM

- Often, there are no pertinent findings on physical exam.
- Gum swelling and eruption cysts are both normal findings.

DIAGNOSTIC TESTS & INTERPRETATION

No laboratory tests are indicated in the otherwise healthy child with teething.

TREATMENT

GENERAL MEASURES

- Nonpharmacologic
 - Application of cold/frozen objects onto the gums causes vasoconstriction and reduces inflammation.
 - Biting on teething rings or other objects can offer relief by applying pressure to the gums.
 - Objects used for this purpose include teething rings, pacifiers, cold spoons, frozen bagels or bananas, or a cold washcloth.
 - Teething rings can be placed in the refrigerator but not the

- freezer, which could disrupt the integrity of the plastic cover.
 - Discard teething rings made prior to 1998, as they may contain diisononyl phthalate, a plastic softening agent which was later found to be toxic and potentially carcinogenic.
 - Do not attach a teething ring to a tether around the child's neck, as that may cause strangulation.
 - Care should be taken to not give the child an object which could be a potential choking hazard.
- Pharmacologic management
 - Acetaminophen (15 mg/kg PO q 4–6 hours) or ibuprofen (10 mg/kg PO q 6–8 hours) may be used for pain relief as needed but should not be given around-the-clock so as not to mask fever.
 - Over-the-counter teething preparations containing benzocaine have been associated with methemoglobinemia and are not recommended. The FDA released a Drug Safety Communication in 2011 to inform the public of this potentially fatal adverse effect.
 - Homeopathic remedies include belladonna, clove oil, olive oil, fennel, green onion, ginger, vanilla, and chamomile. Depending on the amount ingested and the size of the child, toxicity may be a concern.
 - Remedies used in the past that are no longer recommended include alcoholic liquors, honey, emetics, purgatives, and lancing of the gums.

ISSUES FOR REFERRAL

- Children should have a dental home by the age of 12 months.
- Children who have delayed eruption of their first primary tooth beyond 15 months should be evaluated. The following conditions have been associated with delayed eruption: anodontia, impacted teeth, hypothyroidism, hypopituitarism, calcium/phosphorus metabolism problems, ectodermal dysplasias, Gaucher disease, osteopetrosis, Apert syndrome, cleidocranial dysplasia, and Down syndrome.
- Referral to a dentist should be considered for children with significant variation in eruption caused by dental infections, additional teeth in the path of eruption, insufficient space in the dental arch, and/or ectopic placement of teeth.

- Presence of or risk for dental caries at an early age should prompt a dental evaluation.
- Natal teeth should be evaluated only if they are loose and pose an aspiration risk or if they interfere with breastfeeding.

K00.7 Teething syndrome

FAQ

- Q: When does a child need to see the dentist?
- A: Every infant should receive an oral health assessment from the primary care provider by 6 months of age to assess the patient's risk for oral disease or caries. Parents should be provided education on infant oral health and evaluation of fluoride supplementation. The AAP and the AAPD recommend that the patient establish a dental home by 1 year of age or sooner if with concern for dental caries, trauma, teeth staining, or family history of early dental caries.
- Q: What is the proper care of newly erupted teeth?
- A: Brushing with a toothbrush helps reduce bacterial colonization and should be done by a parent twice daily using a soft toothbrush of age-appropriate size. Never put the baby to bed with a bottle due to increased risk for early childhood dental caries.
- Q: Will thumb sucking affect my baby's teeth?
- A: Thumb sucking is a normal part of infancy but, if allowed to continue into early childhood, can cause problems with the child's bite. If it continues past the age of 3 years, the primary care or dental provider should counsel parents on strategies to reduce the behavior.
- Q: Is there a cluster of symptoms that can predict when teeth will emerge?
- A: Studies have failed to show a group of symptoms which is predictive of tooth eruption.
- Q: What are natal and neonatal teeth?
- A: Natal teeth are teeth present at birth, most often representing the premature eruption of primary teeth but occasionally can be a third set of teeth. They are usually left in place unless they cause difficulty with

nursing or are loose and pose an aspiration risk. Neonatal teeth, however, erupt in the 1st month of life. Occurring in approximately 1 in 2,000 children, natal and neonatal teeth are not usually pathologic but have been associated with various syndromes, including Hallermann-Streiff syndrome, Ellis-van Creveld syndrome, craniofacial dysostosis, congenital pachyonychia, Pierre Robin, adrenogenital syndrome, and Sotos syndrome.

TENDONITIS

David D. Sherry

BASICS

DESCRIPTION

Inflammation of a tendon or along the tendon sheath

EPIDEMIOLOGY

- Increases with age and at time of puberty
- May be slightly more common in girls

RISK FACTORS

Genetics

Hypermobile individuals may be prone to tendonitis.

PATHOPHYSIOLOGY

Inflammation and microtearing may be present.

ETIOLOGY

Frequently associated with repetitive motion/overuse activities

DIAGNOSIS

HISTORY

- Trauma or overuse
 - Verify acute nature of injury.
- Signs and symptoms
 - Pain
 - Tenderness

PHYSICAL EXAM

- Evidence of hematoma
 - Palpate around and about affected areas, detecting point tenderness especially at tendon insertions as well as over bony prominences.
- Evidence of bursitis or arthritis

- Systemic conditions, such as spondyloarthropathy, can lead to inflammation of tendons, bursa, and joints, and bursitis can mimic the pain of tendonitis.
- Pop or snap felt at the time of the event
 - Sometimes this is felt when tendons and ligaments are torn or avulsed.
- Caution: false positives
 - Patients may have torn ligaments, fractures, or arthritis and not just tendonitis on examination.
- Pitfalls
 - Overdiagnosis in young children, in whom overuse is rare and other diagnoses should be considered
 - Underdiagnosis in older children in whom repetitive activities are likely to occur

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Erythrocyte sedimentation rate (ESR): occasionally helpful to rule out inflammatory conditions if history and/or physical exam are suggestive

Imaging

Plain radiograph: Affected area may be indicated to rule out a fracture or avulsion or identify a bone spur.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Especially gonococcal disease, septic arthritis, or osteomyelitis; rarely, tuberculosis
- Environmental
 - Fracture
- Metabolic
 - Homocystinuria
- Congenital
 - Generalized hypermobility
 - Marfan syndrome
 - Ehlers-Danlos
- Immunologic

- Ankylosing spondylitis and the reactive spondyloarthropathies (inflammatory bowel disease, reactive arthritis)
- Juvenile idiopathic arthritis
- Psychological or neuropathic
 - Amplified musculoskeletal pain

TREATMENT

MEDICATION

- NSAIDs initially
- Rarely, if ever, do soft tissue steroid injections have a role in children.

ADDITIONAL TREATMENT

General Measures

- Rest/reduced use of the affected tendon/muscle group is essential, occasionally requiring splinting.
- Duration of therapy
 - 1–4 weeks

ADDITIONAL THERAPIES

- Physical or occupational therapy for eccentric muscle strengthening
- Either self-directed or formal help with resumption of desired activity to improve biomechanics

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Improvement often takes 2–6 weeks.

Patient Monitoring

If the provocative activity is resumed too soon, the irritation will recur.

PROGNOSIS

Usually good for children; however, many will suffer recurrences if proper exercises before desired activity are not continued.

COMPLICATIONS

Ongoing pain and predisposition for recurrence

ADDITIONAL READING

CODES

ICD10

M77.9 Enthesopathy, unspecified

FAQ

- Q: Which activities can result in overuse syndromes and tendonitis?
- A: Virtually any repetitive activity in which children engage can cause tendonitis. For example, pain in the tendons of the thumb has occurred in children overusing video games.

TETANUS

Hamid Bassiri

BASICS

DESCRIPTION

- Tetanus is characterized by muscle rigidity and spasms due to production of a neurotoxin in infected wounds by *Clostridium tetani*.
- There are four clinical forms of tetanus: generalized, neonatal, localized, and cephalic.

EPIDEMIOLOGY

- Tetanus remains a problem in certain countries but is rare in countries with widespread immunization (in the United States <40 cases/year).
- Rare cases have been reported in patients with protective levels of antitetanus antibodies.
- Generalized tetanus is the most common form of disease.
- Neonatal tetanus is rare in the United States but is seen in countries in which mothers are not immunized and nonsterile care of the umbilical cord is practiced.

RISK FACTORS

- Inadequate immunization
- Neonate born to unimmunized mother
- Elderly with declining immune status
- Injection drug use
- Chronic wounds
- Acute traumatic injury
- Foreign bodies
- Nonsterile delivery conditions and practice of applying mud or feces to umbilical cord

GENERAL PREVENTION

- All wounds should be cleaned with soap and water and foreign bodies should be removed.

- Universal immunization with tetanus toxoid (for details and information on catch-up schedules, refer to CDC Web site)
- Tetanus postexposure prophylaxis should be initiated at the time of injury:
 - For clean minor wounds:
 - If patient has had ≥ 3 prior doses of tetanus toxoid (DTaP, Tdap, or Td) and it has been < 10 years since the last dose, no prophylaxis is indicated; if it has been ≥ 10 years since last dose, give tetanus toxoid.
 - If patient has had < 3 prior doses of tetanus toxoids, give tetanus toxoid.
 - For all other wounds:
 - If patient has had ≥ 3 prior doses of tetanus toxoid and it has been < 5 years since the last dose, no prophylaxis is indicated; if it has been ≥ 5 years since the last dose, give tetanus toxoid.
 - Patients with < 3 prior doses of tetanus toxoid should receive tetanus immune globulin (TIG) and tetanus toxoid at separate sites.
 - Patients with HIV or severe immunodeficiency should receive TIG regardless of prior immunization history.
 - In neonates or infants < 6 months of age who have not received 3 doses of DTaP, the decision to use TIG should be based on mother's tetanus immunization status; if unknown or inadequate, should give TIG
 - Type of tetanus toxoid to use for prophylaxis:
 - For children < 7 years old, use DTaP; if pertussis vaccine is contraindicated, use DT.
 - For a child 7–10 years old, use Tdap.
 - For an adolescent 11–18 years old who has not received Tdap, use Tdap; for those who have received Tdap or for those whom pertussis is contraindicated, use Td.
 - TIG dose is 250 U IM (regardless of age or weight); if TIG is unavailable, use IV immunoglobulin (IVIG) or tetanus antitoxin (TAT).
 - Because TAT is equine in origin, test patient for sensitivity prior

to use.

- TAT is no longer available in the United States.

PATHOPHYSIOLOGY

- *C. tetani* produces tetanospasmin, a powerful metalloprotease neurotoxin.
- Tetanospasmin can be absorbed directly into skeletal muscles adjacent to the injury.
- Tetanospasmin can travel to the CNS via retrograde axonal transport through peripheral nerves or via lymphocytes.
 - In the CNS, tetanospasmin prevents the release of gamma-aminobutyric acid (GABA) and glycine in inhibitory nerve terminals, resulting in sustained excitatory discharges (motor spasms and increased muscle tone) and autonomic instability; tetanospasmin does not directly affect cognitive processes.
 - In the peripheral nervous system, tetanospasmin may block inhibitory impulses to motor neurons.
 - Loss of regulation of adrenal catecholamine release precipitates tachycardia, hypertension, and sweating.
- Infection does not confer immunity, and all patients need to be immunized during recovery.

ETIOLOGY

- Tetanus is caused by *C. tetani*, a spore-forming, anaerobic Gram-positive bacillus.
- *C. tetani* is found in soil, animal and human feces, house dust, and salt and fresh water.
- Under anaerobic conditions, spores become vegetative and produce tetanospasmin; anaerobic conditions in wounds are promoted by extensive necrosis, foreign bodies, or other suppurative infections.

DIAGNOSIS

HISTORY

- Incubation period is 3–21 days (usually 10 days) but varies, as inoculations distal to CNS are associated with longer incubation

periods.

- Generalized tetanus
 - “Lockjaw” or trismus is initial symptom in 50–75% of cases.
 - Other early complaints include dysphagia, neck pain and stiffness, stiffness and pain in other muscle groups, urinary retention, restlessness, irritability, and headache.
 - More muscle groups involved as disease progresses
 - Noise, light, touch, and other stimuli can trigger painful spasms.
- Neonatal tetanus (generalized tetanus during neonatal period)
 - Occurs following vaginal delivery to unimmunized mothers
 - Usually due to umbilical stump infections
 - Typically presents at around 1 week of life with irritability and poor feeding but progresses rapidly to generalized tetanic spasms
- Local tetanus
 - Painful muscle contractions and stiffness limited to the area near the wound
 - Can persist for several weeks
 - Can progress to generalized tetanus
- Cephalic tetanus (local tetanus of head/neck affecting cranial nerves)
 - Caused by *C. tetani* infections of head/neck including chronic infections of the head/neck (e.g., chronic otitis media)
 - Unlike generalized tetanus, flaccid CN palsies (especially CN VII) predominate; trismus may develop, however; if trismus is absent, could be confused with Bell palsy due to other etiologies

PHYSICAL EXAM

- Vital sign abnormalities
 - Severe, labile episodes of hypertension and tachycardia; hypotension is a late feature.
 - Initially, patients are afebrile but may develop hyperthermia with sustained contractions or from superinfections.
- Trismus is often initial presenting sign.
- Persistent trismus causes risus sardonicus, wrinkling of the forehead, and distortion of the eyebrows and the corners of the mouth.
- With disease progression, other muscle groups develop tetanic contractions and spasms:

- Can lead to a severe opisthotonic posture
- Can mimic seizures
- Can be extremely painful
- Can be associated with laryngospasm and tetany of respiratory musculature
- The anxiety and pain associated with these spasms may precipitate additional spasms.
- Sweating can occur from autonomic instability.
- Normal mental status is the norm.
- In cephalic tetanus, CN palsies can be seen.
 - Look for underlying wounds or chronic infections of the face, scalp, neck, or ear.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Lab tests often yield little information; WBC is usually normal or mildly elevated and CSF studies are unremarkable, but serum calcium levels may help exclude hypocalcemic tetany.
- Gram stain and anaerobic wound cultures yield *C. tetani* in <1/3 of cases.
- Presence of protective tetanus antibody titer does not exclude possibility of disease.
- EEG and EMG findings are nonspecific.

DIFFERENTIAL DIAGNOSIS

- Infections
 - Dental infections, retropharyngeal and peritonsillar abscesses, poliomyelitis, viral encephalitis, and meningoencephalitis may present with trismus and/or CN findings.
- Toxins and medications
 - Dystonic reactions to phenothiazine medications may resemble tetanus.
 - Strychnine poisoning may mimic generalized tetanus.
 - Malignant neuroleptic syndrome causes increased muscular rigidity resembling tetanic spasms.
- Metabolic

- Hypocalcemic tetany is usually not as severe as that seen in tetanus.
- Stiff-man syndrome can result in fluctuating tonic contractions resembling tetanic spasms.
- Bell palsy may resemble cephalic tetanus.

TREATMENT

MEDICATION

First Line

- Neutralization of unbound neurotoxin:
 - Human TIG 3,000–6,000 U IM as a single dose; part of the dose may be infiltrated around the wound.
 - Administer prior to antibiotics and wound manipulation.
- Tetanus toxoid should be administered IM at a site contralateral to where TIG is given.
- Antibiotics can decrease burden of vegetative *C. tetani* that produce tetanospasmin:
 - First line: metronidazole 30 mg/kg/24 h PO or IV in 4–6 divided doses; maximum 4 g/24 h
 - Alternative: parenteral penicillin G 1–200,000 U/kg/24 h IV in 4–6 divided doses; maximum 12,000,000 U/24 h
 - Treat for 10–14 days
 - Cephalosporins are not effective.
- Sedation and muscle relaxation
 - Diazepam 0.1–0.2 mg/kg IV q4–6h
 - Phenothiazines, especially chlorpromazine, may be helpful.
 - Titrate sedation to desired effect and monitor for respiratory depression.
- Nondepolarizing neuromuscular blockade and mechanical ventilation:
 - Use if spasms cannot be adequately controlled or if spasm of airway and respiratory musculature compromises ventilation:
 - Vecuronium 0.08–0.1 mg/kg IV followed by continuous infusion or hourly dosing
 - Avoid succinylcholine due to increased risk of hyperkalemia and arrhythmia.

- Management of autonomic dysfunction
 - Beta-blockers (e.g., labetalol 0.4–1 mg/kg/h) can control hypertension or arrhythmias.
 - Magnesium sulfate can significantly reduce cardiovascular instability and act as an adjunctive agent to control muscle spasms.

Second Line

If TIG is not available:

- IVIG 200–400 mg/kg may be used (not FDA approved for this use)
- TAT can be given in doses of 1,500–3,000 U IM or IV (to achieve a serum concentration of 0.1 IU/mL) but only after a negative skin test or desensitization:
 - TAT is not available in the United States.
 - Anaphylactic reactions can occur with varying severity in up to 20% of patients.

ADDITIONAL TREATMENT

General Measures

- Tetanus is not a transmissible disease.
- Keep patient in a quiet, darkened room with minimum stimulus.
- Monitor cardiac and respiratory status closely.
- Be prepared to perform a tracheotomy to prevent fatal laryngospasm.
- Monitor for and treat urinary retention and constipation.
- Parenteral nutrition is usually required to maintain adequate nutrition and hydration.
- Monitor for and correct electrolyte abnormalities, especially hyperkalemia.

SURGERY/OTHER PROCEDURES

Aggressive surgical debridement of wounds and removal of foreign bodies is critical.

INPATIENT CONSIDERATIONS

Initial stabilization

- Prompt recognition of clinical signs of tetanus and initiation of emergency care are crucial.
- All suspected cases of tetanus should be rapidly transferred to a tertiary

care center capable of providing ventilatory and cardiovascular support in an intensive care setting.

- In the emergency department, treatment with TIG should be initiated to neutralize unbound neurotoxin; however, supportive care including aggressive airway management, ventilatory support, and pharmacologic interventions (sedation, muscle relaxation) are also critical to ameliorate the effects of bound neurotoxin.

ONGOING CARE

PROGNOSIS

- Signs and symptoms usually progress for ~1 week, then plateau for ~1 week, and gradually improve over the next 2–6 weeks.
- Overall mortality rates have decreased with advances in the ability to provide respiratory support in an intensive care setting.
- Mortality rates vary from 1–18% for localized tetanus, 15–30% for cephalic tetanus, 45–55% for generalized tetanus, to 50–100% for neonatal tetanus.
- Children and young adults have a better prognosis than older individuals or neonates.
- A more rapid onset and progression of disease from trismus to generalized spasms is associated with a more severe course.
- In the absence of complications, survivors usually recover fully without sequelae.

COMPLICATIONS

- Most complications are related to the severe tetanic muscle contractions:
 - Rhabdomyolysis and hyperkalemia
 - Vertebral body and other fractures
 - Muscle hemorrhages
- Respiratory failure from spasms of the upper airway or diaphragm is the most common cause of death in acute phase, whereas arrhythmia and myocardial infarction are most common cause of death later in disease.

- Cerebrovascular hemorrhages may be seen in rare cases, especially in neonatal tetanus.
- Pneumonia, including aspiration, can occur.

CODES

ICD10

- A35 Other tetanus
- A33 Tetanus neonatorum

FAQ

- Q: What types of wounds are tetanus-prone?
- A: Punctures, avulsion wounds, crush injuries, burns, wounds from frostbite or missiles, and wounds contaminated with saliva, soil, or feces

TETRALOGY OF FALLOT

Aarti Dalal • Christopher Petit

BASICS

DESCRIPTION

Anatomic hallmark is anterior malalignment of infundibular (outlet) septum which results in

- A large and unrestrictive ventricular septal defect (VSD)
- Various degrees of right ventricular outflow tract obstruction (RVOTO)
- Overriding aorta
- Right ventricular hypertrophy (RVH) secondary to exposure to systemic pressure

EPIDEMIOLOGY

- The most common cyanotic congenital heart disease
- 3.5–10% of all congenital heart disease

RISK FACTORS

Genetics

Some cases of tetralogy of Fallot are associated with a chromosome 22q11 microdeletion.

PATHOPHYSIOLOGY

- Severity of clinical signs and symptoms depends on the degree of RVOTO and related right-to-left shunt at the VSD.
- Physiology is a spectrum ranging from too little pulmonary blood flow due to severe RVOTO (“blue tet”) to moderate pulmonary overcirculation (“pink tet”).

COMMONLY ASSOCIATED CONDITIONS

- May be associated with other syndromes including trisomy 21, Alagille syndrome, fetal alcohol syndrome, and those involving a variety of limb abnormalities.
- Tetralogy of Fallot may also be associated with midline abdominal

defects (e.g., omphalocele) as in the pentalogy of Cantrell.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Heart murmur in the newborn period
- Various degrees of progressive cyanosis
- Paroxysmal cyanosis, especially when crying or during and after physical activity

PHYSICAL EXAM

- Cyanosis may be present at birth or may appear later during infancy or childhood as a result of progressive RVOTO.
- Normal S₁ and single loud S₂ secondary to a more anteriorly located aorta
- Systolic ejection murmur at left upper sternal border secondary to RVOTO

DIAGNOSTIC TESTS & INTERPRETATION

- Electrocardiography
 - Right axis deviation (+90–180 degrees)
 - RVH
- Chest radiograph
 - Right aortic arch (30%)
 - Decreased pulmonary vascular markings
 - Boot-shaped heart (coeur en sabot) with concave main pulmonary artery segment
- Echocardiogram
 - Anterior malalignment VSD
 - Presence of additional VSDs
 - Degree of infundibular stenosis
 - Presence of valvar pulmonary stenosis and/or branch pulmonary artery stenosis
 - Overriding aorta, arch sidedness
 - Coronary artery anatomy
- Cardiac catheterization

- Generally not indicated unless there is concern regarding the branch pulmonary artery anatomy, coronary anatomy, or additional VSDs that need to be defined before surgery

DIFFERENTIAL DIAGNOSIS

- Tetralogy of Fallot should be considered in all infants with a heart murmur and/or various degrees of cyanosis as well as acyanotic infants or children with a history of hypercyanotic episodes.
- Other forms of cyanotic congenital heart disease should be considered, including the following:
 - Double outlet right ventricle (DORV),
 - Transposition of the great arteries (TGAs)
 - Pulmonary atresia with a VSD (PA-VSD).

TREATMENT

MEDICATION

- Hypercyanotic episodes (“tet spells”)
 - The goal is to increase preload and promote pulmonary blood flow.
 - Knee-chest position
 - Intravenous fluid bolus
 - NaHCO_3
 - Oxygen
 - Morphine sulfate (0.1 mg/kg IV or IM)
 - Beta-blocker (esmolol infusion for immediate therapy, propranolol for long-term prophylaxis)
 - Phenylephrine (0.02 mg/kg IV)
 - Polycythemia: oral iron supplement to prevent iron deficiency and microcytosis
 - Subacute bacterial endocarditis (SBE) prophylaxis

SURGERY/OTHER PROCEDURES

- Palliative surgery: Blalock-Taussig systemic-to-pulmonary artery shunt (also known as the Blalock-Taussig-Thomas shunt)
- Corrective surgery: VSD patch closure and right ventricular outflow tract reconstruction

ONGOING CARE

PROGNOSIS

- 35-year survival is approximately 85%.
- More than 90% of children with tetralogy of Fallot are expected to survive to adulthood.
- Higher risk of adverse outcomes in patients with repair at age >3 years.
- There is a higher risk of developmental delay in children with tetralogy of Fallot (as with all congenital heart disease).
- Residual hemodynamic abnormalities are common:
 - Pulmonary insufficiency (with transannular patch repair)
 - Residual RVOTO
 - Right ventricular dysfunction in adulthood due to chronic volume overload
 - Left pulmonary artery stenosis is particularly common in tetralogy of Fallot.
 - Residual VSD
- Conduction abnormalities (e.g., complete heart block, atrial and ventricular tachyarrhythmias)
 - Incidence of sudden death is 2.5% per decade of follow-up and is generally attributed to ventricular arrhythmias
- The need for reintervention (pulmonary valve insertion) increases after the 2nd decade of life.
 - Right ventricular end-diastolic volume >150 mL/m², QRS > 180 ms, history of tachyarrhythmias, RVOTO, exercise intolerance, syncope
 - Surgical versus transcatheter intervention (Melody valve)

COMPLICATIONS

Preoperatively

- Paroxysmal hypoxic episodes (i.e., hypercyanotic episodes, also called tet spell)
- Bacterial endocarditis
- Cerebrovascular accident secondary to cyanosis, polycythemia, and microcytic anemia

Postoperatively

- Right ventricular dysfunction
- Ventricular arrhythmias
- Sudden death (ventricular arrhythmias and/or complete heart block)

CODES

ICD10-CM

Q21.3 Tetralogy of Fallot

FAQ

- Q: What is the etiology of the tet spell?
- A: There is an increase in resistance to flow through the right ventricular outflow tract and/or pulmonary vascular bed that leads to a dramatic decrease in pulmonary blood flow and increased right-to-left shunt at the level of the VSD. Therefore, treatment should be aimed at increasing pulmonary blood flow either by decreasing pulmonary vascular resistance (e.g., oxygen, morphine), increasing systemic vascular resistance (e.g., knee-chest position, phenylephrine), or decreasing dynamic obstruction by decreasing heart rate and thus increasing right ventricular preload (e.g., beta-blockers).
- Q: When is an optimal time for surgical repair of tetralogy of Fallot?
- A: Surgical correction should be guided by symptoms. Progressive hypoxemia or recurrent tet spells indicate a need for surgical intervention. A “pink tet” can be referred for elective repair in early infancy (3–6 months) and before the end of the 1st year of life.

THALASSEMIA

Irina Pateva • Peter de Blank

BASICS

DESCRIPTION

- Thalassemia syndromes are hereditary microcytic anemias that result from mutations that quantitatively reduce globin synthesis.
- Normal hemoglobin is a tetramer of 2 α and 2 β chains:
 - α -Thalassemia: reduced or absent α -globin production
 - β -Thalassemia: reduced or absent β -globin production

GENERAL PREVENTION

Thalassemia can be prevented by identifying and counseling potential parents who can have children with thalassemia. Diagnosis can be made in early pregnancy by chorionic villus sampling.

EPIDEMIOLOGY

- α -Thalassemia: predominantly in Chinese subcontinent, Malaysia, Indochina, and Africa and in African Americans
- β -Thalassemia: Mediterranean countries, Africa, India, Pakistan, Middle East, and China

Genetics

- α -Thalassemia
 - Normally, there are 4 α -globin genes, 2 on each chromosome 16.
 - Most mutations in α -thalassemia are large deletions.
 - Deletions may be in trans conformation (1 deletion on each chromosome, common in African Americans) or cis conformation (2 genes deleted on same chromosome, common in Asians).
 - Hemoglobin Constant Spring is an α -globin gene mutation caused by a point mutation that reduces or eliminates production of α -globin, leading to a more severe phenotype.
 - The 4 α -thalassemia syndromes reflect the inheritance of molecular defects affecting the output of 1, 2, 3, or 4 α genes.
- β -Thalassemia

- Normally, there are 2 β -globin genes, 1 on each chromosome 11.
- Most mutations in β -thalassemia are point mutations.
- Many mutations abolish the expression completely (β^0), whereas others variably decrease quantitative expression (β^+).
- Heterozygous state for β -globin mutation produces β -thalassemia trait.
- Homozygous state produces β -thalassemia major or β -thalassemia intermedia.
- NOTE: Rare dominant β -thalassemia mutations exist, causing ineffective erythropoiesis with a single mutation (due to creation of unstable β -globin variants).

Genotype	Name	Degree of anemia
α -thalassemia		
$\alpha\alpha / \alpha -$	Silent carrier	Asymptomatic
$\alpha - / \alpha -$ or $\alpha\alpha / - -$	α -thalassemia trait	Asymptomatic
$\alpha - / - -$	α -thalassemia intermedia, HbH disease	Moderate to severe
$- - / - -$	α -thalassemia major	Hydrops fetalis
β -thalassemia		
β / β^+ or β / β^0	β -thalassemia trait	Asymptomatic
β / β^0 or β^+ / β^+	β -thalassemia intermedia	Variable, intermittent, or chronic transfusions
β^0 / β^+ or β^0 / β^0	β -thalassemia major	Severe, chronic transfusions

PATHOPHYSIOLOGY

- Decrease in either α - or β -globin synthesis leads to fewer completed $\alpha_2\beta_2$ tetramers produced per RBC, which results in a decrease in intracellular hemoglobin and microcytosis.
- Unpaired globin chains precipitate, resulting in apoptosis of red cell precursors (ineffective erythropoiesis) and damage to the RBC

membrane leading to hemolysis.

- Ineffective erythropoiesis causes hepatosplenomegaly and osseous changes.
- The erythrocyte's lifespan is shortened by hemolysis and splenic trapping.
- Degree of anemia varies depending on the specific gene defect.
- Chronic transfusion therapy and, to a lesser degree, increased absorption of dietary iron in thalassemia major lead to iron accumulation.
- Increased absorption of dietary iron and intermittent transfusions in thalassemia intermedia lead to iron accumulation.
- Iron overload leads to cardiac arrhythmias and congestive heart failure (CHF) that can be fatal, liver inflammation and fibrosis, and endocrinopathies (e.g., diabetes mellitus, hypothyroidism, gonadal failure, osteoporosis).

DIAGNOSIS

HISTORY

- Severe α -thalassemia (4 gene deletion) presents prenatally by ultrasound or at birth with hydrops fetalis and severe anemia.
- Severe β -thalassemia usually presents between 3 and 12 months old, as production of the normal fetal hemoglobin decreases.
- α -Thalassemia syndromes will present with microcytosis in infancy. Hemoglobin H disease may present later, with mild to moderate anemia on screening or after worsening hemolysis related to intercurrent infection.
- Mediterranean, African, or Asian ethnic backgrounds are common in patients with thalassemia.
- Familial history of anemia, long-term transfusions, recurrent iron therapy for presumed iron deficiency anemia, or splenectomy
- Newborn screening varies by state but can contribute to a presumptive diagnosis of α -thalassemia or β -thalassemia major. Abnormal patterns include presence of Hb Barts (consistent with α -thalassemia) or isolated HbF (consistent with β -thalassemia major). Extreme

prematurity and previous blood transfusions can obscure results, and confirmatory testing is required.

PHYSICAL EXAM

- Pallor indicates anemia.
- Heart murmur: Flow murmurs are often heard in significant anemia. Patients with severe anemia may present with CHF.
- Variable degrees of icterus: Hemolysis leads to increased bilirubin production.
- Abnormal facies (frontal bossing and maxillary hyperplasia): facial bone expansion by hypertrophic marrow in poorly transfused patients with β -thalassemia
- Failure to thrive: Related to anemia and energy expended in ineffective erythropoiesis
- Variable degrees of hepatosplenomegaly (or CHF) due to extramedullary hematopoiesis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with RBC indices
 - Mean cell volume (MCV), mean cell hemoglobin (MCH), and mean cell hemoglobin concentration (MCHC) are all decreased in α - and β -thalassemia.
 - RBC volume distribution width (RDW) is usually normal.
 - Peripheral smear may reveal microcytosis, hypochromia, anisocytosis, poikilocytosis, target cells, nucleated RBCs, and/or polychromasia.
 - Hemoglobin 9–12 g/dL in α - or β -thalassemia trait
 - Hemoglobin usually 7–10 g/dL in HbH disease
 - Hemoglobin usually 7–10 g/dL in β -thalassemia intermedia
 - Hemoglobin <7 g/dL in thalassemia major (without transfusions)
- Reticulocyte count: usually mildly elevated in HbH and β -thalassemia intermedia and major
- Indirect bilirubin: may be elevated in severe thalassemia where there is significant red cell destruction
- Hemoglobin electrophoresis

- α -Thalassemia trait (2 defective genes) will have 5–10% Hb Barts (a tetramer of 4 γ chains) at birth, which should be detected on the newborn's screen. This disappears in 1–2 months, after which time the electrophoresis will be normal in α -thalassemia trait.
- β -Thalassemia trait: HbF 1–5%, HbA2 3.5–8%, remainder HbA. The elevated HbA2 will distinguish α - from β -thalassemia trait.
- HbH disease (3 defective α genes): 5–30% HbH (β_4), remainder HbA
- Hydrops fetalis (4 defective α genes): mainly Hb Barts(γ_4)
- β -Thalassemia major (2 defective β genes): HbF 20–100%, HbA2 2–7%. In most cases, little or no HbA is detected, unless recently transfused.
- Iron studies, serum ferritin: useful to help distinguish thalassemia from iron deficiency
- Mentzer Index: MCV/RBC <13 is more likely thalassemia, >13 more likely iron deficiency

DIFFERENTIAL DIAGNOSIS

- Iron deficiency anemia can be distinguished with iron studies.
- Anemia of chronic inflammation (can be distinguished with soluble transferrin receptor assay)
- Lead poisoning

TREATMENT

- Silent carriers (single α gene deletion) and α - and β -thalassemia trait
 - Genetic counseling only
 - Distinguish from iron deficiency microcytosis to avoid excess iron supplementation
- For HbH disease:
 - Folic acid daily
 - Transfusions whenever necessary (aplastic episode, infection)
 - Splenectomy if with evidence of hypersplenism
 - Cholecystectomy if necessary
- For β -thalassemia intermedia:

- Folic acid daily
- No iron supplements
- Transfusions whenever necessary (aplastic episode, infection, acute complication)
- Splenectomy is less commonly performed due to increased risk of thrombosis and pulmonary hypertension.
- Cholecystectomy if necessary
- HbF-inducing agents such as hydroxyurea may be beneficial.
- Monitoring and treatment of iron overload
- β -Thalassemia major
 - Stem cell transplantation (umbilical cord blood or bone marrow) using histocompatible sibling donor can cure the disease and is being used more frequently.
 - Regular transfusions of RBCs every 3–4 weeks to maintain hemoglobin at 9–10 g/dL
 - Chelation therapy: It is important to balance the treatment of iron overload with the dangers of overchelation (toxicity to ears, eyes, bone).
 - Chelation options include the following:
 - ▢ Deferoxamine (SC or IV infusion over 8–24 hours)
 - ▢ Deferasirox (once daily PO chelator). Side effects include GI discomfort, rash, renal failure +/- proteinuria, hepatic failure
 - ▢ Deferiprone (t.i.d. PO chelator), FDA approved for iron overload in thalassemia syndromes. Especially useful for cardiac iron removal. Side effects include arthropathy, GI upset, and agranulocytosis.
 - Folic acid daily
 - Penicillin V potassium oral prophylaxis (125–250 mg b.i.d.) for splenectomized patients
 - Pneumococcus, Meningococcus, and Haemophilus influenzae vaccines before splenectomy and annual influenza A vaccination
 - Cholecystectomy if indicated
 - No iron supplements
 - Genetic counseling for those with any thalassemia syndrome

ALERT

Thalassemia trait is often treated incorrectly as presumptive iron deficiency anemia. Iron studies should be performed to confirm the diagnosis if there is no improvement in hemoglobin level after a few weeks of iron therapy.

ONGOING CARE

For patients with thalassemia major and intermedia:

- Serum ferritin, blood chemistries, and liver function tests should be monitored.
- Annual monitoring for cardiac complications (echocardiogram, EKG) and endocrine function is recommended.
- Liver iron quantitation by biopsy, MRI, or other techniques are necessary intermittently to quantitate the status of iron overload accurately.
- Newer cardiac T_2^* MRI techniques to assess the degree of cardiac iron loading, which correlates with risk of cardiac complications
- Annual audiologic and ophthalmologic screening is recommended for persons receiving chelation therapy (to monitor for chelator toxicity).
- Dual-energy x-ray absorptiometry (DEXA) scan or bone peripheral quantitative computed tomography (PQCT) annually

PROGNOSIS

- Life expectancy for patients with β -thalassemia major has improved over the years because of regular transfusions and chelation therapy.
- Bone marrow transplant from a histocompatible sibling donor may be curative.

COMPLICATIONS

Most complications occur in patients with β -thalassemia intermedia or major and can be divided into 2 categories:

- Complications related to anemia/ineffective erythropoiesis and hemolysis (seen mostly in thalassemia intermedia):
 - Skeletal abnormalities secondary to hyperplastic marrow
 - Osteopenia, osteoporosis, and fractures
 - Growth retardation

- Extramedullary hematopoiesis
- Leg ulcers
- CHF owing to severe anemia
- Thrombophilia, particularly in thalassemia intermedia after splenectomy
- Hypercoagulability: DVT, PE
- Gallstones from hemolysis
- Pulmonary hypertension
- Allo- or autoimmunization with RBC antibodies
- Complications of iron overload:
 - Cardiac abnormalities: pericarditis, arrhythmias, CHF
 - Hepatic abnormalities: cirrhosis and liver failure (onset usually after 2nd decade)
 - Endocrine disturbances: delayed puberty, growth retardation, diabetes mellitus, hypothyroidism, hypoparathyroidism
 - Infection: particularly *Yersinia* species

CODES

ICD10

- D56.9 Thalassemia, unspecified
- D56.0 Alpha thalassemia

- D56.1 Beta thalassemia

FAQ

- Q: Is prenatal testing available?
- A: Yes.
- Q: In a transfused patient, when does iron overload become a problem and when is chelation started?
- A: Usually after the age of 3–4 years.
- Q: At what age should monitoring for cardiac iron overload begin in β -thalassemia major?
- A: 6–10 years of age.

THORACIC INSUFFICIENCY SYNDROME

Stamatia Alexiou • Robert Campbell • Oscar H. Mayer

BASICS

DESCRIPTION

- Thoracic insufficiency syndrome (TIS) is the inability of the thorax to support normal respiration or lung growth.
- Patients are skeletally immature with varied anatomic deformities that often include the following:
 - Flail chest syndrome: rib absence due to a congenital malformation or chest wall tumor resection, rib instability in cerebrocostomandibular syndrome, and others
 - Constrictive chest wall syndrome, including rib fusion and scoliosis: VACTERL association, chest wall scarring from radiation treatment, windswept deformity of the chest from progressive scoliosis, and others
 - Hypoplastic thorax syndrome including Jeune syndrome, Ellis–van Creveld syndrome, Jarcho-Levin syndrome, or spondylothoracic dysplasia (STD)
 - Scoliosis (without rib anomaly) or neuromuscular scoliosis
- The recognizable anatomic abnormalities often occur before respiratory insufficiency, with patients compensating for low lung volumes and poor respiratory mechanics by increasing their respiratory rate.
- Subsequently decreased activity and chronic respiratory insufficiency

PATHOPHYSIOLOGY

- The thorax is the respiratory pump, requiring adequate diaphragm (abdominal) and chest wall movement. Limitation in resting lung volume (functional residual capacity [FRC]) and/or the ability of the rib cage to expand during respiration can significantly alter respiratory function and cause TIS.
- The window of rapid lung growth and alveolar development is during the first 3 years of life.
 - Although alveolar development is felt to continue up until 5 or 8

years of age, recent evidence suggests that it can occur through childhood and adolescence.

- Without concurrent thoracic growth, however, the lung cannot grow normally.
- Growth of the thoracic pump is also necessary so that the respiratory system can continue to meet a patient's metabolic demands.
 - Thoracic spinal height (TSH) directly contributes to thoracic volume and lung volume.
 - At birth, the TSH is 13 cm normally, then during the first 5 years of life, thoracic spinal growth is 1.4 cm/year, 0.6 cm/year from 5 to 10 years, and 1.2 cm/year from 10 to 18 years of age.
 - A thoracic length of 22 cm at skeletal maturity, the normal TSH of a 10-year-old, appears to be the minimum height necessary for normal respiration.
- Complex scoliosis with spinal rotation and lordosis into the convex hemithorax, the “windswept” deformity of the thorax, can further restrict lung volume.
- In neuromuscular disorders, unilateral caudal rotation of the ribs, the “collapsing parasol deformity,” typically occurs on the convex side of the scoliosis and may also severely narrow the thorax, worsen thoracic mechanics, and further increase work of breathing.

ETIOLOGY

- The etiologies of TIS can be grouped into unilateral or bilateral volume depletion deformities (VDDs) of the thorax that reduce the volume available for the lungs in certain subsets of patients with rare syndromes. This causes primary TIS or deformity of the chest from scoliosis.
 - Type I: absent ribs and scoliosis
 - Type II: fused ribs and scoliosis
 - Type III: hypoplastic thorax
 - Type IIIa: foreshortening (Jarcho-Levin)
 - Type IIIb: narrowed (Jeune)
- In addition, progressive congenital scoliosis without rib anomalies can result in TIS from a variant of type II VDD of the thorax.
- Type IIIB VDD of the thorax can also develop in neurogenic scoliosis,

as in spinal muscular atrophy with marked intercostal muscle weakness.

- Spinal deformity, such as lumbar kyphosis in spina bifida, collapses the torso into the pelvis, raising abdominal pressure blocking diaphragm excursion, and causing secondary TIS.

COMMONLY ASSOCIATED CONDITIONS

- Congenital renal abnormalities can occur in 25–30% of congenital scoliosis.
- Cervical spine abnormalities, causing stenosis and proximal instability
- Spinal cord abnormalities, including spinal cord syrinx and tethered cord, which are especially prevalent in meningocele
- Jeune syndrome
 - Congenital renal abnormalities
 - Hepatic fibrosis
 - Cervical spinal stenosis in 60% of cases
 - Retinal dystrophy
- Ellis–van Creveld syndrome: tracheomalacia
- STD: congenital diaphragmatic hernia
- Cerebrocostomandibular syndrome, Pierre Robin sequence: micrognathia
- Severe tracheal compression and narrowing can occur in advanced scoliosis or severe anteroposterior narrowing.

DIAGNOSIS

HISTORY

- Prenatal ultrasound showing a hypoplastic thorax
- Onset of clinical scoliosis
- Onset of respiratory symptoms:
 - Relative exertional intolerance
 - Ineffective cough resulting in recurrent respiratory infections
 - Need for supplemental oxygen or noninvasive ventilatory support (bilevel positive airway pressure [BLPAP] or continuous positive airway pressure [CPAP])

- Progression of the spinal or chest wall deformity
- Signs and symptoms:
 - Exertional limitation relative to age and gross motor capability
 - Recurrent respiratory illnesses
 - Balance problems
 - Back pain

PHYSICAL EXAM

- Comprehensive respiratory examination:
 - Assessment of work of breathing including accessory muscle use and thoracoabdominal asynchrony
 - Qualitative assessment of chest wall compliance and motion
 - Symmetry of aeration during auscultation
- Thoracic circumference is usually found to be <75% of head circumference at birth.
- Thumb excursion test: The palms of each hand are loosely positioned posteriorly over each side of the chest with the thumbs aligned on either side of the spinal column, and relative excursion is assessed by the amount of lateral thumb movement.
- Assessment for rib hump by having the patient bend forward while standing upright.
- Measure of liver size to evaluate for hepatomegaly and possible cor pulmonale

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum bicarbonate as an indirect assessment for chronic hypoventilation
- Arterial blood gas if there is a concern for acute respiratory failure
- Liver function testing to assess for coincident liver failure
- Brain-type natriuretic peptide to help assess for progressive heart strain or failure
- Genetic testing as indicated based on suspected underlying condition

Imaging

- Standing anteroposterior and lateral radiographs to establish severity of scoliosis in the sagittal and coronal planes; bending films to establish

the flexibility of the curve

- Chest CT scan with 5-mm cuts noncontrast with optimal pediatric settings to minimize radiation, with spinal and chest wall reconstruction to assess 3-dimensional anatomy
- MRI of spine and spinal cord to look for spinal cord abnormality
- Dynamic MRI to assess motion of chest wall, diaphragm, and abdomen
- Additional radiologic testing may be employed in certain cases (e.g., ventilation–perfusion scan of the lungs to quantify right vs. left functional perfusion asymmetry)
- Echocardiogram to evaluate for cor pulmonale and pulmonary hypertension

Diagnostic Procedures/Other

- Pulmonary assessment: baseline and subsequent pulmonary function testing at each clinic visit
 - Dynamic lung volumes and flows
 - Forced vital capacity (FVC)
 - Timed expiratory volume (forced expiratory volume in 0.5 or 1 second) and the ratio to FVC
 - Forced expiratory flow between 25% and 75% of vital capacity (FEF25–75%)
 - Static lung volume measurements
 - Total lung capacity (TLC), functional residual capacity (FRC), residual volume (RV), and RV/TLC
 - Maximal inspiratory (MIP) and maximal expiratory pressure (MEP) measurements
- Specialized measurements of respiratory system compliance (stiffness) and partitioned measurements of chest wall and lung compliance
- Pulse oximetry and end-tidal carbon dioxide measurement
- Overnight polysomnography to assess the degree of underlying respiratory insufficiency and need for supplemental oxygen or noninvasive ventilation
- Exercise testing adapted for the capabilities of the patient (6-minute walk test) can be used to assess for exertional limitation.
- If there is significant thoracospinal abnormality and certainly if there is other dysmorphology, a genetics assessment is very helpful to

comprehensively assess for other comorbidities and help anticipate future problems.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Bracing and halo-gravity traction can be used as a temporizing procedure and at best has been shown to control some forms of scoliosis or partially improve, but not correct, scoliosis.
- Physical and occupational therapy

SURGERY/OTHER PROCEDURES

- The goal of surgical treatment is to stabilize the chest and spine in order to support normal growth until skeletal maturity is attained, at which point procedures such as a spinal fusion can be considered.
- Vertical expandable prosthetic titanium rib (VEPTR) expansion thoracoplasty techniques enable 5 types of acute thoracic reconstructions to handle each of the subtypes of TIS.
 - The procedure can be performed as early as 4–6 months of age to exploit the growth potential of the developing lungs and provide additional thoracic volume and compensatory lung growth.
 - After implantation to stabilize the initial thoracospinal reconstruction, it can then be expanded about every 6 months commensurate with patient growth until skeletal maturity.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- After TIS surgery, patients are followed with radiographs at regular intervals.
- Pulmonary follow-up should include careful assessment for respiratory insufficiency.
- Longitudinal measure of lung function and growth to demonstrate an improvement in respiratory status or lung function, or at the very least

a decrease in the rate of decline, in the most severely affected patients

PROGNOSIS

- Prognosis will vary depending on the underlying cause of TIS, severity of respiratory insufficiency, and the age of the patient at surgery.
 - In infants and toddlers, however, there may be preservation of lung growth, but there has not been evidence to support regaining lung function that has been lost.
 - The expectation in infancy would be for growth preservation and an increase in lung volume above the preoperative value as a percent of predicted. There does appear to be an inverse relationship between the age of the patient at the time of surgery and the level of positive impact of VEPTR insertion on lung function.
 - In school-aged and older children, lung volume remains stable.
 - For older patients near skeletal maturity, the focus is chest wall reconstruction, spinal stabilization, and stabilization in pulmonary function.
- Jeune syndrome is one of the more severe forms of TIS, with 60–70% mortality in early infancy from respiratory failure. However, after VEPTR insertion, there has been a 50% decrease in mortality.
- Of those patients with TIS due to an STD, 47% die in infancy from respiratory complications and pulmonary hypertension. VEPTR treatment of STD remains controversial.
- Improved quality of life following VEPTR insertion

COMPLICATIONS

- In the immediate postoperative period—wound infection, skin slough, and bleeding
- Implant-related complication such as device breakage or dislodgement is uncommon.
- Decreased chest wall compliance
- Neurologic complications are rare.

THROMBOSIS

Char Witmer

BASICS

DESCRIPTION

Pathologic arterial or venous intravascular occlusion secondary to abnormal thrombus formation.

The following are common thrombotic events:

- Deep venous thrombosis (DVT): involves large systemic veins outside the central nervous system (CNS)
- Cerebral sinovenous thrombosis (CSVT): involves intracranial venous sinuses
- Ischemic stroke: CNS arterial occlusion with infarction of brain tissue
- Intracardiac thrombosis: mural, valvular, or foreign body associated
- Femoral artery thrombosis: can be associated with vessel catheterization
- Renal vein thrombosis: commonly in the neonatal period; may be unilateral or bilateral
- Myocardial infarction: Kawasaki disease, antiphospholipid antibody syndrome or with severe familial hypercholesterolemia
- Budd-Chiari syndrome: thrombosis of the hepatic vein
- Portal vein thrombosis

EPIDEMIOLOGY

- Incidence of venous thrombosis in children is estimated at 4.9 per 100,000 per year.
- Age distribution is bimodal; peak rates are found in the neonatal and adolescent age groups.
- Idiopathic thrombosis is rare in children.
- >90% of pediatric venous thrombosis is associated with additional risk factors.
- Central venous lines are the most common risk factor for venous thrombosis in children.

RISK FACTORS

- Neonatal
 - Prematurity
 - Maternal diabetes
 - Umbilical catheters or other central lines
 - Sepsis
 - Polycythemia
 - Perinatal asphyxia
- Malignancy/bone marrow disorders
 - Leukemia (hyperleukocytosis, acute promyelocytic leukemia)
 - Myeloproliferative disorders
 - Paroxysmal nocturnal hemoglobinuria
- Medications
 - L-Asparaginase
 - Oral contraceptives (with estrogen)
 - Heparin-induced thrombocytopenia
 - Steroids
- Anatomic
 - Indwelling catheters
 - Congenital heart disease
 - Prosthetic heart valves
 - Intracardiac baffles
 - Tumor compression
 - Atresia of the inferior vena cava
 - Thoracic outlet obstruction (Paget-Schroetter syndrome)
 - May-Thurner syndrome (compression of the left iliac vein by the right iliac artery)
- Miscellaneous
 - Infection
 - Trauma
 - Surgery
 - Obesity
 - Prolonged immobilization or paralysis
 - Dehydration
 - Antiphospholipid syndrome

- Inherited prothrombotic state
- Risk factors/conditions specific for arterial disease
 - Kawasaki disease
 - Takayasu arteritis
 - Hyperlipidemia
 - Antiphospholipid syndrome

COMMONLY ASSOCIATED CONDITIONS

- Nephrotic syndrome
- Inflammatory disorders
- Liver disease
- Sickle cell disease
- Diabetes mellitus

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other disorders that cause extremity swelling:
 - Low albumin
 - Obstruction of venous flow by a catheter without thrombus formation
 - Hemihypertrophy
- A high hematocrit in neonates can make the cerebral veins appear “dense” on a head CT and be misinterpreted as thrombosis.
- Arterial stroke mimics: complex migraine, demyelinating disease, metabolic disease, tumor

ALERT

- Normal ranges for coagulation tests are age dependent: Diagnosing an inherited deficiency in any of the anticoagulant proteins can be difficult in the neonatal period. Repeat testing at 6–12 months of age is necessary.
- Consumption can occur during acute thrombosis; therefore, low levels of the anticoagulant proteins must be repeated.
- Warfarin will decrease the levels of protein C, protein S, and clotting factors II, VII, IX, and X.

APPROACH TO THE PATIENT

- Phase 1
 - Perform complete history and physical exam.
 - Establish diagnosis using the appropriate radiographic study.
- Phase 2
 - Send initial laboratory studies (CBC, PT/aPTT, D-dimer, β -hCG testing in postmenarchal females).
 - If deemed safe, begin anticoagulation therapy with unfractionated heparin or low-molecular-weight heparin.
 - Patients with life- or limb-threatening thrombosis may require thrombolysis.
- Phase 3
 - If appropriate, consider sending a complete lab workup for a hypercoagulable state; outpatient anticoagulation; follow thrombosis radiologically.

HISTORY

- Presence of risk factors previously listed
- Family history of thrombosis
- Personal history of thrombosis
- Neonatal seizure: common and often the only presenting sign for CSVT or arterial ischemic stroke in neonates

PHYSICAL EXAM

- Extremity DVT: unilateral swelling/edema of a limb
- Thrombosis of the inferior vena cava: bilateral lower extremity edema of a limb
- Superior vena cava syndrome: plethoric, swollen head and neck
- Arterial thrombosis: pale extremity with decreased perfusion/pulses
- Renal vein thrombosis: abdominal mass in neonate with hematuria
- Pulmonary embolism: tachypnea, shallow respirations
- Peripheral venous collateral formation: superficial dilated cutaneous veins
- Postthrombotic syndrome: chronic discoloration (darkening) of the skin, ulcerations, pain, intermittent swelling

DIAGNOSTIC TESTS & INTERPRETATION

- The following tests can be used to investigate for a prothrombotic state:
 - Factor V Leiden mutation analysis
 - Prothrombin 20210A mutation analysis
 - Lupus anticoagulant screen (dilute Russell viper venom time, aPTT)
 - Anticardiolipin antibodies (IgG, IgM)
 - Anti- β 2-glycoprotein antibodies (IgG, IgM)
 - Protein C activity
 - Protein S activity
 - Antithrombin activity
 - Homocysteine
 - Lipoprotein(a)
 - Factor VIII activity

Imaging

Radiologists should be consulted for choosing the best imaging study for diagnosis and follow-up.

- Contrast angiography: gold standard, but invasive and sometimes technically difficult to perform in small children
- Ultrasound: most commonly used imaging study because of noninvasiveness, absence of radiation, and ability to be performed at the bedside
- In the diagnosis of upper extremity-related DVT, often a combination of ultrasound and venography is necessary:
 - Compression ultrasound of the upper central veins may be impeded by the distal end of the clavicle.
 - Venography has poor sensitivity for diagnosing thrombosis of the internal jugular veins.
 - Recommended approach for diagnosis of an upper extremity thrombosis is to start with ultrasound and proceed to venography if the ultrasound is normal and there is a high clinical suspicion for thrombosis.
- Echocardiogram may be useful in evaluating atrial thrombi, which may result from central venous catheters.
- Pulmonary angiography, ventilation–perfusion scans, and spiral CT scans are the imaging studies used for the diagnosis of pulmonary embolism, although none of these have been studied in children.

- In patients with a pulmonary embolism, it is important to look for a source of thrombosis in the upper and lower extremities.
- Other diagnostic imaging options include CT or MRV:
 - Noninvasive
 - Sensitivity and specificity not known
 - May be helpful in evaluating proximal thrombosis
- For diagnosis of CSVT, the most sensitive imaging study is a brain MRI with venography.

TREATMENT

- Unfractionated heparin:
 - Given as a bolus followed by an infusion, adjusted to maintain the aPTT at 1.5–2.5 times baseline
 - Younger children require higher doses of heparin to achieve a therapeutic level secondary to physiologically decreased antithrombin levels.
- Low-molecular-weight heparin
 - More predictable dose response
 - Given subcutaneously twice a day
 - Equivalent in efficacy to unfractionated heparin in the acute management of uncomplicated DVT
 - Renal clearance
- Thrombolytic therapy
 - Recombinant tissue plasminogen activator
 - May be given systemically or locally
 - High risk of bleeding
- Warfarin
 - Oral anticoagulant
 - Initially started when a patient is already receiving a form of heparin. The heparin is discontinued when the warfarin is in the therapeutic range.
 - Warfarin is adjusted to maintain an international normalized ratio (INR) of 2–3 for treatment of DVT.
 - Used for outpatient management

- Aspirin
 - Beneficial in stroke and other arterial events
 - Irreversibly inhibits platelet function

GENERAL MEASURES

- Therapy for acute thrombosis and long-term management is individualized.
- Consult a pediatric hematologist or someone with expertise in pediatric anticoagulant therapy.

ONGOING CARE

COMPLICATIONS

- Inferior vena cava filters are used to prevent pulmonary embolism. There are limited pediatric studies. They should only be considered in the setting of a lower extremity DVT with a contraindication to anticoagulation (i.e., recent extensive surgery or active bleeding) or if a patient experiences a pulmonary embolism while on therapeutic anticoagulation. Temporary filters should be placed and removed as soon as possible, as they are a nidus for further thrombosis formation. The risk/benefit ratio needs to be considered individually.
- Vary depending on the location and severity of the thrombosis
- In acute DVT, pulmonary embolism is the most significant complication.
- Recurrent thrombosis and postthrombotic syndrome are common chronic complications.
- In arterial thromboembolic disease, the ischemic injury to the involved organ determines the acute and long-term complications.

ALERT

- Central venous catheter–related thrombosis may be subtle despite extensive damage to the venous system. Recurrent line infection, line occlusion, and prominent venous collaterals on the chest suggest upper extremity DVT. The long-term consequences of this are not known.
- Warfarin can cause purpura fulminans if started in a nonheparinized patient.

- I82.409 Acute embolism and thrombosis of unspecified deep veins of unspecified lower extremity
- G08 Intracranial and intraspinal phlebitis and thrombophlebitis

FAQ

- Q: When is it appropriate to use low-molecular-weight heparin rather than unfractionated heparin?
- A: There are several advantages to low-molecular-weight heparin. The pharmacokinetics is predictable, and frequent monitoring is not necessary. It is administered subcutaneously, not intravenously. Alternatively, low-molecular-weight heparin cannot be completely reversed with protamine and it is renally cleared.
- Q: When is it appropriate to use thrombolytic therapy?
- A: If a thrombus is high risk (i.e., limb-threatening), thrombolytic therapy can be used. Intracranial bleeding, other active bleeding, and

surgery within 7 days are contraindications to thrombolytic therapy. For arterial thrombotic events, thrombolytic therapy is often the treatment of choice because of the rapid resolution of the clot and restoration of blood flow.

- Q: What precautions should be taken for invasive procedures and for athletics when a patient is on anticoagulant therapy?
- A: Lumbar punctures, arterial punctures, and surgical procedures should be avoided. If they are necessary, then the anticoagulant should be reversed or held prior to the procedure. While on anticoagulation, participation in contact sports such as football, karate, and boxing is discouraged.

TICK FEVER

Gordon E. Schutze

BASICS

DESCRIPTION

- Tick-borne relapsing fever (TBRF) and Colorado tick fever (CTF) will be discussed in this chapter.
- TBRF is a vector-borne infection characterized by recurrent fevers caused by several species of spirochetes of the genus *Borrelia*. In the United States, the vector for TBRF is the soft-bodied tick of the genus *Ornithodoros*.
- CTF is a febrile, usually benign, systemic illness caused by coltivirus in the family Reoviridae and transmitted by a tick bite. Although the primary reservoir for infection is the *Dermacentor andersoni* tick (wood tick), the causative organism has been isolated from many other ticks.

EPIDEMIOLOGY

- TBRF
 - Reported in almost all western states up to and including Texas
 - Sites of high exposure include limestone caves and forested areas.
 - Most cases present during June through September; ~450 cases were reported in the United States between 1977 and 2000.
- CTF
 - Human infections typically occur in areas where *D. andersoni* is found: Western United States and southwestern Canada at elevations of 4,000–10,000 feet
 - Cases usually occur between May and June when adult ticks are most active.
 - There are only a very small number of cases reported annually the United States.
 - Infection is more common in males and the median age of those infected is 43 years, but 25% of cases occur in those younger than 20 years.

- Transfusion-related and laboratory-associated infection are rare but have been reported.

GENERAL PREVENTION

- Both of these infections can be prevented by avoidance or protection from the tick vector.
- Light-colored, long-sleeved shirts and pants should be worn when tick-infested areas cannot be avoided.
- Permethrin should be applied to clothing and diethyltoluamide (DEET) and picaridin applied to exposed skin to help repel ticks.
- Persons who enter endemic areas should inspect themselves and each other frequently for adherent ticks.
- Avoid rodent-infested homes in endemic areas. If necessary, rodent-nesting materials should be removed with protective gloves.
- Confirmed cases should be reported to health authorities so that control measures can be instituted.

PATHOPHYSIOLOGY

- TBRF
 - Ornithodoros ticks typically feed at night and for short periods.
 - When an Ornithodoros tick feeds on a natural host (e.g., squirrels, chipmunks, and rodents), Borrelia subsequently invade all tissues of the tick including the salivary glands. Ticks in the larval stage are unlikely to be infectious.
 - Borrelia is transmitted to humans when the tick takes a blood meal and then detaches itself. Transmission is possible within minutes of the start of a blood meal. After transmission, spirochetemia develops, resulting in systemic symptoms.
 - Between episodes of spirochetemia, organisms likely persist in the CNS, bone marrow, liver, and spleen.
 - Pathologic findings in humans include petechial hemorrhages on visceral surfaces, hepatosplenomegaly, and a histiocytic myocarditis.
- CTF
 - Ticks are infected during their larval stage when they feed on viremic, intermediate hosts such as chipmunks, ground squirrels,

and porcupines.

- Once infected, ticks remain infected for life (as long as 3 years).
- Human infection typically takes place when the adult *D. andersoni* wood tick attaches and ingests a blood meal from an incidental human host.
- CTF virus is thought to infect hematopoietic cells, causing leukopenia and prolonged viremia for up to 3–4 months.

ETIOLOGY

- TBRF is caused by several species of spirochetes in the genus *Borrelia*. *Borrelia hermsii*, *Borrelia turicatae* and *Borrelia parkeri* are the most common species found in the United States.
- CTF is caused by CTF virus, a double-stranded RNA coltivirus in the family Reoviridae.

DIAGNOSIS

HISTORY

- Both TBRF and CTF most commonly present with high fever, headache, myalgias, and chills. A thorough history documenting recent travel and a description of the fever curve are necessary to help direct the clinician to either diagnosis.
- TBRF
 - Fevers present after a mean incubation period of 5–7 days (range 4–18 days). Symptoms resolve after 3–6 days but then recur within 7 days. Relapses may be less severe than the initial episode with prolonged asymptomatic intervals. Average number of relapses is 3–5 in untreated patients.
 - Patients commonly complain of headache, myalgia, nausea, vomiting, arthralgias, and abdominal pain. Less commonly, patients are symptomatic with confusion, dry cough, diarrhea, photophobia, rash, dysuria, or hepatosplenomegaly.
 - Patients rarely are aware of a recent tick bite.
- CTF
 - CTF has a usual incubation period of 3–4 days (range 0–14 days):

- In ~50% of patients, fever will present in a “saddleback” pattern. The fever persists for 2–3 days with resolution for 2–3 days. Fever then recurs and lasts for another 2–3 days. Some patients will have a 3rd febrile period.
- Patients may complain of lethargy, photophobia, retro-orbital pain, and conjunctival injection.
- Less commonly, patients will have gastrointestinal symptoms, pharyngitis, nuchal rigidity, and a rash.
- Unlike TBRF, 90% of patients presenting with CTF will have a previous history of tick exposure.

PHYSICAL EXAM

The presentation for TBRF and CTF are varied. High fevers (39–41°C) are common to both. Additional findings for each may include the following:

- TBRF
 - Elevated pulse and BP are common.
 - Tender hepatosplenomegaly with jaundice
 - Nuchal rigidity suggesting meningitis.
 - Gallop on cardiac auscultation suggesting underlying myocarditis
 - A macular rash starting on the trunk that becomes generalized and or petechial in nature
 - Neurologic deficits are less common but can include delirium, cranial nerve deficits (7th or 8th nerve palsy), and visual impairment from iridocyclitis.
- CTF
 - A small, red painless papule may be seen.
 - A maculopapular rash with petechial lesions has been reported in ~10% of cases.
 - Pharyngitis is reported in 20% of cases.
 - Hepatosplenomegaly has been found in some patients.
 - Nuchal rigidity and delirium are rare but, if present, suggest meningitis or encephalitis.

DIAGNOSTIC TESTS & INTERPRETATION

- TBRF
 - The diagnosis can be readily made by identification of loosely

coiled spirochetes on thick and thin smears of the peripheral blood. Blood samples taken at the time of fever have the highest yield.

- Increased sensitivity can be obtained by examining acridine orange–stained preparations of dehemoglobinized thick smears or buffy coat preparations.
 - The organism can only be cultured on special culture medium. Intraperitoneal inoculation of mice with the patient's blood can lead to spirochetemia in the mice.
 - Multiple serologic antibody studies exist, including direct and indirect immunofluorescence, ELISA, and immunoblot analysis:
 - A 4-fold rise in titers between acute and convalescent studies is considered confirmatory.
 - These studies may have false-positive reactions in patients with prior spirochete infections such as Lyme disease.
 - Polymerase chain reaction (PCR) analysis can be useful in identifying the causative organism but is not readily available.
 - Other nonspecific laboratory findings may include leukocytosis, anemia, thrombocytopenia, unconjugated hyperbilirubinemia, elevated hepatic transaminases, and proteinuria.
 - If myocarditis is present, an electrocardiogram can reveal abnormalities such as a prolonged corrected QT interval.
 - In cases complicated by meningitis, the CSF will typically have moderately elevated protein and a mononuclear pleocytosis.
- CTF
 - Leukopenia is a hallmark of this illness.
 - Direct immunofluorescent examination of blood smears for intraerythrocytic viral antigen is a rapid approach to the diagnosis.
 - PCR testing and viral cultures are available in certain laboratories. PCR testing is the most sensitive and timely approach for diagnosing acute infection.
 - Various techniques (e.g., complement fixation, indirect immunofluorescence, EIA, and Western blot) have been used to establish a serologic diagnosis:
 - Serologic testing for antibody presence is not diagnostic in the acute phase because antibodies are slow to rise. Presence of a 4-

fold rise in neutralizing antibody titers at >2 weeks after onset can be confirmatory.

- ▣ Associated laboratory findings include leukopenia and thrombocytopenia.
- In patients with meningitis or encephalitis, CSF studies may also reveal elevated protein and a lymphocytic pleocytosis.

DIFFERENTIAL DIAGNOSIS

- TBRF and CTF are similar clinically. The presence of biphasic or relapsing fever along with a history of travel to an area where appropriate vectors are found are helpful clues in diagnosing either disease. Leukopenia and a history of a tick bite may differentiate CTF from TBRF. TBRF and CTF may be misdiagnosed as influenza or enteroviral infections, especially with the 1st febrile episode.
- Other infectious illnesses that may present with recurrent fevers include yellow fever, dengue fever, lymphocytic choriomeningitis, brucellosis, malaria, leptospirosis, rat bite fever, and chronic meningococcemia. The patient's travel history and animal exposure should help differentiate among some of these diagnoses.

TREATMENT

MEDICATION

- TBRF
 - The treatment of choice is oral tetracycline/doxycycline for 7–10 days. Children <8 years of age and pregnant women should receive erythromycin or penicillin.
 - Newer macrolides may be effective but are not routinely recommended.
 - In >50% of cases, treatment results in a Jarisch-Herxheimer reaction (severe fevers, rigors, diaphoresis, and hypotension) related to rapid clearing of the spirochetemia. Close observation, IV fluids, and good supportive care are important in treating possible reactions.
 - Some experts support the use of an initial single dose of oral penicillin V potassium (7.5 mg/kg) or IV penicillin G (10,000 U/kg

given over 30 minutes) in patients presenting with systemic symptoms. It is thought that this initial dose of penicillin leads to gradual clearance of spirochetes, decreasing the risk of the Jarisch-Herxheimer reaction. These patients should then receive a 10-day course of tetracycline or erythromycin because penicillin has been associated with an increased rate of relapse.

- Single-dose tetracycline or erythromycin has been successful for the treatment of louse-borne epidemic relapsing fever in Ethiopia.
- CTF
 - There is no specific therapy for patients with CTF, as the treatment is primarily supportive.

ONGOING CARE

PROGNOSIS

- TBRF
 - Generally responds rapidly to appropriate antibiotic therapy
 - Mortality in patients treated appropriately is thought to be <1%.
- CTF
 - Usually a self-limiting illness without sequelae
 - Death is rare but has been reported in children with generalized bleeding likely secondary to thrombocytopenia; thus, thrombocytopenia should be monitored closely.
 - Prolonged weakness may persist for ≥ 3 weeks and is more likely in those patients >30 years old.

COMPLICATIONS

- TBRF
 - May be associated with splenic rupture, diffuse histiocytic interstitial myocarditis, hepatitis, pneumonia, ARDS, and iridocyclitis
 - CNS complications include meningitis, meningoencephalitis, and focal deficits such as cranial nerve palsy.
 - In utero infection may result in fetal loss or severe neonatal infection.

- CTF
 - Complications are rare but most commonly occur in children.
 - May lead to aseptic meningitis, encephalitis, myocarditis, pneumonitis, hepatitis, hemorrhage, and epididymo-orchitis

CODES

ICD10

- A68.1 Tick-borne relapsing fever
- A93.2 Colorado tick fever

FAQ

- Q: When should a clinician suspect tick fever?
- A: A history of recurring or relapsing fever in the appropriate epidemiologic setting (such as travel history to the western parts of the United States, summertime illness, history of tick exposure) should

raise the possibility of a tick fever.

TICS

Rebecca K. Lehman

BASICS

DESCRIPTION

- A tic is a sudden, repetitive, stereotyped, involuntary movement (e.g., blinking, grimacing) or vocalization (e.g., throat clearing, sniffing). Tics can be further classified as simple (e.g., nose twitching, grunting) or complex (e.g., hand gestures, jumping, echolalia). Tics characteristically change in anatomic location, frequency, type, complexity, and severity over time, although each tic has a stable appearance from one occurrence to the next. Most individuals are able to suppress their tics for brief periods of time, and some endorse having premonitory sensory urges that precede their tics. Tics typically abate during sleep but can persist in some cases.
- DSM-5 classification of tic disorders:
 - Tourette syndrome (TS): Both ≥ 2 motor and ≥ 1 vocal tics have been present at some time, although not necessarily concurrently; tics have been present for >1 year since first tic onset (regardless of the duration of tic-free periods); onset <18 years
 - Persistent (chronic) motor or vocal tic disorder: ≥ 1 motor or vocal tics but not both; tics have been present for >1 year since first tic onset; onset <18 years
 - Provisional tic disorder: ≥ 1 motor and/or vocal tics; tics have been present for <1 year since first tic onset; onset <18 years
 - Other specified tic disorder: tics causing clinically significant distress or impairment but not meeting the full criteria for a tic disorder. Provider should specify the atypical feature(s), for example, “with onset after age 18 years.”
 - Unspecified tic disorder: as above, but provider chooses not to specify the reason that full criteria for a tic disorder are not met (e.g., there is insufficient information to make a more specific diagnosis)

- When there is evidence of an underlying organic etiology, a diagnosis of “other specified tic disorder” should be used.
- Pediatric autoimmune neuropsychiatric disorder associated with Streptococcus (PANDAS): a controversial entity first described in 1998. In theory, group A β -hemolytic streptococcal (GABHS) infection triggers antibodies that cross-react with the basal ganglia and cause obsessive-compulsive disorder (OCD) symptoms and/or tics in some individuals. The National Institute of Mental Health defines PANDAS as follows:
 - Presence of OCD and/or a tic disorder
 - Prepubertal onset
 - Sudden, explosive onset of symptoms and a course of dramatic exacerbations and remission
 - Temporal relationship between symptom onset and exacerbations and GABHS infections
 - Presence of neurologic abnormalities (hyperactivity, choreiform movements, tics) during exacerbations
 - These diagnostic criteria do not always prove helpful in distinguishing PANDAS from other “standard” tic disorders. The high incidence of GABHS infections and high prevalence of asymptomatic carriers make it difficult to prove a link between GABHS infection and tics.
- Other autoimmune neuropsychiatric conditions with less restrictive diagnostic criteria have been proposed, including Pediatric Acute-Onset Neuropsychiatric Syndrome (PANS) and Childhood Acute Neuropsychiatric Symptoms (CANS).

EPIDEMIOLOGY

- Described in almost all ethnic groups
- Affects males > females
- Typical onset is between ages 5 and 7 years.

Prevalence

- The prevalence of chronic tics and TS in school-age children is 3–6% and 0.1–1%, respectively.
- Transient tics occur in 20–25% of children.

RISK FACTORS

Genetics

No single gene has been associated with tics or TS; however, the family history is often positive for tics. The prevalence of TS in 1st-degree relatives is 10 times that in the general population.

GENERAL PREVENTION

Tics cannot be prevented, but educating patients, families, and school personnel about tics can minimize their impact. Aggressive management of comorbid conditions strongly influences patient outcomes.

PATHOPHYSIOLOGY

The pathophysiology underlying tics and TS is not completely understood but is thought to involve abnormal dopamine neurotransmission within the basal ganglia. Evidence also implicates problems with serotonin, norepinephrine, and acetylcholine.

ETIOLOGY

Theory: Environmental or hormonal perturbations trigger tics in genetically susceptible individuals.

COMMONLY ASSOCIATED CONDITIONS

- ~50% of children with chronic motor tics or TS meet diagnostic criteria for attention-deficit/hyperactivity disorder (ADHD), and ~50% have OCD or obsessive-compulsive traits.
- Anxiety, learning disabilities (LD), oppositional defiant disorder, conduct disorder, and rage episodes are also associated with TS.

DIAGNOSIS

The diagnosis of tics is clinical. Physical examination and ancillary studies are typically normal.

HISTORY

- Document a description of the patient's past and current tics, including age of onset, type, anatomic location(s), duration, number, frequency, complexity, severity, and exacerbating or alleviating factor(s).

- Determine the degree to which the tics are causing interference and/or impairment.
- Assess for commonly associated conditions.
- In prepubertal patients with severe, sudden-onset OCD symptoms and/or tics, inquire about recent GABHS infections.

PHYSICAL EXAM

Physical examination is usually normal. Tics may not be seen; thus, it may be necessary to depend on history. Having the child intentionally reproduce the sound(s) and/or movement(s) of concern and/or having the parents provide video can aid in differentiating tics from other movement disorders.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

There is little evidence to support routine testing for GABHS in children suspected of having PANDAS. Throat cultures should be obtained in children with symptoms of pharyngitis.

Diagnostic Procedures/Other

Diagnosis depends largely on history. Diagnostic tests are unnecessary. Psychological testing may elucidate comorbid conditions (ADHD, OCD, LD).

DIFFERENTIAL DIAGNOSIS

- Certain simple tics (eye blinking, sniffing, throat clearing) may be mistaken for allergy symptoms, whereas complex tics may be mistaken for purposeful, voluntary movements.
- Stereotypies are patterned, episodic, repetitive, purposeless, rhythmic movements. The movements are constant in pattern and location, without variation over time.
- Chorea is characterized by rapid, random, purposeless movements that often have a “dance-like” quality. Unlike tics, chorea is not stereotyped.
- Dystonia is characterized by repetitive, sustained muscle contractions that cause abnormal postures and movements, often with a twisting quality. Dystonic tics result in sustained postures and can be difficult to

distinguish from dystonia; however, the presence of a premonitory urge suggests the former diagnosis.

- Myoclonus is a sudden, brief, shock-like movement. It is not suppressible and is not associated with a premonitory sensation.
- Automatism, seen in some forms of epilepsy, may look like tics but are neither associated with premonitory sensations nor under partial voluntary control. EEG is normal in children with tics but may be abnormal in those with seizures.
- Hemifacial spasm (HFS) is a rare condition that results in frequent, involuntary muscle contractions involving one side of the face. Early cases of HFS may be difficult to distinguish from motor tics, but HFS is limited to one side of the face, and the spasms last longer than tics.

TREATMENT

Many tics do not interfere with children's lives and therefore do not require specific treatment. Educating the child and family about tics is often sufficient. Clinical decisions must take comorbid symptoms into account, and treatments must target the most impairing symptoms first. The waxing and waning nature of tics confounds treatment; it may take weeks to identify whether an intervention is helping.

MEDICATION

- Mild/occasional tics: Medication is not needed.
- Moderate or severe: α -2 Agonist or dopamine antagonist may reduce severity/frequency.
- With OCD: Selective serotonin reuptake inhibitors can be helpful. Fluoxetine, fluvoxamine, and sertraline appear to be equally effective.
- With ADHD: α -2 Agonist may help hyperactivity/impulsivity. Consider addition of a stimulant if symptoms are refractory or if inattention is the primary complaint.
- PANDAS: As above. There is insufficient evidence to support the use of long-term antibiotics and/or immunomodulation.

First Line

- Clonidine and guanfacine are used off-label as 1st-line treatments for

tics. Both are available in immediate- and extended-release forms.

- Clonidine: Start 0.05 mg at bedtime. Increase by 0.05 mg/week to effect, side effects, or a maximum of 0.4 mg/day, divided 3 or 4 times/day. Available as a tablet and transdermal patch.
- Guanfacine: Start 0.5 mg at bedtime. Increase by 0.5–1 mg/week to effect, side effects, or a maximum of 3 mg/day, divided twice a day.
- Sedation and orthostatic hypotension are common initial adverse effects, more so with clonidine than guanfacine.
- Avoid abrupt discontinuation, which can cause rebound hypertension.

Second Line

- Antipsychotic medications are considered 2nd-line treatments. Weight gain is common with all antipsychotic medications, but the atypical agents are generally preferred because they are better tolerated overall and are less likely to cause extrapyramidal side effects.
- Commonly used atypical agents include risperidone, aripiprazole, ziprasidone, and olanzapine.
- Typical antipsychotics (haloperidol, pimozide) are potent but are associated with troublesome side effects; therefore, they should only be used for those with refractory, disabling tics. Common side effects: sedation, weight gain, metabolic syndrome, and galactorrhea. Serious side effects: extrapyramidal reactions, neuroleptic malignant syndrome, and tardive dyskinesia.

ALERT

Poor metabolizers of pimozide may be at increased risk for QT prolongation and cardiac arrhythmias; therefore, the FDA has stated that CYP2D6 genotyping should be performed before exceeding 4 mg of pimozide in adults or 0.05 mg/kg/day in children and that the dose of pimozide should not be increased earlier than 14 days in patients who are known CYP2D6 poor metabolizers.

ADDITIONAL TREATMENT

General Measures

There is no evidence that lifestyle changes or restriction of activities modify the course of tic disorders.

ADDITIONAL THERAPIES

- A recent randomized controlled trial of children and adolescents with TS and chronic tic disorder demonstrated that a comprehensive behavioral intervention—consisting of awareness training, competing response training, relaxation training, and social support—resulted in greater improvement in tic severity than supportive therapy and education alone. The effect size of the intervention was on par with that of medication.
- Focal motor (or vocal) tics, especially those that are dystonic, may be treated with botulinum toxin injections to the affected muscles.

SURGERY/OTHER PROCEDURES

Recent experimental data have shown deep brain stimulation (DBS) as a potential treatment for adults with severe and refractory tics.

ONGOING CARE

DIET

There is no evidence that dietary modifications alter the course of tic disorders.

PATIENT EDUCATION

The Tourette Syndrome Association (www.tsa-usa.org) is a valuable resource for information. There are many local chapters.

PROGNOSIS

Although common, tics cause impairment in a minority of children. Peak severity occurs in preadolescence. Most patients have partial or complete resolution of tics as adults. Long-term outcome depends on associated comorbidities.

COMPLICATIONS

Tics can be emotionally distressing and can result in social disability. Injuries—due to complex tics, compulsions, impulsivity, inattention, and other factors—may be more common in patients with TS than in the general population. Chronic, repetitive, and forceful tics can cause musculoskeletal problems (e.g., cervical spine arthritis, disc herniation) or

other neurologic problems (e.g., cervical myelopathy, stroke secondary to vertebral artery dissection).

- F95.0 Transient tic disorder

FAQ

- Q: Can a child with tics and ADHD be treated with stimulant medication?
- A: Although there have been concerns of stimulants making tics worse, there is no evidence that stimulants cause chronic tics. Furthermore, several recent studies have shown that treatment of ADHD with stimulants does not worsen tics and may lead to improvement.
- Q: Should mild tics be treated if they lead to teasing?

- A: The best approach is to educate the child, parents, and teacher about tics. The child can be armed with a response to questions, such as “Those are tics. They are just something I do, and I can’t help it.”

TOXIC ALCOHOLS

Richard Loffhagen • Robert J. Hoffman

BASICS

DESCRIPTION

- Toxic alcohols discussed here include ethylene glycol, isopropyl alcohol, and methanol.
- Ethylene glycol is a sweet, odorless, colorless liquid, commonly used as automobile antifreeze solution as well as for other uses.
- Isopropyl alcohol is used as rubbing alcohol, as well as in liquid soaps and for other uses.
- Methanol is wood alcohol used in windshield wiper fluid, Sterno, and other products.

GENERAL PREVENTION

Poison proofing homes and giving parents poison prevention advice is the most effective way to prevent toxic alcohol exposures in children.

RISK FACTORS

Toxicity via dermal absorption can occur in infants or young children with permeable skin.

PATHOPHYSIOLOGY

All toxic alcohols have direct effects as intoxicants. More importantly, ethylene glycol and methanol are metabolized to toxic by-products that result in severe morbidity or mortality.

- All toxic alcohols may result in altered mental status or coma similar to ethanol. CNS depression may result in respiratory depression requiring ventilatory support.
- Ethylene glycol is metabolized to oxalic acid and glycolic acid, ultimately forming calcium oxalate crystals, which may precipitate in the renal tubules and cause renal failure.
- Methanol is metabolized to formaldehyde and then formic acid, which may damage the retina and cause visual impairment or blindness.

- The metabolism of ethylene glycol and methanol to their toxic metabolites may be prevented by competitively inhibiting alcohol dehydrogenase with either fomepizole or ethanol.
- Therapy to inhibit alcohol dehydrogenase is used for ethylene glycol and methanol exposure.
- Isopropyl alcohol is metabolized to acetone.
- Inhalational absorption of isopropyl alcohol may rarely occur.

DIAGNOSIS

- Signs and symptoms:
 - Inebriation may occur after exposure.
 - Isopropyl alcohol may cause severe gastrointestinal irritation or hemorrhage.

HISTORY

- Typically, a history of exposure is available.
- In absence of this history, and osmolal gap or anion gap with metabolic acidemia is suggestive of toxic alcohol exposure.

PHYSICAL EXAM

- Tachycardia and hypotension are the most frequent vital sign abnormalities that occur.
- Hyperpnea or tachypnea often accompanies metabolic acidemia.
- Cardiovascular effects may include hypocalcemic QT prolongation and myocarditis.
- Neurologic abnormalities may include ataxia, CNS depression, coma, dysarthria, focal neurologic changes, hyporeflexia, hypotonia, nystagmus, or seizure.
- Gastrointestinal effects may include gastritis, emesis, hematemesis, pain, or pancreatitis.
- Ophthalmologic findings may include blurred vision, diplopia, hazy vision, or nystagmus.
- Constricted visual fields, hyperemic optic disks with retinal edema, and transient or permanent blindness may result from methanol exposure.
- Hematuria, renal insufficiency, or renal failure may occur, particularly

from ethylene glycol.

- Fluid and electrolyte abnormalities from ethylene glycol or methanol may include hypokalemia, hypocalcemia, hypomagnesemia, and elevated anion gap metabolic acidosis.
- Acetonemia and ketonemia may result from isopropyl alcohol ingestion.
- Hypoglycemia may be associated with toxic alcohol exposure as well as with ethanol therapy.
- Respiratory irritation from isopropyl alcohol inhalation or respiratory depression from any toxic alcohol ingestion may occur.

DIAGNOSTIC TESTS & INTERPRETATION

- Check serum electrolytes, BUN, creatinine, and glucose.
 - As metabolism occurs, an increased anion gap metabolic acidemia results with ethylene glycol or methanol toxicity.
 - Absence of this gap early after ingestion is expected and does not rule out ingestion.
 - Elevated anion gap metabolic acidemia supports the diagnosis of ethylene glycol or methanol exposure.
 - Acidemia is an indication for use of fomepizole or ethanol as well as potential indication for hemodialysis.
 - Fomepizole treatment should not be delayed waiting to determine if acidemia will develop.
 - Anion gap metabolic acidemia does not result from isopropyl alcohol poisoning.
- Blood gas analysis should be performed to assess for degree of metabolic acidemia in any patient with low serum bicarbonate.
 - Initial use of venous blood gas to screen for abnormality is acceptable.
 - Repeated blood gas analysis should occur every 1–2 hours if acidemia results.
- Serum level of ethylene glycol, isopropyl alcohol, or methanol should be obtained.
 - An ethylene glycol or methanol level greater than 20 mg/dL is an indication for fomepizole or ethanol infusion.
 - An ethylene glycol or methanol level greater than 50 mg/dL is an

indication for hemodialysis.

- Serum ionized calcium is useful in managing ethylene glycol toxicity.
- Urinalysis with microscopic examination is recommended with ethylene glycol exposure.
 - Presence of oxalate crystals corroborates poisoning.
 - Absence of crystals does not exclude the possibility of ethylene glycol toxicity.
 - Fluorescence of urine is unreliable and is neither sensitive nor specific for exposure.
- A spurious rise in creatinine may occur.
- Proteinuria and hematuria may be present with ethylene glycol or isopropyl alcohol exposure.
- Serum osmolality or osmolarity may be useful in predicting the level of ethylene glycol, isopropyl alcohol, or methanol if rapid laboratory quantification cannot be performed.
- Serum ethanol level should simultaneously be performed to determine quantity of ethanol contribution to osmolal gap.
- An elevated osmolal gap can be used to rule in, but not exclude, toxic alcohol exposure.
- An elevated osmolal gap indicates the presence of unmeasured solute such as ethanol, ethylene glycol, isopropyl alcohol, or methanol.
- Absence of an osmolal gap does not exclude the possibility of toxic alcohol exposure.
- Osmolal gap is calculated as follows: $\text{Osmolal gap} = (\text{calculated serum osmolality} - \text{measured osmolality})$.
- The measured osmolality is determined by the laboratory.
- The calculated osmolality is determined as follows: $2 \times [\text{Na (mEq/L)}] + [\text{BUN (mg/dL)/2.8}] + [\text{glucose (mg/dL)/18}]$.
- Normal osmolal gap is less than 15 mEq/L.
- Any patient with increased osmolal gap should be presumed to have toxic alcohol exposure.
- Additional tests may include ECG to detect cardiac conduction disturbance or serum acetaminophen and salicylate levels in patients with intentional ingestion or with presumed intent of self-harm.
- Tests necessary to rule out differential diagnoses should be obtained

when appropriate.

DIFFERENTIAL DIAGNOSIS

Drugs and disorders that may alter lab values include acetone, diethylene glycol, ethanol, iron, isoniazid, lactic acidemia, mannitol, methanol, propylene glycol, renal failure, salicylates, toluene, and various forms of ketoacidosis.

Imaging

Neuroimaging to rule out intracranial pathology may rarely be indicated.

TREATMENT

INITIAL STABILIZATION

- Prompt evaluation of airway, breathing, circulation, serum glucose, and ECG (A,B,C,D,E) is critical.
- Consultation with a medical toxicologist or poison center is recommended.

General Measures

Supportive care is the most important general principle. The illness is managed with intent of close monitoring and addressing issues as they arise.

- For ingestion less than 1 hour previously, an attempt to aspirate gastric contents with a nasogastric tube is reasonable.
- Treatment for ethylene glycol or methanol exposure should focus on acid-base correction and preventing organ damage.
- Hemodialysis should be considered for the following:
 - Any patient with severe metabolic acidemia from ethylene glycol or methanol
 - Any patient with evidence of end organ damage, particularly if metabolic acidemia is present
 - Any patient with profound hypotension or life-threatening symptoms resulting from isopropyl alcohol toxicity

Nursing

- Protect inebriated patients from falls.

- For the duration of inebriation or therapy with ethanol, vigilance for detection of hypoglycemia should be maintained.

IV Fluids

- IV fluid to maintain adequate blood pressure may be necessary.
- Maintenance IV fluid may be required in patients who are unable to take PO.
- IV fluid may be necessary to aid in prevention of calcium oxalate crystals in the urine.
- IV fluid may be helpful to prevent renal injury if rhabdomyolysis occurs.
- 8.4% sodium bicarbonate may be used in resistant acidosis and should be given via a central line if available.

MEDICATION

- For ethylene glycol or methanol poisoning (but NOT isopropyl alcohol), either fomepizole or ethanol are used to competitively inhibit alcohol dehydrogenase.
- Fomepizole is highly preferable to ethanol for this purpose, as ethanol has many severe, adverse side effects and fomepizole does not.
- Indications for fomepizole or ethanol include the following:
 - Serum level of ethylene glycol or methanol greater than 20 mg/dL
 - Metabolic acidemia with any quantity of detectable ethylene glycol or methanol
- Use of fomepizole or ethanol will prolong the half-life of ethylene glycol and methanol.
 - Without therapy, the ethylene glycol half-life is 3–4 hours, and methanol 14–20 hours.
 - With fomepizole or ethanol, the ethylene glycol half-life is 12 hours, and methanol 30–50 hours.
- Some clinicians consider a necessary duration of therapy longer than several days to be an indication for hemodialysis. Successful use of prolonged therapy with fomepizole to avoid hemodialysis has been reported.
- Fomepizole is contraindicated in patients with documented allergic reaction to the drug.

- Ethanol should be used with extreme caution in Asians, as aldehyde dehydrogenase deficiency may result in severe illness and hypotension.
- The loading dose of fomepizole is dose of 15 mg/kg IV.
- Initial maintenance dosing is 10 mg/kg q12h for 4 doses. Because fomepizole induces its own metabolism, the subsequent maintenance dose is increased to 15 mg/kg q12h thereafter.
- Each dose is diluted into normal saline or D5W (<25 mg/mL) and infused over 30 minutes.
- Each time after hemodialysis is performed, a loading dose must be readministered.
- Ethanol is administered as a 10% solution in D5W. This dilution requirement often results in a very large quantity of free water administration.
- The ethanol loading dose is 10 mL/kg (max 200 mL) of a 10% solution infused IV over 1 hour.
- A maintenance dose of 1–2 mL/kg of 10% ethanol is then given IV.
- Target blood ethanol level is 100–125 mg/dL.
- Patients receiving ethanol should have the ethanol level and serum glucose checked hourly.
- Oral ethanol may be used when IV is not available or if the patient is willing and capable of drinking. This is possibly feasible in adolescents.
- Adjunctive treatment with folate or leucovorin for methanol, and thiamine and pyridoxine for ethylene glycol may be given:
 - This continues until methanol or ethylene glycol levels are undetectable.
 - Folate or tetrahydrofolate (leucovorin) may hasten the elimination of formic acid resulting from methanol exposure.
 - Leucovorin 1–2 mg/kg may be administered IV every 6 hours.
 - Pyridoxine and thiamine hasten elimination of ethylene glycol metabolites.

FOLLOW-UP RECOMMENDATIONS

- Asymptomatic patients with undetectable ethylene glycol or methanol levels and no metabolic acidemia may be safely discharged.
- Most exposures for which ethylene glycol or methanol levels cannot be

obtained should be followed for 12–24 hours to detect development of metabolic acidemia or other symptoms.

- From the hospital, patients with ethylene glycol or methanol level less than 20 mg/dL, no anion gap, no metabolic acidemia, and stable renal function and vision may be discharged.
 - Patients with isopropyl alcohol exposure who develop no symptoms or have only mild symptoms may be discharged within 4–6 hours.

Admission Criteria

- Any patient requiring therapy with fomepizole, ethanol, or hemodialysis
- Any patient with renal impairment, visual impairment, or other organ effect
- Any patient for whom consequential ingestion is suspected and ethylene glycol or methanol levels are unavailable

Discharge Criteria

- Inpatients who have received therapy with fomepizole, ethanol, or hemodialysis must be medically and metabolically stable for at least 12–24 hours prior to discharge.
- Patients with ethylene glycol or methanol exposure who have not developed symptoms or metabolic derangement may be discharged within 24 hours.

ONGOING CARE

PROGNOSIS

- For ethylene glycol and methanol exposure, prognosis depends on the degree of toxin metabolism, as well as adequacy of care.
- Speed and adequacy of therapy with fomepizole or ethanol, as well as prompt hemodialysis when indicated is critical.
- For isopropyl alcohol, prognosis depends on severity of intoxication and adequacy of supportive care.

COMPLICATIONS

Blindness, coma, hepatic injury, hypertension or hypotension, myocarditis, temporary or permanent neurologic injury, pancreatitis, renal failure,

respiratory depression, rhabdomyolysis, seizure may occur as a result of toxic alcohol exposure.

Patient Monitoring

Symptomatic exposure to ethylene glycol or methanol may warrant intensive care monitoring.

TOXIC SHOCK SYNDROME

Amanda C. Schondelmeyer • Erin E. Shaughnessy

BASICS

DESCRIPTION

Toxic shock syndrome is an acute febrile illness characterized by hypotension and gastrointestinal and respiratory distress progressing to multisystem organ failure. The clinical syndrome is caused by bacterial exotoxins produced most commonly by the following:

- TSS toxin-1 (TSST-1)—producing strains of *Staphylococcus aureus*—referred to as TSS
- Group A β -hemolytic streptococci (GAS or *Streptococcus pyogenes*), referred to as streptococcal toxic shock–like syndrome (STSS)
- Cases have also been reported in association with groups B, C, and G1 streptococci and *Streptococcus mitis*.

EPIDEMIOLOGY

- In the 1980s, most cases were associated with superabsorbent tampon use; subsequently, these products have been removed from the market, resulting in a decline in menstrual-related staphylococcal TSS.
- Developing countries bear a much higher burden for STSS.
- Currently, ~50% of cases are non–menstrual related.

Incidence

- TSS: 3.4 cases per 100,000 in 2003
- Current incidence of menses-related TSS: 1–5 per 100,000 women of menstrual age per year
- STSS: 2–4 cases per 100,000 in developed countries with >10 per 100,000 per year in developing countries
- STSS incidence is highest among young children and associated with focal infections, pneumonia, or bacteremia.

RISK FACTORS

- Use of superabsorbent tampon, diaphragm, or contraceptive sponge; local or invasive staphylococcal or streptococcal infection

- Recent gynecologic procedure
- Focal infections including surgical and postpartum wounds, sinus, soft tissue, and musculoskeletal infections and respiratory infections
- STSS most often occurs with skin and soft tissue infections.
 - Preceding varicella infection increases risk.

GENERAL PREVENTION

- Scrupulous wound care
- Limitation of intravaginal foreign body use (e.g., tampon, sponge) and strict adherence to manufacturer's directions
- Early recognition and appropriate treatment of infections

PATHOPHYSIOLOGY

- Both *Staphylococcus aureus* and *Streptococcus pyogenes* can produce exotoxins.
- Some exotoxins function as superantigens, interacting with immune cells to induce massive cytokine production leading to the predominant symptoms.
- Cytokines result in fever, capillary leak, hypotension, and end-organ dysfunction.

DIAGNOSIS

HISTORY

- Patients may report use of tampons, contraceptive sponge, or diaphragm.
 - TSS may occur at any time during menses.
- Inquire about recent wounds or surgical procedures including catheters (e.g., intravenous, peritoneal dialysis).
 - Incubation period for postoperative TSS may be as short as 12 hours.
- Patient may report recent childbirth or abortion.
- Patients may report abrupt onset of high fever, chills, malaise, headache, pharyngitis, erythroderma fatigue, and dizziness or syncope.
- Gastrointestinal symptoms including profuse watery diarrhea, vomiting, abdominal pain

PHYSICAL EXAM

- Initial exam should evaluate for soft tissue or musculoskeletal focus of infection or retained foreign body.
- Patients are typically ill appearing and may have general erythroderma.
 - Skin findings may be less prominent with severe hypotension.
- Vitals signs: fever, tachycardia, tachypnea, orthostasis, or frank hypotension
 - Tachycardia with normotension may occur early in disease.
- Skin: erythroderma, peripheral cyanosis, and edema
 - Desquamation: begins on trunk and extremities 5–7 days after symptom onset
 - There may be vesicle or bullae formation or presence of violaceous hue.
- Mucosa: bulbar conjunctival injection and oral mucosal hyperemia
- Mental status: may be altered, somnolent, agitated, disoriented, or obtunded
 - Mental status changes may worsen as disease progresses.
- Caveats for physical exam
 - Patients may not have all symptoms upon presentation.

DIAGNOSTIC TESTS & INTERPRETATION

- U.S. Centers for Disease Control and Prevention (CDC) criteria for diagnosis of staphylococcal TSS requires 6 criteria for confirmed cases and 5 for probable:
 - Fever 38.9°C (102.0°F) or higher
 - Diffuse macular erythroderma
 - Desquamation 1–2 weeks after onset, particularly affecting palms and soles
 - Hypotension defined as systolic blood pressure below 5th percentile for children, orthostatic changes >15 mm Hg, or orthostatic syncope or dizziness
 - Involvement of three or more organ systems: gastrointestinal, muscular, mucous membrane, renal, hepatic, hematologic, or neurologic
 - Negative blood (may be positive for *S. aureus*), throat, or CSF cultures and/or negative titers for Rocky Mountain spotted fever

(RMSF), leptospirosis, or measles

- U.S. CDC criteria for diagnosis of streptococcal TSS. Confirmed cases meet clinical definition in addition to isolation of GAS from normally sterile site; probable cases meet clinical definition with isolation of GAS from nonsterile site:
 - Hypotension as defined above
 - Any 2 of the following: renal impairment, coagulopathy, hepatic impairment, acute respiratory distress syndrome (ARDS), erythematous macular rash that may desquamate, or soft tissue necrosis

Lab

Initial laboratory evaluation should be aimed at diagnosing organ dysfunction to guide supportive therapy and identifying potential source and pathogen to guide antimicrobial therapy.

- Cultures
 - Blood cultures: ideally obtained prior to antimicrobial therapy but still helpful if patient has been on outpatient therapy prior to presentation
 - Positive in 60% of STSS but <5% of staphylococcal TSS
 - Other cultures
 - Culture of other fluids (abscess, pleural, cerebrospinal) should be guided by clinical presentation.
 - *S. aureus* may be isolated from vagina or cervix in menstrual TSS, although asymptomatic carriage can occur.
 - Culture of GAS from the throat or other nonsterile site may be helpful although does not confirm STSS.
- Antibodies (Ab)
 - TSST-1 Ab are available for informational purposes/research only.
 - Antistreptolysin O (ASO), antideoxyribonuclease B, or other streptococcal extracellular products
 - May increase 4–6 weeks after infection in streptococcal-mediated disease
 - May not be helpful in acute phases of disease
- Arterial blood gas
 - Helpful in cases of respiratory distress and poor perfusion to help

guide ventilation strategies

- Complete blood count
 - Leukocytosis with left shift (neutropenia is an ominous sign)
 - Thrombocytopenia may indicate ongoing disseminated intravascular coagulation (DIC).
- Renal profile: may reflect acute kidney injury with elevated creatinine
- Hepatic profile: may have elevations in liver enzymes and evidence of synthetic dysfunction with decreased fibrinogen and coagulation factor levels
- Coagulation studies
 - May reveal prolonged prothrombin and partial thromboplastin times (PT/PTT) with or without evidence of DIC; low fibrinogen, elevated fibrin degradation products.
- Urinalysis
 - May reveal sterile pyuria
- Lumbar puncture
 - May reveal CSF pleocytosis
 - Gram stain positive for organisms or overt abnormalities indicating meningitis argue against STSS or TSS.
- Creatine phosphokinase (CPK)
 - May be elevated, reflecting skeletal muscle involvement

Imaging

Chest x-ray should be obtained if there is evidence of respiratory distress or oxygen requirement.

- May show diffuse bilateral infiltrates in ARDS

DIFFERENTIAL DIAGNOSIS

- Septic shock from other bacterial or viral
- Streptococcal scarlatiniform eruption
- Leptospirosis
- RMSF or ehrlichiosis if travel to or living in endemic areas
- Kawasaki disease:
 - TSS may present simultaneously with Kawasaki disease.
 - Coronary artery dilatation has been reported in cases presenting as TSS.

- Toxic epidermal necrolysis (TEN)
- Drug-induced hypersensitivity reaction

TREATMENT

SPECIAL THERAPY

- Remove all foreign bodies.
- Incision and drainage and or surgical debridement for abscess, myositis, and necrotizing fasciitis

MEDICATION

First-line therapy should be broad initially and guided by local rates of methicillin-resistant *Staphylococcus aureus* (MRSA).

- Vancomycin IV (15 mg/kg every 6 hours, max daily dose 4,000 mg) should be administered as first line if MRSA is a consideration.
 - Renal toxicity is a known adverse effect.
 - Dose should be adjusted for renal impairment and serum creatinine followed.
 - Trough levels (before 4th dose) should be used to adjust dose under the guidance of an experienced pharmacist.
- Clindamycin IV (40 mg/kg divided every 6–8 hours, max daily dose 2,700 mg) should be administered in addition to 1st-line therapy to end production of toxins.
- Ceftriaxone (100 mg/kg divided every 12–24 hours, max daily dose 2,000 mg) should be added empirically for gram-negative coverage until organism or diagnosis is confirmed.
- Antistaphylococcal penicillins (i.e., nafcillin, oxacillin, dicloxacillin) may be considered in place of vancomycin if local MRSA rates are low.
- IVIG is commonly used as adjunct therapy to antibiotics, but its efficacy is unclear.
 - Proposed mechanism is by providing neutralizing antibodies to exotoxins and inhibiting T-cell activation.
- Continue antibiotic therapy for at least 10–14 days; total treatment length should be guided by initial focus of infection if present.

- Consultation with infectious disease specialist is recommended in cases where the diagnosis is unclear.
- Therapy can be changed to oral when patient is tolerating oral nutrition.

INITIAL STABILIZATION

Treatment of suspected TSS or STSS should occur ideally at a tertiary care center with close access to a pediatric intensive care unit.

- Initial resuscitation should proceed rapidly to support adequate tissue perfusion and oxygenation.
 - IV isotonic fluid bolus should be given initially with further fluid boluses and pressor therapy guided by perfusion and vital signs
 - Be mindful of potential cardiac dysfunction when providing fluid resuscitation.
 - Stabilize airway if respiratory distress
- Antibiotic therapy should be administered as soon as possible.

ONGOING CARE

Aside from antimicrobial therapy, the mainstays of treatment are supportive care for organ dysfunction.

- Temperature usually returns to normal within 2 days if on effective therapy.
- Gastrointestinal, hepatic, and musculoskeletal changes resolve rapidly with rare permanent sequelae except for muscle weakness.
- Full-thickness desquamation of fingers, toes, palms, and soles begins 10–12 days after onset.
 - Hair and nail loss may occur 4–16 weeks after illness onset; should resolve within 5–6 months.
- Encephalopathy is common but rarely causes seizures; usually resolves within 4–5 days.
- Poor prognosis is often heralded by development of pulmonary edema and worsening cardiac function.
 - Cardiac and pulmonary failure are the most common causes of death.

- Toxin-mediated cardiomyopathy should resolve with effective treatment.

PROGNOSIS

- Nonmenstrual TSS has a case fatality rate of 5%; menstrual TSS case fatality rate was approximately 1.8% between 1987 and 1996.
- STSS case fatality rate exceeds 50%.
- Recurrences are associated with inadequate treatment or persistent focus.
- Death usually occurs within the first few days but may occur as late as 2 weeks following onset.

COMPLICATIONS

Multisystem organ failure secondary to distributive shock/hypotension, including the following:

- Pulmonary edema
- DIC
- Acute renal failure (oliguric and nonoliguric)
- Hepatic failure
- Myocardial dysfunction; may have arrhythmias
- Cerebral edema with toxic or ischemic encephalopathy
- Metabolic disturbances
- Tissue death and potentially limb amputation
- Neuropsychological disturbances including memory loss; abnormal electroencephalograms (EEGs) are rare

FAQ

- Q: Can TSS recur?
- A: Yes. Inadequate eradication of the nidus of infection or inadequate treatment may result in recurrence. Poor immune function may also contribute to recurrence.
- Q: Can TSS be diagnosed in patients who have no risk factors?
- A: Yes. There have been reports meeting the case definition where none of the known associated factors was present.
- Q: Should I wait for confirmation of the diagnosis prior to treating with antibiotics?
- A: No. Antibiotic therapy should be initiated immediately in any patient suspected of having TSS.

TOXOPLASMOSIS

Caitlin Messner • Rebecca Schein

BASICS

DESCRIPTION

Toxoplasmosis is caused by *Toxoplasma gondii*, an obligate intracellular protozoan parasite with a complex life cycle, which can cause a wide range of clinical symptoms depending on individual strain virulence and the host immune system.

- Primary infection is often asymptomatic and may result in fever, lymphadenopathy, and eye disease.
- Congenital infection classically presents with triad of chorioretinitis, hydrocephalus, and brain calcifications.
- Reactivation of disease may develop after either primary or congenital infection and most commonly presents as chorioretinitis.
- Patients with immune deficiency can develop brain abscesses, encephalitis, fever of unknown origin, or pneumonia.

EPIDEMIOLOGY

- Toxoplasmosis is the leading cause of death due to foodborne illness in the United States.
- *T. gondii* is found worldwide and can infect most warm-blooded animals.
- Cats are the definitive hosts, and the parasite replicates sexually in the feline small intestine.
- Vertical transmission is more common with primary infection during pregnancy or within 3 months prior to conception. Treatment of primary maternal infection can decrease fetal transmission rate by half from 50–60% to 25–30%.

Incidence

Congenital infection in the United States occurs in an estimated 1 per 10,000 live births or 400 new cases annually.

Prevalence

- Worldwide, the rate of infection varies greatly and ranges from 7% to 80%.
- In the United States, overall seroprevalence is 11% but may be as high as 40% in areas with lower socioeconomic status.

GENERAL PREVENTION

- Main risk factors for *T. gondii* infection are eating raw or rare meat, consuming local cured or smoked meat, working with meat, drinking unpasteurized goat milk, or having more than 3 kittens.
- Untreated or contaminated water is also a risk factor and has been responsible for outbreaks of toxoplasmosis.
- Pregnant women should be counseled to avoid cat feces exposure including gardening, landscaping, and changing litter boxes and to avoid consuming undercooked meat.

PATHOPHYSIOLOGY

- Cats shed oocysts in feces, which then sporulate and become infectious.
- Humans are infected by eating raw or undercooked meat infested with oocytes; accidental ingestion of contaminated soil, food, or water; contaminated blood transfusion or organ donation; or via transplacental transmission from mother to fetus.
- In the human host, tissue cysts are formed in skeletal muscle, myocardium, brain, and eyes.
- Tissue cysts persist for the life of the host.
- Reactivation can occur when the immune system is compromised particularly due to T-cell deficiency.

DIAGNOSIS

HISTORY

- Exposure to raw meat, unfiltered water, cats or kittens
- Immune deficiency disease
- Maternal illness during pregnancy

PHYSICAL EXAM

- Primary infection may be asymptomatic.
- Symptoms are nonspecific and include lymphadenopathy, fever, headache, sore throat, malaise, myalgia, or arthralgia. A mononucleosis-like syndrome with rash and hepatosplenomegaly is seen occasionally.
- Congenital infection is asymptomatic at birth in 70–90% of patients. Visual impairment, learning disabilities, or mental retardation commonly develop over time.
- Signs of symptomatic congenital infection include rash, generalized lymphadenopathy, hepatosplenomegaly, jaundice, pericarditis, thrombocytopenia, meningoencephalitis, hydrocephalus, microcephaly, and brain calcifications.
- The classic triad of toxoplasmosis in neonates is chorioretinitis, hydrocephalus, and brain calcifications.
- Ocular toxoplasmosis commonly is due to reactivation of chronic infection.
- In persons with secondary immunodeficiency, reactivation disease can result encephalitis, pneumonia, or systemic toxoplasmosis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serology testing for *T. gondii*–specific antibodies is the primary means of diagnosis.
- The presence of immunoglobulin G (IgG) determines if a person has ever been infected, whereas immunoglobulin M (IgM) or IgG avidity test detect primary infection.
- Pregnant women in high-prevalence area should be screened with both IgM to detect acute infection and IgG for latency. If IgG is present, an avidity test will determine if infection occurred within the last 3–4 months.
- Infants suspected of congenital toxoplasmosis should be tested for the presence of *T. gondii* immunoglobulin A (IgA) in addition to IgG and IgM due to higher sensitivity in this age group.
- As serology testing can vary, any positive tests should be confirmed by a reference laboratory.
- Amniotic fluid may tested for *T. gondii* DNA.

- Diagnosis can be made by direct observation of the parasite in tissue specimens, cerebral spinal fluid, or biopsy material.
- Immunocompromised patients including those with HIV should be tested for *T. gondii*-specific IgG, prior to starting therapy.

Imaging

- Prenatal ultrasound is useful to detect signs of congenital infection including hydrocephalus, brain calcifications, or pericarditis.
- Head CT or MRI will detect calcifications and hydrocephalus.

Diagnostic Procedures/Other

- Ophthalmologic examinations for characteristic retinal lesions
- Hearing exams, as hearing loss may be absent in infancy and develop over time

DIFFERENTIAL DIAGNOSIS

- Primary infection
 - Epstein-Barr virus (EBV)
 - Cytomegalovirus (CMV)
 - HIV
 - Lymphoma
- Congenital infection
 - CMV (calcifications are periventricular)
 - Herpes simplex virus (HSV)
 - Rubella
 - Syphilis

TREATMENT

MEDICATION

- Most cases of acute infection do not require treatment.
- Persons with eye disease, severe organ damage, pregnant women, congenital infection (symptomatic or asymptomatic), and immunocompromised hosts should be treated.
- Therapy is a combination of pyrimethamine and sulfadiazine.
- Folinic acid is also given to protect against the hematologic side effects of pyrimethamine.

- Spiramycin treatment of pregnant women may reduce congenital transmission.
- Treatment is prolonged and congenital infection is treated for 1 year.
- Trimethoprim/sulfamethoxazole should be used for prophylaxis to prevent disease in those with HIV infection and CD4 count less than 100/ μ L or severe immunosuppression with known IgG antibody to toxoplasma.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Children with congenital infection should be monitored for neurologic manifestations, including hearing loss and chorioretinitis that may develop over time.
- Ophthalmologic exams and audiometry should be performed periodically for at least the first 10 years of life after congenital infection.
- Head circumference should be monitored due to development of hydrocephalus in congenital infections.

PROGNOSIS

- Congenital infections are also mostly asymptomatic at birth; however, hearing loss, vision loss, and seizures may present months to years later.
- Bad neurologic outcomes are associated with early maternal infection, lack of prenatal treatment, presence of chorioretinitis, and clinical signs noted at birth.
- Treatment improves clinical outcomes, including cognitive function.
- Immunocompromised patients require chronic suppressive therapy until demonstrated immune recovery.
- Appropriately treated patients typically do well.

COMPLICATIONS

- Congenital infection
 - Chorioretinitis
 - Hydrocephalus

- Seizures
- Intellectual delay
- Seizures
- Sensorineural hearing loss
- Microcephaly
- Primary infection: Rare complications are myocarditis, pericarditis, pneumonia, meningitis, or encephalitis.

CODES

ICD10

- B58.9 Toxoplasmosis, unspecified
- P37.1 Congenital toxoplasmosis
- B58.3 Pulmonary toxoplasmosis

FAQ

- Q: What newborns require evaluation for congenital toxoplasmosis?
- A: Newborns with known maternal disease or concerning exposure and those with hydrocephalus, intracranial calcifications, strabismus, intrauterine growth restriction, or other concern for congenital infection should have serologic testing for *T. gondii* specific IgG, IgM,

and IgA.

- Q: How do people get toxoplasmosis?
- A: By ingesting oocytes from undercooked meat, drinking unpasteurized milk, or by exposure to cat feces in litter or soil.
- Q: Who is at risk developing severe toxoplasmosis?
- A: Infants born to mother infected with *T. gondii* during pregnancy and persons with immune suppression due to acquired immune deficiency syndrome (AIDS), chemotherapy, or organ transplantation.
- Q: How can I prevent toxoplasmosis?
- A: Thoroughly cook meat, wash all fruits and vegetables well, eat only pasteurized dairy products, and wash hands well after contact with sand or soil.

TRACHEITIS

Charles A. Pohl

BASICS

DESCRIPTION

Infection of the trachea associated with airway inflammation and obstruction

- Acute tracheitis: sudden onset; higher morbidity and mortality
- Subacute tracheitis: indolent presentation and course; more common among children with prolonged intubation, tracheostomy, and/or underlying respiratory or neurologic conditions

EPIDEMIOLOGY

- Viral prodrome common
- Increased incidence during viral respiratory season (fall and winter): up to 75% coinfecting with influenza A
- Gender predisposition unclear (2:1 male-to-female ratio has been reported)
- 3% mortality rate

GENERAL PREVENTION

- Routine childhood immunization with Haemophilus influenzae type b, influenza, measles, and pneumococcal vaccines
- Avoid overaggressive suctioning of children with artificial airways.

PATHOPHYSIOLOGY

- Epithelial damage from a viral infection or mechanical trauma (e.g., endotracheal intubation, surgical procedure) occurs in the trachea at the level of the cricoid cartilage. As a result, the damaged tissue is more susceptible to bacterial superinfection.
- Mucosal damage characterized by marked subglottic edema, copious purulent secretions, and a pseudomembrane (mucosal lining, inflammatory products, and bacteria). These changes lead to marked airway obstruction.

- Toxic shock syndrome may be a consequence if the infection is associated with toxin-producing strains of *Staphylococcus aureus* or *Streptococcus pyogenes*.

ETIOLOGY

- Bacteria
 - *Staphylococcus aureus* (most common), group A β -hemolytic *Streptococcus*, *Moraxella catarrhalis*, nontypeable *H. influenzae*, *Streptococcus pneumoniae*
 - *Pseudomonas aeruginosa* and other gram-negative enteric bacteria have been associated with nosocomial infections.
 - *Mycobacterium tuberculosis*, *Mycoplasma pneumoniae*, *Corynebacterium diphtheriae*, *H. influenzae* type b, and respiratory anaerobic bacteria are uncommon pathogens.
- Viruses: Influenza, parainfluenza, respiratory syncytial, herpes simplex, and measles viruses have been found with bacterial pathogen(s).
- Fungi: seen with underlying immunodeficiency disorders or chronic steroid use

DIAGNOSIS

HISTORY

- Hyperpyrexia; nonpainful, brassy cough; noisy respirations; lethargy; dyspnea; rapid progression of airway occlusion (hours to a few days)
- Hoarseness, dysphagia, neck pain, drooling, and croupy cough are less common with bacterial tracheitis.
- Presence of upper airway infection
- Lack of clinical improvement with racemic epinephrine should raise the suspicion for tracheitis.
- An indolent progression of symptoms, including increase of supplemental oxygen requirement and tracheal secretions (thicker and color changes), may be seen in subacute tracheitis.
- Affects any age (peak age 1–6 years)

PHYSICAL EXAM

- Toxic appearance; anxious, agitated, or lethargic; labored breathing with signs of severe respiratory distress (e.g., air hunger posture, retractions); pallor or cyanosis; severe stridor; concomitant signs of pneumonia
- Deviated uvula suggests a peritonsillar abscess.
- Asymmetric lung sounds are often found in patients with foreign bodies in the airway.
- Generalized lymphadenopathy and splenomegaly are clues for infectious mononucleosis.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Radiographs must be completed in controlled settings by personnel who are trained in airway management.
- Lateral and anteroposterior neck films: Findings include distention of the hypopharynx, subglottic narrowing, and irregularity of the tracheal wall owing to mucosal sloughing or the presence of a pseudomembrane.
- Chest radiograph: Obtain if pneumonia, which may be concurrent, is suspected.

Diagnostic Procedures/Other

- Laryngoscopy or bronchoscopy
 - Direct visualization and suctioning of obstructed airway is both diagnostic and therapeutic.
 - Findings include a red, edematous, and/or eroded trachea and bronchi with purulent secretions and pseudomembrane.
 - Consider in an ill-appearing child with an unclear diagnosis or when the child's condition does not respond to current management
- Tracheal bacterial culture (for aerobic and anaerobic bacteria): the gold standard for diagnosis
- Tracheal Gram stain for pathogens and white blood cells (especially polymorphonuclear leukocytes): helps differentiate bacterial infection from colonization
- Blood culture: rarely helpful in diagnosis (<50% positive)
- CBC: little diagnostic value but may show leukocytosis with a left shift

- ESR and/or C-reactive protein: may be elevated

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Epiglottitis/supraglottitis (presence of supraglottic inflammation)
 - Laryngotracheitis (croup)
 - Peritonsillar and parapharyngeal abscesses
 - Retropharyngeal abscess
 - Infectious mononucleosis (Epstein-Barr virus)
 - Diphtheria (rare)
- Environmental
 - Aspiration or inhalation of a caustic substance, including alkali products (e.g., oven cleaner) or smoke
 - Foreign body aspiration
 - Generalized allergic reaction or anaphylaxis leading to angioedema
- Tumors (rare)
 - Papillomas secondary to human papillomavirus
 - Hamartoma and inflammatory pseudotumor
 - Laryngeal tumors
- Trauma
 - Posttraumatic tracheal stenosis
 - Blunt trauma to neck
- Congenital
 - Tracheal stenosis
 - Vascular ring and slings
 - Laryngotracheal web and clefts
 - Laryngotracheomalacia
 - Vocal cord paralysis
 - Arnold-Chiari malformation

ALERT

- Watch for sudden deterioration from tracheal inflammation and secretions. Continuous monitoring is necessary.
- Bacterial tracheitis must be considered in all children with sudden upper respiratory distress and hyperpyrexia.

TREATMENT

MEDICATION

Select antibiotic therapy based on Gram stain and culture results of tracheal secretions and the most likely pathogens. Also consider known prior colonization and institutional pathogens in children with preexisting artificial airway and hospital-acquired infections:

- Mild illness
 - Empiric therapy with amoxicillin-clavulanic acid or a 2nd-generation cephalosporin for 10–14 days (50 mg/kg/24 h depending on the antibiotic used)
 - Consider a semisynthetic penicillin such as dicloxacillin (40 mg/kg/24 h) if H. influenzae type b vaccine completed and clindamycin (10–30 mg/kg/24 h) if presence of a penicillin allergy or MRSA suspected
- Moderate to severe illness
 - Empiric therapy with an antistaphylococcal agent such as clindamycin plus a 3rd-generation cephalosporin or with ampicillin-sulbactam
 - Consider vancomycin IV (60–80 mg/kg/24 h) if a hospital-acquired infection (MRSA) is present or in cases of toxic shock pending culture results.
- Anaerobic, pseudomonas, and other gram-negative coverage should be considered in children not responding to initial therapy or having preexisting artificial airways.
- In contrast to croup, nebulized racemic epinephrine and steroids do not provide significant relief.
- Duration: based on clinical response; usually 10–14 days

ADDITIONAL TREATMENT

General Measures

- Support by stabilizing circulation, airway, breathing (ABCs).
- Maintain airway.
- Initiate IV, oxygen, and monitor.
- Rapid assessment of ABCs is essential with emphasis on airway

control.

- Supplemental oxygen is usually needed.
- Pediatric ICU care is initially recommended.
- Anticipate and prepare for emergent endotracheal intubation and tracheostomy.
- Endoscopy with suctioning and debridement is often necessary for diagnosis and therapy.
- Subsequent airway suctioning and monitoring prevents adverse outcomes.
- Increased ventilatory support is often required for children with preexisting artificial airways.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Routine surveillance cultures in children with artificial airways are not recommended. They usually represent colonization in an asymptomatic patient.
- Signs to watch for:
 - Toxic appearance, excessive secretions, persistent fever, or worsening respiratory distress after introducing antibiotics suggest a resistant organism, an unusual pathogen, or a different diagnosis.
 - Recurrent respiratory distress, especially stridor, with subsequent respiratory tract infections suggests underlying tracheal stenosis.
 - Sudden deterioration on a ventilator may indicate endotracheal tube obstruction, pneumothorax, or mechanical problems.

DIET

NPO until the airway is stabilized and the patient is able to tolerate oral foods

PROGNOSIS

- Most children recover without any sequelae.
- Younger patients are more likely to require intubations and longer hospital stays.
- Children at risk for subacute tracheitis are more likely to have recurrent

episodes.

COMPLICATIONS

- Atelectasis
- Pulmonary edema and pneumonia
- Septicemia
- Staphylococcal toxin syndromes (e.g., toxic shock syndrome)
- Prolonged mechanical ventilation with associated complications (including air leak, infection, pneumothorax, and tracheal stenosis)
- Subglottic stenosis
- Respiratory failure and arrest
- Death (<3.7%)

CODES

ICD10

- J04.10 Acute tracheitis without obstruction
- J04.11 Acute tracheitis with obstruction
- J05.10 Acute epiglottitis without obstruction

FAQ

- Q: How can you differentiate a child with severe croup from one with tracheitis?
- A: Infectious croup and tracheitis can present with similar features of fever, toxic appearance, respiratory distress, and stridor. Direct endoscopic visualization and culture of the upper airway is the test of choice to distinguish these medical conditions. Croup is commonly associated with parainfluenza virus and a “steeple sign” of the upper trachea on an anteroposterior neck radiograph.
- Q: Is influenza A virus a common pathogen of tracheitis?
- A: This subject is controversial. Influenza A virus is frequently recovered from tracheal cultures in children who present with tracheitis. It remains unclear, though, whether this virus is a pathogen or predisposing factor in tracheitis.
- Q: Is the supraglottic area usually involved in tracheitis?
- A: No. Unlike with epiglottitis, the supraglottic region is usually spared in tracheitis. Lack of supraglottic involvement suggests bacterial tracheitis rather than epiglottitis.

TRACHEOESOPHAGEAL FISTULA AND ESOPHAGEAL ATRESIA

Kimberly M. Lumpkins • F. Dylan Stewart

BASICS

DESCRIPTION

- Esophageal atresia with tracheoesophageal fistula (EA-TEF) is a congenital condition of incomplete formation of the esophagus. In most cases, the atretic (blind-ending) esophagus has an aberrant fistula to the trachea (TEF).
- Five types are described:
 - EA with distal TEF is the most common (Gross type C, 85%).
 - Pure EA without TEF occurs in 10% (Gross type A).
 - EA with proximal TEF and EA with both distal and proximal TEFs are quite rare (1% each, gross types B and D).
 - Pure TEF without EA occurs in 3–4% (“H type fistula”, Gross type E).

EPIDEMIOLOGY

- The prevalence of EA-TEF is 1 in 2,500–4,000 live births. This appears to be consistent worldwide.
- Slight male predominance (1.2:1)

RISK FACTORS

- Many maternal exposures have been postulated to contribute, but none are well established.
 - Maternal diabetes (nongestational) during 1st trimester, older age, maternal diethylstilbestrol (DES) exposure, horticultural work, alcohol, and smoking have all been implicated.

Genetics

- No specific genetic cause of EA-TEF has been established.
- Twin concordance is only 2.5%.

ETIOLOGY

- The foregut diverticulum separates into the trachea and esophagus at approximately 4–5 weeks of gestation.
- In EA-TEF, it is postulated that the lateral folds that fuse to separate the trachea and esophagus fail to form. Disruption of signalling in the Wnt and Bmp pathways has been implicated in this chain of development. This theory remains controversial, and the exact nature of the defect is unresolved.

COMMONLY ASSOCIATED CONDITIONS

- EA-TEF is associated with the VACTERL (vertebral defects, anal atresia, cardiac defects, TEF, radial or renal anomalies, and limb anomalies) sequence of congenital anomalies (10–25% of EA-TEF infants).
- Can be found in association with trisomies 13, 18, and 21 as well as CHARGE (coloboma, heart disease, choanal atresia, retarded growth, genital hypoplasia, and ear anomalies with deafness) syndrome, Feingold syndrome, DiGeorge syndrome, and others

DIAGNOSIS

HISTORY

- Prenatal ultrasound may demonstrate features suggestive of EA-TEF such as absence of a stomach bubble, a dilated proximal pouch, or polyhydramnios.
 - Only a minority of patients are prenatally identified, and the positive predictive value of these signs is low.
 - Prenatal diagnosis most common in cases of pure EA without TEF
- In patients without a prenatal suspicion of EA-TEF, the diagnosis is usually first entertained when a newborn has excessive secretions and repeated bouts of choking and spitting up during attempts at feeding.
- In patients with an H-type fistula, diagnosis may be delayed. These patients often present with recurrent respiratory infections or aspiration events later in childhood.

PHYSICAL EXAM

- Infants with EA-TEF are frequently normal in physical appearance.

- Failure of passage of a stiff 10F or 12F nasogastric tube at 10–12 cm is the major diagnostic test.
- Exam should focus on evidence of VACTERL anomalies.
- Careful cardiac auscultation
- Respiratory auscultation may reveal crackles or other signs of aspiration.
- Documentation of patent anus
- Examination of limbs for skeletal abnormalities (absent radii or thumbs)
- Observation of other congenital anomalies consistent with genetic syndromes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- There are no specific laboratory findings associated with EA-TEF.
- Underlying pathology may lead to expected laboratory findings (e.g., electrolyte derangement with severe renal anomalies).

Imaging

- CXR/abdominal XR: first recommended test
 - NG tube coiled in the proximal pouch in the upper chest or neck
 - Bowel gas present distally (type C)
 - No bowel gas with pure atresia (type A)
 - Possible vertebral and rib anomalies
 - Rule out “double bubble” of coincident duodenal atresia.
- Additional required imaging studies include a renal ultrasound, echocardiogram, and spinal ultrasound to rule out other VACTERL anomalies. Limb radiographs are indicated if abnormalities are seen on physical exam.
- Echocardiogram is crucial for operative planning as well as to assess for cardiac defects. Ask the cardiologist to comment specifically on the sidedness of the aortic arch.
- Esophagram
 - For a suspected H-type fistula: Prone pressure esophagram may demonstrate the communication between the trachea and esophagus; however, the finding can be subtle and repeated studies may be

necessary.

- Esophagram is otherwise contraindicated in patients with EA-TEF because of high risk of aspiration.

DIFFERENTIAL DIAGNOSIS

- Congenital esophageal stricture
- Severe gastroesophageal reflux disease (GERD)
- Vascular ring
- Tracheal bronchus (H-type fistula)
- Laryngotracheoesophageal cleft (H-type fistula)

TREATMENT

GENERAL MEASURES

Preoperative management

- Strict NPO until surgical correction is undertaken
- Maintain a Replogle suction tube in the proximal pouch to decrease aspiration from pooled secretions.
- Initiate acid suppression therapy.
- Maintain head of bed (HOB) elevated to 45 degrees.

ADDITIONAL TREATMENT

Complete workup for VACTERL anomalies as described above

SURGERY/OTHER PROCEDURES

- Surgical repair is required for all forms of EA-TEF.
- Repair is performed as early as feasible in the newborn period to avoid ongoing lung damage from repeated aspiration events.
- Extremely premature or ill infants can undergo fistula ligation without esophageal repair. The esophagus can be reconstructed at a later date when the infant is more stable.
- Bronchoscopy at time of repair is controversial. It may identify the rare case of dual TEF or laryngotracheoesophageal cleft.
- Repair via thoracotomy or thoracoscopy at the surgeon's discretion through the right chest (except in cases of a right-sided arch on echocardiogram, where a left-sided approach may be preferable).

- The fistula is ligated by sutures or clips; the proximal esophageal pouch is mobilized and the esophagus brought together with a sutured anastomosis.
- In a long-gap atresia (esophageal ends separated by more than 3 vertebral bodies) where the esophageal ends do not meet, a gastric pull-up or esophageal growth induction (Foker) process may be used. Alternately, a gastrostomy tube can be placed for nutrition and esophageal anastomosis performed in delayed fashion.
- Most surgeons place a feeding tube across the esophageal anastomosis to act as a stent and allow early enteral feeding.
- Chest tube placement is at the discretion of the surgeon.
- Postoperative paralysis and prolonged intubation are sometimes employed to reduce tension on the repair, but there is no strong evidence in favor of this practice.
- Pure H-type TEF can often be repaired by a cervical incision, avoiding entry into the chest.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

EA-TEF patients require long-term follow-up for GERD, dysphagia, and esophageal motility issues. Surveillance endoscopy may be considered in young adulthood for risk of esophageal cancer, but this strategy is not yet established.

PROGNOSIS

Survival depends predominantly on the presence or absence of cardiac anomalies. Overall survival is approximately 95%. Survival of babies >1.5 kg without cardiac anomalies is 98%.

COMPLICATIONS

- Esophageal leak
 - Early complication of EA-TEF repair
 - Seen on contrast esophagram
 - Will usually resolve with conservative management (NPO, TPN, and chest tube drainage of any collection)

- Predisposes to the subsequent development of esophageal stricture and recurrent TEF
- Esophageal stricture
 - Common complication of EA-TEF repair
 - Symptoms include coughing and choking during feeds.
 - An esophagram is diagnostic.
 - Serial esophageal dilations may relieve symptoms.
 - Acid suppression can improve response to dilation and fundoplication may be required in refractory cases.
- Tracheomalacia
 - Symptomatic tracheomalacia occurs in 20% of patients with EA-TEF.
 - Diagnose by rigid or flexible bronchoscopy.
 - Presents at 2–3 months of age with barking cough or stridor
 - Although children will outgrow tracheomalacia, the occurrence of “death spells” may mandate a surgical aortopexy to reduce severity of symptoms.
- GERD
 - Very common in EA-TEF patients due to disordered esophageal motility and anatomic alteration of the lower esophageal sphincter (LES) by esophageal traction
 - Unlike typical pediatric patients, reflux does not improve with age.
 - 15–70% of TEF patients eventually require fundoplication.
 - Predisposes the patient to Barrett esophagus, and recent data suggest that the lifetime risk of esophageal carcinoma may be 50 times higher than average
- Recurrent TEF is a difficult problem requiring endoscopic or operative correction.
- As most complications of EA-TEF present with choking, coughing, and cyanosis, it can be hard to distinguish between potential etiologies. A rational strategy of esophagram and bronchoscopy is needed to determine the appropriate treatment plan.

ALERT

- Positive pressure ventilation (PPV) preoperatively may lead to preferential ventilation of the fistula. Avoidance of PPV is preferred

when feasible.

- If intubation is required, placement of the endotracheal tube past the fistula is the textbook recommendation. However, the fistula is frequently at the carina, which can render this process impossible.
- In case of dislodgement, the postoperative nasogastric feeding tube should not be replaced without consultation with the surgeon to avoid disruption of the esophageal repair.
- If a postoperative EA-TEF infant requires urgent reintubation, mask-ventilate as gently as possible during induction to avoid disruption of the esophageal anastomosis. Maximize visualization of the vocal cords, as inadvertent esophageal intubation can be catastrophic.

CODES

ICD10

- Q39.1 Atresia of esophagus with tracheo-esophageal fistula
- Q39.2 Congenital tracheo-esophageal fistula without atresia
- Q39.0 Atresia of esophagus without fistula

FAQ

- Q: What is the diagnostic workup for suspected TEF?
- A: A chest radiograph with gentle forward pressure held on the nasogastric tube is the preferred diagnostic study. Without pressure, the film may imply a falsely high level of the cervical pouch. Once TEF is confirmed, the recommended evaluation includes echocardiogram, spinal and renal ultrasounds, and a surveillance radiograph of the spine.
- Q: What is the prognosis for babies with TEF?
- A: Overall survival is approximately 95%, with most mortalities occurring in very preterm babies and those with congenital cardiac defects. Reflux is common and may require fundoplication in some cases. Esophageal dysmotility is nearly universal, but the long-term implications of this are unclear.

TRACHEOMALACIA/LARYNGOMALACIA

Thomas G. Saba • Amy G. Filbrun

BASICS

DESCRIPTION

- Malacia refers to “softness” of airway structures.
- Laryngomalacia
 - Dynamic collapse of the supraglottic structures of the larynx resulting in airway obstruction
 - Most common congenital anomaly of the larynx
 - Most common noninfectious cause of stridor in children
- Tracheomalacia
 - Dynamic collapse of the trachea resulting in airway obstruction
 - Common cause of chronic wheezing in infants and children
 - Clinical manifestations depend on if lesion is part of the intrathoracic or extrathoracic portions of the trachea.

ETIOLOGY

- Laryngomalacia
 - Anatomic abnormalities:
 - Short aryepiglottic folds
 - Elongated, flaccid, omega-shaped epiglottis prolapses posteriorly.
 - Redundant arytenoid mucosa
 - Neurologic abnormalities:
 - Immaturity of neuromuscular control results in hypotonia of pharyngeal muscles.
- Tracheomalacia
 - Weakness of the tracheal wall secondary to softening of the anterior cartilaginous rings and/or decreased tone of the posterior membranous wall
 - Classified as primary or secondary
 - Primary: congenital; results from immature development of the tracheal structures; may occur with other congenital anomalies such as tracheoesophageal fistula, laryngomalacia, and facial

anomalies

- Secondary: acquired in a normally developed trachea after some insult such as prolonged positive pressure ventilation, recurrent infection or aspiration, or external compression
- During exhalation, increased collapsing pressure across a compliant airway wall causes invagination of the posterior membrane.
- With increasing age, the length, area, thickness, and amount of cartilage increases in the anterior rings as well as the size and contractility of the membranous wall.

DIAGNOSIS

HISTORY

- Laryngomalacia
 - Symptoms may be present at birth or delayed until 1–2 months of age.
 - Inspiratory stridor
 - May be asymptomatic during sleep or quiet breathing
 - Worsens with crying, agitation, feeding, upper respiratory infections, supine positioning
- Tracheomalacia
 - Primary: Symptoms may be delayed until 2–3 months of age.
 - Secondary: Symptoms delayed until after causative insult occurs.
 - Expiratory wheeze, if intrathoracic portion of trachea involved
 - Inspiratory stridor, if extrathoracic portion of trachea involved
 - Harsh barking cough
 - Symptoms worsen with crying, agitation, feeding, and infections.
 - Impaired mucus clearance, frequent infections
 - Rarely, cyanosis, hyperextension of neck, breath-holding spells, feeding difficulties

PHYSICAL EXAM

- Laryngomalacia
 - High-pitched or vibratory, inspiratory stridor
 - Suprasternal retractions

- Positional changes noted: usually worsens with flexion of neck, supine position
- Stridor transmitted throughout the chest on auscultation
- Tracheomalacia
 - Homophonous expiratory wheeze (intrathoracic malacia)
 - High-pitched inspiratory stridor (extrathoracic malacia)
 - Intercostal retractions, worse during activity, and acute respiratory infections

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Flexible fiberoptic laryngo/bronchoscopy
 - Gold standard for diagnosis of dynamic airway collapse
 - Performed during spontaneous breathing
 - Visualize the degree, extent, and location of laryngomalacia and/or tracheomalacia.
 - Evaluate for other airway lesions in the differential diagnosis.
- Barium esophagography
 - Used to evaluate for external vascular compression of the esophagus
 - Might help to identify gastroesophageal reflux
- Chest radiograph
 - Usually normal in both laryngomalacia and tracheomalacia
 - Important to rule out other causes of chronic cough or abnormalities that may cause external airway compression
- Airway fluoroscopy
 - Insensitive except in severe cases; unable to visualize AP and lateral caliber simultaneously
- MRI
 - Useful to evaluate for extrinsic vascular airway compression
- CT
 - Paired end-inspiratory and dynamic expiratory multidetector CT, free-breathing cine CT—both sensitive and specific
 - Exposure to radiation
- Pulmonary function tests
 - Might show flow limitation, typical notching in expiratory portion of flow-volume loop

DIFFERENTIAL DIAGNOSIS

- Laryngomalacia: differential diagnosis of chronic stridor
 - Vocal cord abnormalities: vocal cord paralysis/paresis
 - Laryngeal abnormalities: laryngeal cleft, laryngeal web, subglottic hemangioma, papilloma
 - Subglottic stenosis (biphasic stridor)
- Tracheomalacia: differential diagnosis of chronic homophonous wheeze
 - Structural abnormalities: vascular compression/ring, tracheal stenosis/web, cystic lesion, mass/tumor
 - Nonstructural abnormalities: gastroesophageal reflux disease (GERD), retained foreign body, persistent bacterial bronchitis

ALERT

- The differential diagnosis for stridor in children includes life-threatening causes.
- If history or clinical course deviates from expected pattern, consider comorbidities (asthma, GERD) or investigating for alternative diagnosis.
- Investigate lower airways in more severe cases of laryngomalacia for other airway anomalies.
- The use of beta₂ agonists may increase the tracheal wall collapsibility by decreasing muscular tone, thereby making the symptoms worse.
- Bronchoscopy should ideally be done under conscious sedation during spontaneous breathing to avoid altering vocal cord movement and airway dynamics.
- The use of rigid bronchoscopy may stent open the trachea, making tracheomalacia more difficult to identify; flexible bronchoscopy is a more appropriate test.

TREATMENT

GENERAL MEASURES

- Laryngomalacia
 - Most cases resolve spontaneously by 15–18 months of age.

- Observation and reassurance
- Consider feeding modifications (pacing, positioning, texture change).
- Strong association with GERD. Treat if symptomatic; empiric treatment is controversial.
- Tracheomalacia
 - Usually resolves spontaneously by 18–24 months of age
 - Observation and reassurance, chest physiotherapy for mucus clearance
 - Treatment of exacerbating factors, such as upper respiratory infections, asthma, or GERD

Surgery

- Laryngomalacia
 - 10% of cases of laryngomalacia are severe (apnea, cyanosis, severe retractions, failure to thrive, feeding difficulty, obstructive apnea), and require further investigation and treatment.
 - Supraglottoplasty: excision of redundant arytenoid mucosa, trimming of epiglottis, division of tight aryepiglottic folds
 - Tracheostomy
 - Postoperative complications: scarring, dysphagia
- Tracheomalacia
 - For severe cases, little evidence supporting noninvasive and surgical therapies
 - Tracheostomy may be needed in severe cases to bypass lesion or to provide continuous positive airway pressure.
 - Consider aortopexy (suspending the anterior trachea to widen the airway) in severe cases refractory to more conservative management.
 - Airway stents are associated with significant complications; reserved for children with otherwise poor prognosis
 - External airway splints currently under investigation

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Monitor for recurrent respiratory symptoms, poor growth, and other exacerbating conditions (asthma, GERD).

PROGNOSIS

- In cases of isolated laryngomalacia and/or tracheomalacia, prognosis is usually excellent.
- In patients with history of tracheoesophageal fistula, vascular ring, or other airway anomalies, tracheal dysfunction may persist after corrective surgery.

CODES

ICD10

- Q32.0 Congenital tracheomalacia
- Q31.5 Congenital laryngomalacia

FAQ

- Q: When will the symptoms improve?
- A: As anatomic structures mature with age, laryngomalacia symptoms may improve by 6 months of age, with usual resolution by 18 months

of age. Primary tracheomalacia may last longer, but in both entities symptoms usually resolve completely by age 2 years. Natural history of secondary tracheomalacia is dependent on cause.

- Q: Should all patients have an endoscopic evaluation?
- A: No. Diagnosis is usually made based on the history and physical examination. Infants with mild to moderate typical presentation need only careful monitoring for recurrence or worsening of symptoms and for poor growth. However, airway evaluation should be performed in all cases where a different pathology is considered or when symptoms worsen or persist past the expected age of resolution.

TRANSFUSION REACTION

Kristin A. Shimano

BASICS

DESCRIPTION

- Any acute or subacute adverse reaction that develops as a consequence of the administration of blood components
- Types include the following:
 - Acute reactions: hemolytic, febrile, allergic, anaphylactic, septic, transfusion-related acute lung injury (TRALI), transfusion-associated circulatory overload (TACO)
 - Delayed reactions: delayed hemolytic, transfusion-associated graft-versus-host disease (TA-GVHD)
 - Late complications of transfusion: infection, alloimmunization, iron overload

EPIDEMIOLOGY

1% of pediatric blood product recipients develop some type of transfusion reaction.

PATHOPHYSIOLOGY

- Acute hemolytic transfusion reaction
 - Antigen–antibody interaction leads to complement activation on the surface of the transfused RBCs, resulting in acute intravascular hemolysis and vasomotor instability.
 - Usually ABO blood group incompatibility
 - Most commonly due to medical error
- Febrile nonhemolytic transfusion reaction (FNHTR)
 - Cytokines released by leukocytes in the product
 - 40% of patients with one febrile reaction will have a subsequent one.
- Urticarial (allergic)
 - IgE-mediated
 - Recipient allergic response to donor plasma proteins or other

constituents of plasma

- Sporadic and donor dependent
- Anaphylactic
 - Overwhelming acute allergic reaction. Can be mediated by anti-IgA formed by a recipient who is IgA deficient and receives blood products containing IgA
- Bacterial sepsis
 - Intravascular infusion of viable bacteria and endotoxins leads to fever, chills, and/or acute septic shock.
 - Contaminated blood product; most commonly a platelet product near the end of shelf life
- Delayed hemolytic transfusion reaction (DHTR)
 - Previously transfused patients who are sensitized to a minor blood group antigen, especially Jk^a or Jk^b (Kidd antigen), develop an anamnestic response on reexposure.
 - Antibody is below detectable levels in antibody screen and crossmatch; after transfusion, titers rise (usually within 2–10 days) and extravascular hemolysis occurs.
- TRALI
 - Antileukocyte antibodies or neutrophil-activating factors in transfused product interact with recipient neutrophils, causing leukocyte aggregates that deposit in the lung.
 - Multiparous female donors with HLA sensitization often are implicated.
- TACO
 - Circulatory overload leading to heart failure
 - Administration of an excessive volume of a blood product or infusion at an excessive rate
- TA-GVHD
 - Patients with inherited or acquired T-cell immunodeficiency can develop TA-GVHD from transfused immunocompetent T cells.
 - Can also occur if the donor and recipient are related and share HLA types

DIAGNOSIS

HISTORY

- Acute hemolytic
 - Fever/chills
 - Abdominal or flank pain
 - Pink or tea-colored urine
 - Tachycardia
 - Hypotension
 - Oliguria
- FNHTR
 - Fever, chills 1–6 hours after transfusion
- Urticarial
 - Urticaria
 - Flushing
 - Pruritus
- Anaphylactic
 - Urticaria
 - Bronchospasm
 - Hypotension
- Bacterial sepsis
 - Fever
 - Chills
 - Hypotension
- DHTR
 - Fever
 - Malaise
 - Dark urine
 - Jaundice
 - Shock (rarely)
 - Renal failure 2–10 days after transfusion
- TRALI
 - Acute dyspnea, tachypnea, rales, decreased oxygenation within 6 hours of transfusion
- TACO
 - Hypertension
 - Dyspnea

- Rales
- Cardiac arrhythmia
- TA-GVHD
 - Fever
 - Rash
 - Diarrhea
 - Cough 4–30 days after transfusion

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Acute hemolytic
 - Direct Coombs test: positive
 - CBC: anemia
 - Urinalysis: hemoglobinuria
 - Prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, fibrin split products: disseminated intravascular coagulation (DIC)
- FNHTR
 - Direct Coombs test: negative or no change from pretransfusion
 - Immediate Gram stain of the product
 - Blood culture of the patient and product
 - All results should be negative; a diagnosis of exclusion.
- Urticarial
 - No specific testing
- Anaphylactic
 - IgA level in recipient. If undetectable, test for anti-IgA antibody (of the IgE class).
- Bacterial sepsis
 - Immediate Gram stain and blood culture of the transfused product: result positive for bacteria
- DHTR
 - CBC: anemia
 - Bilirubin: elevated
 - Indirect Coombs test (antibody screen): positive
 - Direct Coombs test: positive (mixed field) if done early
- TRALI

- Leukocyte antibody testing in the implicated donor(s)

Imaging

- Chest radiograph: increased pulmonary vascular markings or infiltrates for hypervolemia (TACO) and TRALI

TREATMENT

GENERAL PREVENTION

- Acute hemolytic
 - Proper labeling of blood specimens and products and adherence to procedures for correct identification of product and recipient will eliminate most acute hemolytic transfusion reactions.
- FNHTR
 - Administration of leukodepleted products, especially for long-term transfused patients who have a high incidence of febrile transfusion reactions
 - No evidence to support premedication with Tylenol or Benadryl to prevent FNHTR
- Urticarial
 - Administration of washed erythrocyte products (in patients with repeated or severe allergic reactions)
 - No conclusive evidence to support premedication with antihistamines
- Anaphylactic
 - If due to anti-IgA in an IgA-deficient recipient, provision of IgA deficient products may be possible.
- Bacterial sepsis
 - Sterile technique in blood collection, storage, and administration; inspection of product before transfusion
 - Bacterial screening of platelet products before they are transfused
- DHTR
 - Appropriately performed antibody screen and crossmatch as pretransfusion testing
 - Check blood bank records for previous antibodies.

- TRALI
 - Deferral of donors is implicated in proven TRALI cases.
- TACO
 - Administer appropriate volumes (typically 10–15 mL/kg) at appropriate rate, usually over 3–4 hours unless hypovolemic or actively bleeding.
 - Patients with chronic anemia are euvolemic and should be transfused with smaller volumes over longer time periods.
- TA-GVHD
 - Patients at risk (immunocompromised, neonates) must receive irradiated blood products.

ADDITIONAL TREATMENT

General Measures

- Acute hemolytic
 - Stop transfusion immediately.
 - Supportive care with hydration, pressors, and diuretics to maintain circulation and urine output
- FNHTR
 - Stop transfusion.
 - Antipyretics (acetaminophen)
 - Demerol for severe chills and rigors
 - May resume transfusion if patient is stable and acute hemolytic transfusion reaction and bacterial sepsis are ruled out
- Urticarial
 - Stop transfusion.
 - Antihistamine (diphenhydramine)
 - Steroids or epinephrine in severe reactions
 - Transfusion may be resumed if mild reaction
- Anaphylactic
 - Epinephrine
 - IV fluids, pressors
 - Respiratory support
- Bacterial sepsis
 - Stop transfusion.
 - Fluids if hypotensive

- Antibiotics to eradicate Staphylococcus and Gram negatives including Yersinia species
- DHTR
 - Depends on degree of hemolysis; if profound, management as acute hemolytic reaction. If mild, no therapy may be needed.
- TRALI
 - Supportive care, usually resolves in 12–24 hours
- TACO: diuretics (furosemide)
- TA-GVHD: no treatment, almost always fatal

ONGOING CARE

COMPLICATIONS

- Posttransfusion hepatitis: caused by hepatitis B or C viruses, others
- AIDS: caused by HIV
- Cytomegalovirus (CMV)
 - Symptomatic infection in patients with inherited or acquired immunodeficiency states, premature neonates
 - These individuals should receive CMV-safe products.
- Other transfusion-transmissible infections
 - Epstein-Barr virus, syphilis, malaria, toxoplasmosis, human T-lymphotropic virus I (HTLV-I), Chagas disease, babesiosis, filariasis, West Nile virus, parvovirus B19
- Alloimmunization
 - Formation of antibodies to erythrocyte, platelet, and HLA antigens can develop in some multiply transfused patients; may cause delays in pretransfusion testing, febrile transfusion reactions, delayed hemolytic transfusion reactions, and platelet transfusion refractoriness.
 - HLA alloimmunization may also affect eligibility and organ procurement for solid organ transplantation.
- Iron overload
 - Long-term transfusion recipients will accumulate iron as a by-product of erythrocyte breakdown.
 - An iron-chelating drug will enhance its excretion.

CODES

ICD10

- T80.92XA Unspecified transfusion reaction, initial encounter
- T80.919A Hemolytic transfusion reaction, unspecified incompatibility, unspecified as acute or delayed, initial encounter
- R50.84 Febrile nonhemolytic transfusion reaction

FAQ

- Q: What is the risk of acquiring certain viral infections?
- A: Hepatitis B: 1:300,000 transfused units; hepatitis C: 1:1,800,000 transfused units; HIV: 1:2,300,000 transfused units
- Q: What is the risk of developing bacterial sepsis?
- A: 1:1,000,000 red cell units; 1:13,000–100,000 platelet units
- Q: Is directed donor blood safer?
- A: No. There is no evidence that the infection risk is lower, and some studies suggest that the infection risk may be higher.
- Q: Is it safe to give a transfusion to a patient with fever?
- A: Yes. However, if the temperature rises during the transfusion or if symptoms such as chills or hypotension develop, the transfusion

should be stopped and the patient evaluated for a transfusion reaction.

TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD

Julie W. Stern

BASICS

DESCRIPTION

An acquired, self-limited suppression of red cell production in an otherwise healthy child

EPIDEMIOLOGY

- Mean age at diagnosis is 26 months.
- <10% are >3 years of age at diagnosis.
- Slight male predominance (male:female ~5:3)
- No seasonal predominance

RISK FACTORS

Genetics

- There is no simple genetic pattern.
- Familial transient erythroblastopenia of childhood has been reported (rarely), suggesting a combination of environmental factors and genetic propensity.

GENERAL PREVENTION

There is no known way to prevent transient erythroblastopenia of childhood.

ETIOLOGY

- Unknown
- Possible viral causes include parvovirus B19 and human herpesvirus 6 (HHV-6), but this remains hypothetical.
- A serum inhibitor, such as an IgG directed at the committed erythroid stem cell progenitor, has also been proposed but not yet proven.

DIAGNOSIS

HISTORY

- Pallor
 - Typically slow in onset and therefore often missed by parents
 - Often noted by an adult who sees the child less frequently
- Activity level
 - Often preserved because of slow onset of anemia
 - An extremely anemic child may be irritable, sleepy, and/or lethargic.
- History of fever, easy bruisability, or frequent/severe infections (especially bacterial): should alert the clinician to consider other diagnoses such as leukemia and bone marrow failure syndromes

PHYSICAL EXAM

- Child is generally well appearing and not chronically ill.
- Pallor
- Tachycardia secondary to anemia
- Usually no organomegaly, ecchymosis, petechiae, or jaundice

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- CBC
 - Low hemoglobin, normal mean corpuscular volume (MCV), normal RBC morphology
 - Total WBC count/morphology and platelet count should be normal; if not, consider leukemias.
 - Absolute neutrophil count may be decreased (rarely $<500/\mu\text{L}$), but morphology must be normal.
 - Red cell distribution width may be elevated during recovery.
- Reticulocyte count
 - Low to zero during anemic phase
 - Should be high during recovery
- Chemistry/blood bank:
 - Bilirubin, lactate dehydrogenase, ferritin, iron levels, and direct and indirect Coombs testing should be normal to rule out iron deficiency anemia and immune hemolysis.
- Parvovirus titers, parvovirus polymerase chain reaction (PCR) testing

- Immunoglobulin (Ig) levels in some cases
- Hemoglobin electrophoresis with quantitative fetal hemoglobin
 - Should be normal in transient erythroblastopenia of childhood
 - Fetal Hgb elevated in Diamond-Blackfan anemia
- Chest radiograph: to determine degree of cardiomegaly
- Bone marrow aspiration
 - Not mandatory to make diagnosis
 - May be necessary to rule in transient erythroblastopenia of childhood and rule out other diagnoses such as Diamond-Blackfan or leukemia
 - Presence or absence of early RBC precursors may help predict time to recovery.
 - Maturation of megakaryocytes and the myeloid cell line must be normal, especially if neutropenia is present.

DIFFERENTIAL DIAGNOSIS

- Environmental: iron deficiency anemia
- Metabolic: hypothyroidism
- Diamond-Blackfan anemia (this diagnosis usually made within 1st year of life)
- Neoplasm
 - Leukemia
 - Myelodysplastic syndromes
- Miscellaneous
 - Renal disease
 - Anemia of chronic disease
 - Blood loss (usually GI)

TREATMENT

MEDICATION

- No role for prednisone, iron supplements, anabolic steroids, or other immunosuppressive agents
- Short-term folic acid may be indicated during reticulocytosis.

ADDITIONAL TREATMENT

General Measures

- Initial inpatient observation for complications of severe anemia; daily CBC at least initially to gauge rate of fall of hemoglobin/rise of reticulocyte count and to estimate time to recovery
- Packed RBC transfusion
 - If there is evidence of cardiovascular compromise
 - If a transfusion is needed, transfuse slowly to prevent fluid overload. A good rule of thumb is to transfuse the same number of mL/kg as the patient's hemoglobin over 3–4 hours. Should a 2nd transfusion be needed, attempt to use a 2nd aliquot of the same unit to decrease donor exposure.
- Normal activity and diet for age, as tolerated
- Instruct family on signs and symptoms of severe anemia.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Clinic visits weekly to monitor hemoglobin and reticulocytes. These visits may need to be more frequent in the beginning of the illness and less frequent as recovery becomes evident.
- Elevation of reticulocyte count is the first sign of recovery.

PROGNOSIS

- All children recover usually within 1–2 months from diagnosis (may take up to 8–12 months for full recovery).
- Prognosis is excellent.
- Recurrence is rare.

COMPLICATIONS

- Cardiovascular compromise secondary to severe anemia is often less than expected given the level of anemia. High-output CHF is unusual.
- Neurologic symptoms including confusion and transient hemiparesis have been reported but are rare.
- A significant number of patients also have neutropenia (absolute neutrophil count $\leq 1,500/\mu\text{L}$) during either the acute or recovery phase of the illness.

ALERT

- Isolation is necessary because of possible teratogenicity of parvovirus 19 and contagion within the hospital.
- Transient erythroblastopenia of childhood must be an isolated normocytic, normochromic anemia. If the other cell lines are affected (except for mild neutropenia) or if the anemia is macrocytic, consider bone marrow failure syndromes.
- Iron therapy has no place in the treatment of transient erythroblastopenia of childhood. Be sure to check RBC indices and reticulocyte count prior to instituting iron therapy for anemia.

ADDITIONAL READING

CODES

ICD10

D60.1 Transient acquired pure red cell aplasia

FAQ

- Q: Can other children in a family get this illness?
- A: The cause(s) of this illness in otherwise normal children is unknown. It is very rare for other family members to be affected. It is appropriate to reassure parents regarding this issue.
- Q: Are transfusions always necessary?
- A: No. Only in cases of heart failure is a transfusion necessary. Most

often, children can be managed with watchful waiting.

- Q: How can transient erythroblastopenia of childhood be distinguished from Diamond-Blackfan syndrome?
- A: Children with Diamond-Blackfan syndrome are usually <1 year old and can have elevated hemoglobin F levels. If a bone marrow aspirate is obtained during the recovery phase of transient erythroblastopenia of childhood, the diagnosis will be clear. Often, however, only time will tell. Children with transient erythroblastopenia of childhood always recover; those with Diamond-Blackfan syndrome do not.
- Q: Is transient erythroblastopenia of childhood a precursor to leukemia?
- A: No. However, if recovery does not occur in a timely manner, or if neutropenia worsens, a bone marrow aspirate may be indicated if not previously completed.

TRANSIENT TACHYPNEA OF THE NEWBORN

Colleen A. Hughes Driscoll • Bernadette A. Hillman

BASICS

DESCRIPTION

- Early onset of tachypnea (respiratory rate >60 breaths/minute) in the newborn following an uneventful delivery
- Symptoms of respiratory distress including mild retractions, expiratory grunting, and nasal flaring may occur. Cyanosis is rarely involved.

EPIDEMIOLOGY

Incidence

- Estimated 4–6 per 1,000 live births
- Incidence is likely underestimated.
- Most common cause of respiratory distress in newborns
- Higher in males

RISK FACTORS

- Early gestation
- Cesarean section delivery (with or without preceding labor)
- Male gender
- Maternal diabetes
- Macrosomia
- Low birth weight
- Maternal history of asthma
- Unexplained transient tachypnea of the newborn (TTN) in individuals belonging to the same family suggests a genetic predisposition.

GENERAL PREVENTION

- Vaginal delivery should be recommended in the absence of maternal or fetal indications for cesarean section.
- Elective cesarean section before 39 weeks' gestation should be avoided.

ETIOLOGY

- During fetal life, pulmonary epithelial cells are secretory, delivering chloride into the alveolar space.
- Sodium and water follow chloride into the alveoli, establishing and maintaining fetal lung fluid.
- During labor and delivery, fetal lung fluid is absorbed through a variety of proposed mechanisms:
 - Epithelial cells transition from secretory cells to absorptive cells in response to circulating epinephrine levels, which trigger opening of epithelial sodium channels (ENaC).
 - Compression of the fetal thorax from uterine contractions and passage through the vaginal canal contributes to removal of fluid from the lungs through the pulmonary circulation.
 - Prostaglandin-mediated dilation of lymphatic vessels occurs with resultant absorption of interstitial lung fluid into the lymphatic system.
- TTN occurs when there is inadequate fluid clearance from the lungs.
- It is believed that this excess interstitial lung fluid contributes to decreased lung compliance.

DIAGNOSIS

HISTORY

- Tachypnea presenting within the first few hours of life
- Presence of familial risk factors
 - Maternal diabetes
 - Maternal asthma
 - Family history of unexplained TTN
- Birth-related risk factors
 - Perinatal depression
- Absence of risk factors that suggest an infectious, metabolic, or anatomic disease process such as the following:
 - Maternal chorioamnionitis or other untreated maternal infections
 - Meconium or blood-stained amniotic fluid
 - Prolonged rupture of membranes

- Long-standing oligohydramnios or anhydramnios
- Advanced resuscitation at delivery
- Presence of risk factors for other conditions should prompt additional investigations.

PHYSICAL EXAM

- Respiratory rate >60 breaths/minute
- Grunting, nasal flaring, mild to moderate retractions; rarely, cyanosis
- Symmetric breath sounds on auscultation
- Symmetry of thoracic cavity, possibly with barrel-shaped chest appearance due to lung hyperinflation
- Lungs are generally clear on auscultation, but crackles may be present.
- Absence of stridor
- Absence of signs, symptoms, or other abnormalities in one or more additional organ systems

DIAGNOSTIC TESTS & INTERPRETATION

- TTN is a diagnosis of exclusion.
- Degree of diagnostic workup will vary and will depend on risk factors and clinical manifestations of the mother and baby.
- Risk factors or physical findings consistent with other disease processes should prompt diagnostic testing as clinically indicated.
- CBC
 - Leukopenia or leukocytosis with increased immature to total neutrophil count suggests infection.
- C-reactive protein
 - May be elevated within the first 24 hours with infectious etiology
- If abnormalities exist on these laboratory evaluations, a workup for infection is warranted and should minimally include a blood culture and chest radiograph.
- Arterial blood gas
 - Respiratory acidosis (particularly for $\text{PCO}_2 > 60$ mmHg), metabolic acidosis, or metabolic alkalosis suggest alternative etiologies for respiratory distress.
 - A significantly elevated A–a gradient may suggest an extrapulmonary or intrapulmonary right-to-left shunt.

- Pulse oximetry
 - Typically, preductal saturations will be greater than 95% on room air.
 - Supplemental oxygen is rarely required; oxygen supplementation of more than 40% FiO₂ suggests an alternative etiology.
- Echocardiogram
 - Respiratory distress and cyanosis may be a manifestation of congenital heart disease.

Imaging

- Chest radiograph
 - Findings are variable but generally include pronounced perihilar vascular marking and fluid opacity in the interlobar spaces.
 - Slight flattening of the diaphragms and increase in the intercostal spaces can be present if air trapping occurs.
- Of note, there may be poor concordance between the clinical diagnosis of TTN and the presence of radiographic findings of TTN, as radiographic interpretation in cases of TTN is relatively variable.

DIFFERENTIAL DIAGNOSIS

- Respiratory
 - Delayed adaption of the newborn
 - Meconium/blood/amniotic fluid aspiration
 - Respiratory distress syndrome
 - Pulmonary hypoplasia
 - Persistent pulmonary hypertension of the newborn
 - Pneumothorax
 - Pneumomediastinum
- Infection
 - Pneumonia
 - Sepsis
- Neurologic
 - Hypoxic brain injury
 - Conditions that present with central hypotonia
- Cardiac
 - Congenital cyanotic heart disease

- Cardiovascular anatomy that contributes to pulmonary overcirculation
- Metabolic
 - Conditions that present with metabolic acidosis or hyperammonemia
- Miscellaneous
 - Disorders related to abnormal embryonic pulmonary development (e.g., congenital diaphragmatic hernia, congenital cystic adenomatous malformation, congenital emphysema)
 - Congenital airway abnormalities (e.g., Pierre Robin sequence, choanal atresia)

ALERT

TTN is a diagnosis of exclusion. A thorough review of the maternal history, birth history, and physical examination is essential in determining the degree of workup needed to exclude more severe etiologies.

TREATMENT

GENERAL MEASURES

- Resolution of symptoms will occur in time, most often within the first 2 days of life.
- Initial management
 - Direct observation under radiant heat for signs of worsening tachypnea/distress or other abnormal vital signs
 - NPO for initial observation period
 - Monitoring for hypoglycemia
 - Continuous cardiorespiratory monitoring and pulse oximeter monitoring—preductal saturation goal of >95% as the infant transitions to extrauterine circulation
 - Administration of antibiotics and appropriate diagnostic workup if infection or metabolic condition is suspected

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Admission to a Special Care Nursery or Neonatal Intensive Care Unit and chest radiography are indicated for the following:
 - Symptoms persisting beyond 2 hours from onset
 - Worsening of symptoms or onset of additional symptoms
 - Infection is suspected.
 - Persistent need for oxygen
 - Chest radiograph is abnormal.
 - IV fluids are required to maintain nutrition/hydration.

PATIENT EDUCATION

Infant can transition to routine care when

- There has been steady improvement in symptoms during the observation period.
- The respiratory rate permits adequate oral nutrition.
- When oxygen is no longer required to maintain normal oxygen saturations

PROGNOSIS

- TTN is typically self-resolved and few, if any, long-term sequelae exist.
- Recent studies have shown an association between TTN and developing wheezing symptoms at school age.

COMPLICATIONS

- Hypoxia requiring oxygen administration
- Occasionally, mechanical ventilation is necessary, and rarely, extracorporeal membrane oxygenation is needed if persistent pulmonary hypertension develops.

CODES

ICD10

P22.1 Transient tachypnea of newborn

FAQ

- Q: For how long does the tachypnea generally occur?
- A: Most babies' respiratory rates improve within 72 hours; in persistent cases, it may last longer.
- Q: What respiratory rate is safe for trial of PO feeds?
- A: <70 breaths/minute without an exaggerated respiratory effort.

- Q: What respiratory rate is safe for hospital discharge?
- A: <60 breaths/minute for greater than 12 hours to ensure resolution of symptoms and confirm the diagnosis of TTN.

TRANSPOSITION OF THE GREAT ARTERIES

Bradley S. Marino • Pirouz Shamszad

BASICS

DESCRIPTION

Abnormal anatomic relationship between the great arteries and the ventricles in which the aorta arises from the anatomic right ventricle and the pulmonary artery arises from the anatomic left ventricle

Incidence

Incidence is 20–30 per 100,000 live births, with a 60–70% male predilection.

Prevalence

Transposition of the great arteries represents up to 7% of all cases of congenital heart disease.

PATHOPHYSIOLOGY

- Systemic and pulmonary circulations are separated and function in parallel.
- Desaturated systemic venous blood is ejected from the right heart to the aorta, whereas the oxygenated pulmonary venous blood is ejected from the left ventricle into the lungs.
- Degree of hypoxemia depends on amount of intercirculatory mixing (patent ductus arteriosus [PDA], patent foramen ovale [PFO], ventricular septal defect [VSD]).
 - Degree of left-to-right shunting is the effective systemic blood flow, whereas right-to-left shunting determines effective pulmonary flow.

COMMONLY ASSOCIATED CONDITIONS

- PDA and PFO with intact ventricular septum (50%)
- VSD (40%)
- Posterior malalignment VSD with left ventricular outflow tract obstruction (e.g., subpulmonic stenosis, pulmonary stenosis, pulmonary atresia) (10%)

- Anterior malalignment VSD with right ventricular outflow tract obstruction (e.g., subaortic stenosis, aortic stenosis, coarctation of the aorta or interruption of the aortic arch) (10%)
- Leftward juxtaposition of the atrial appendages (5%)
- Straddling of the atrioventricular valve

DIAGNOSIS

HISTORY

- Infants are of normal birth weight or sometimes large for gestational age.
- Cyanosis
- Tachypnea often without retractions
- Poor feeding

PHYSICAL EXAM

- General
 - Moderate to severe cyanosis
- Cardiovascular
 - Heart sounds: Single loud S₂, but no heart murmur is heard in infants with intact ventricular septum; soft systolic murmur in those infants with a VSD and a systolic ejection murmur of valvar or subvalvar aortic or pulmonic stenosis may be heard.
- Respiratory
 - Generally, dyspnea and tachypnea present without retractions in a neonate without a VSD; with a large VSD and congestive heart failure (CHF), retractions may be present.
- Abdomen
 - Hepatomegaly may occur with a large VSD and CHF.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Arterial blood gas

- Hypoxemia (PO₂ often in low 30s) unchanged in 100% FiO₂. Infants with inadequate mixing have PO₂ <25 torr with metabolic acidosis.

Imaging

- Chest radiograph
 - Mild cardiomegaly with an egg-shaped heart with narrow superior mediastinum (so-called egg on a string) and increased pulmonary vascular markings
- ECG
 - Initially normal, progressing to right ventricular hypertrophy and right axis deviation
- Echocardiogram
 - 2D ECHO and color-flow Doppler studies usually provide all anatomic and functional information required for management of infants with D-transposition of the great arteries (D-TGA). The study should focus on the alignment of the great arteries and other associated anomalies, specifically defects that promote intercirculatory mixing, the presence of left or right ventricular outflow tract obstruction, and the coronary anatomy.

Pathologic Findings

- In D-TGA, the aorta is oriented anteriorly and rightward from the pulmonary artery and originates from the right ventricle, carrying desaturated blood to the body. The pulmonary artery originates posteriorly from the left ventricle and carries oxygenated blood to the lungs. There is fibrous continuity between the pulmonary and mitral valves; subaortic conus (infundibulum) is present. In the normal heart, the aorta arises posteriorly from the left ventricle and carries oxygenated blood to the body, there is fibrous continuity between the aortic and mitral valves, and subpulmonary conus is present.
- TGA types
 - The most common type of TGA, known as D-TGA, has transposed great arteries with cardiac segments S, D, and D: situs solitus of the atria and viscera (S), dextroventricular segment situs (D), aortic valve annulus to the right of the pulmonary artery (D). There is atrioventricular concordance and ventriculoarterial discordance.
 - L-TGA, or “corrected transposition,” has transposed great arteries with cardiac segments S, L, and L: situs solitus of the atria and viscera (S), levoventricular segment situs (L), and the aortic valve

annulus is to the left of the pulmonary artery (L). There is atrioventricular discordance and ventriculoarterial discordance.

- Abnormal coronary artery (CA) branching occurs in 33%.
 - Circumflex artery off the right CA (16%), single right CA (4%), single left CA (2%)

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for the neonate with TGA is that for the cyanotic neonate.

- Cardiac
 - Lesions with ductal-dependent pulmonary blood flow
 - ▢ Tricuspid atresia with normally related great arteries
 - ▢ Tetralogy of Fallot
 - ▢ Tetralogy of Fallot with pulmonic atresia
 - ▢ Critical pulmonic stenosis
 - ▢ Pulmonary atresia with intact ventricular septum
 - ▢ Ebstein anomaly
 - ▢ Heterotaxy (most forms)
 - Ductal-independent mixing lesions
 - ▢ Total anomalous pulmonary venous connection without obstruction
 - ▢ Truncus arteriosus
 - Lesions with ductal-dependent systemic blood flow
 - ▢ Hypoplastic left heart syndrome
 - ▢ Interrupted aortic arch
 - ▢ Critical coarctation of the aorta
 - ▢ Critical aortic stenosis
- Pulmonary
 - Primary lung disease
 - Airway obstruction
 - Extrinsic compression of the lungs
- Neurologic
 - CNS dysfunction
 - Respiratory neuromuscular dysfunction
- Hematologic
 - Methemoglobinemia

- Polycythemia

TREATMENT

MEDICATION

- Correction of metabolic acidosis, hypoglycemia, and hypocalcemia improves myocardial function.
- Prostaglandin E1 (PGE1) is used for severe cyanosis to promote left (aorta) to right (pulmonary artery) shunting at the ductus arteriosus, thereby increasing pulmonary blood flow, distention of the left atrium, and improved mixing at the atrial level. Side effects of PGE1 include apnea, fever, and hypotension.

SURGERY/OTHER PROCEDURES

- Interventional catheterization
 - Balloon atrial septostomy (Rashkind procedure) is used in the severely hypoxemic infant with an intact or restrictive atrial septum to promote intercirculatory mixing at the atrial level and stabilize the neonate before definitive or palliative surgery.
- Definitive surgery for D-TGA includes procedures that redirect the pulmonary and systemic venous return at the atrial, ventricular, and great artery levels.
 - Atrial inversion: Atrial inversion procedures involve baffling the pulmonary venous blood flow to the tricuspid valve (systemic circulation) and the systemic venous blood flow to the mitral valve (pulmonary circulation). The 2 atrial inversion operations include the Mustard procedure, in which prosthetic or pericardial baffles are used to redirect the blood, and the Senning procedure, in which the baffles are composed of an atrial septal flap and the right atrial free wall. The Senning or Mustard procedures may be used in the following infants:
 - Infants with D-TGA with intact ventricular septum who have not had surgical repair within the 1st month of life
 - Neonates with D-TGA with intact ventricular septum and severe pulmonic stenosis. Most centers would perform a Rastelli

- procedure for this anatomic variant (see subsequent list items).
 - Neonates with D-TGA with “unswitchable coronaries” (<1% of cases)
- Ventricular inversion
 - D-TGA with a VSD and severe pulmonic stenosis: The Rastelli operation may be used to redirect blood flow at the ventricular level. In this operation, the proximal main pulmonary artery is divided and oversewn, and the left ventricular blood flow is baffled to the aorta by creating an intraventricular tunnel between the VSD and the aortic valve. A conduit is placed from the right ventricle to the pulmonary artery to redirect the right ventricular blood flow.
- Arterial switch
 - D-TGA with intact ventricular septum and “switchable” coronaries: The arterial switch operation (ASO) is performed in which the great arteries are transected above their respective semilunar valves and switched with reimplantation of the CAs into the neo-aortic root (native pulmonary valve root).
 - D-TGA with anterior malalignment VSD with severe aortic stenosis: ASO with VSD patch closure and transannular patch of the right ventricular outflow tract

ONGOING CARE

PROGNOSIS

- Without treatment, mortality is 30% within the 1st week of life, 50% within the 1st month, 70% within the first 6 months, and 90% within the 1st year.
- In most centers, the mortality rate after ASO for D-TGA with intact ventricular septum or D-TGA with a VSD is <3%. Factors that have been shown to increase the mortality risk include an intramural course of the left CA, retropulmonary course of the left CA, complex arch abnormalities, right ventricular hypoplasia, multiple VSDs, and straddling atrioventricular valves.

COMPLICATIONS

- Complications of intra-atrial surgeries include absence of sinus rhythm (>50% of cases), supraventricular arrhythmias (50%), moderately to severely depressed right ventricular function (20%), residual intra-atrial baffle shunt (20% of cases), tricuspid regurgitation (5–10% of cases), obstruction of systemic venous return (5% of cases), and obstruction of pulmonary venous return (<2% of cases). Follow-up observation is recommended every 12 months to detect arrhythmias, tricuspid regurgitation, or depressed right ventricular function that generally occurs years after surgery. Arrhythmias include sinus node dysfunction (e.g., marked sinus bradycardia, ectopic atrial rhythm, junctional rhythm, or junctional bradycardia) and supraventricular tachycardia, especially atrial flutter.
- Complications after the Rastelli operation include left ventricular outflow tract obstruction, conduit obstruction, and complete heart block. Follow-up observation is recommended every 12 months to monitor for conduit obstruction, left ventricular outflow tract obstruction, and heart block.
- The most common complication after the ASO is neoaortic root dilation with or without neoaortic insufficiency. Other rarer complications include supralvalvar pulmonary stenosis at the anastomotic site (5% of cases), supralvalvar aortic stenosis at the anastomotic site (5% of cases), and CA obstruction, which may lead to ischemia and infarction. These complications are uncommon and usually hemodynamically insignificant. Mortality varies depending on the period of time being assessed:
 - Early mortality is usually related to kinking or obstruction of the CAs during transfer to the neoaorta, an “unprepared” left ventricle, or hemorrhage from the multiple suture lines.
 - Late mortality (i.e., 1–2%) usually results from myocardial ischemia, pulmonary vascular obstructive disease, or during reoperation for supralvalvar stenosis.
- Follow-up observation is recommended every 12 months to monitor for neoaortic root dilation, neoaortic valve insufficiency, supralvalvar aortic or pulmonic stenosis, and CA ischemia.

- Q20.5 Discordant atrioventricular connection

TRANSVERSE MYELITIS

Paul R. Lee • Avindra Nath

BASICS

DESCRIPTION

An acute or subacute inflammatory lesion of the spinal cord manifesting with the appearance of new autonomic, motor, and sensory symptoms. The “transverse” descriptor is a reference to the classic symptom presentation with an identifiable sensory level traversing the midline. Transverse myelitis (TM) is associated with cerebrospinal fluid (CSF) or radiographic abnormalities consistent with an inflammatory spinal cord lesion. TM is usually monophasic but can be a manifestation of a chronic disease.

EPIDEMIOLOGY

- Incidence: Estimated 1–8/million cases per year in the United States (20% children) or approximately 300 affected children annually. There are two incidence distributions in children—a peak between 0 and 2 years of age and another broader distribution from 5 to 17 years of age.
- Prevalence: estimated 34,000 in the United States with disabilities due to TM
- The female-to-male ratio is approximately 1:1 for <10 years, with a female predominance observed after age 10 years (2.6:1) in a North American cohort.

RISK FACTORS

- Fever, findings consistent with infection, or vaccinations in the preceding weeks are reported in the majority (>50%) of children with TM, but specific infections are rarely diagnosed.
- Mild trauma and obesity are associated with an increased risk of TM.

ETIOLOGY

Unknown. Several infectious and autoimmune conditions have been associated with TM without a clear unifying immunopathogenesis.

COMMONLY ASSOCIATED CONDITIONS

- TM in children is predominantly idiopathic.
- TM can be a manifestation of the acquired demyelinating syndromes, for example, acute disseminated encephalomyelitis (ADEM), multiple sclerosis (MS), or neuromyelitis optica (NMO).
- The enteroviruses (coxsackie A7, 9, 23, and B strains) and other viruses (dengue fever, hepatitis, human herpes, influenza, polio, and West Nile virus) have been reported in association with acute TM.
- TM can occur during acute mycoplasma, spirochete, or parasitic infections.
- TM has been reported in combination with Guillain-Barré syndrome (GBS).
- TM can occur as part of a systemic autoimmune inflammatory disease (mixed connective tissue disease, systemic sclerosis, systemic lupus erythematosus, sarcoidosis, Sjögren syndrome, Behçet disease, juvenile rheumatoid arthritis, autoimmune thyroid disease, or antiphospholipid syndrome).
- Metabolic deficiencies and mitochondrial disease can cause TM-like presentations.

DIAGNOSIS

HISTORY

- Children with TM most commonly (~60%) report pain (in neck, back, and lower extremities) as their initial symptom, followed by motor deficits (~30%) and sensory loss (~10%). Loss of bladder/bowel control, gait disturbances, and visual loss are also noted.
- Pediatric TM is often postinfectious and can be found after vaccinations. A history within the past 30 days of vaccination, fever, upper respiratory symptoms, leukocytosis, or other indications of a recent infection is noted in the majority of cases.
- A sudden precipitous onset or acute total sensory/motor/reflex loss below a spinal level should provoke an emergent exploration of potential obstructive, vascular, or traumatic etiologies, as TM symptoms evolve over hours to days, not minutes.
- A prior history of paroxysmal neurologic symptoms such as transient

sensory deficits, weakness, trigeminal neuralgia, or visual loss may suggest this TM presentation is a relapse of a neuroimmune disease.

- A prior history of known/suspected systemic autoimmune disease or coagulopathy should be used to guide subsequent evaluation.
- Radiation exposure can cause a TM-like presentation with a latency of up to 10 years.

PHYSICAL EXAM

- A complete neurologic examination is imperative. Typical examination findings include a bandlike sensory level with distal sensory loss, weakness of the lower extremities, ataxia, and urinary retention. Reflexes may be increased or diminished, and abnormal extensor response of the great toe (Babinski sign) is often present.
- Findings are usually bilateral and symmetric and referable to a spinal level (usually thoracic) but can be relatively asymmetric or in rare instances exclusively unilateral.
- Closely monitor heart rate and blood pressure. TM lesions anywhere from the brainstem to the upper thoracic cord could disrupt sympathetic–parasympathetic balance, resulting in bradycardia and hypotension. In lesions of the thoracic cord, autonomic dysreflexia can occur as a late complication.
- Follow patient respiratory status because lesions of the cervical cord at or above level C5 could impair diaphragm function. Brainstem lesions can involve the nucleus of spinal accessory nerve, causing pharyngeal muscle weakness and loss of airway patency. Respiratory decompensation is less common in TM than in GBS.
- Also observe for deficits of proprioception and vibration sense indicating involvement of the posterior columns (suggesting syphilis, B₁₂ deficiency.)
- Concurrent diminished visual acuity, blindness, loss of color vision, or optic nerve pallor indicates optic neuritis. Rapid vision loss with TM is likely NMO and mandates aggressive treatment.
- Spinal shock, characterized by suspension of spinal cord function and areflexia below a spinal level, may occur early in TM. Loss of reflexes also raises concern for GBS.
- Fever and neck pain are common findings in TM but when present

with other indications of meningeal irritation increases importance of evaluation for meningitis.

- Excessive irritability, stupor, altered awareness, or neurocognitive problems suggest encephalopathy due to ADEM.
- The examination of the infant with TM is challenging. Lack of spontaneous movement or resistance to examination, asymmetric movements, absent response to painful stimuli, bladder distension or abdominal fullness, or priapism can be presenting signs in infants. Muscle, bone, or joint pain may cause refusal to ambulate/bear weight without spinal cord pathology.

DIAGNOSTIC TESTS AND INTERPRETATION

Lab

- Complete blood cell count and differential to assess for acute infection
- Serum aquaporin-4 IgG. Consider repeating if prior negative result for recurrence of TM (~80% of children seropositive in relapsing NMO vs. 13% in initial TM), if optic neuritis also present, or MRI findings suggestive of NMO. CSF aquaporin-4 IgG may be more sensitive than serum assay.
- Lumbar puncture (if no risk of herniation) and CSF analysis
 - Cell count (mean ~200 WBCs/ μ L in TM; cell counts >30–50 more likely to have NMO than MS)
 - Protein (elevated in 20–50% of TM cases; elevated protein and low CSF cell count is more typical of GBS)
 - Glucose (if low consider infectious etiology)
 - CSF Gram stain and culture
 - IgG index (elevated in MS)
 - Oligoclonal bands (present in 90% of MS and 30% of NMO cases)

If history, examination findings, or endemic likelihood, consider these additional studies:

- CSF: Enterovirus, human herpesvirus (HHV) 1/2/6, varicella-zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), dengue, or West Nile viral DNA polymerase chain reaction (PCR); paraneoplastic panel, lactate, pyruvate
- *Mycoplasma pneumoniae* IgM/IgG with throat swab PCR, *Bartonella henselae* IgM/IgG titer, *Borrelia burgdorferi* IgM/IgG, rapid plasma

- reagin (RPR), hepatitis A/B/C, or influenza testing
- If chronic myelopathy is present, evaluate for mumps, measles, HIV, human T-lymphotropic virus (HTLV) I/II
- Purified protein derivative (PPD) with anergy panel, tuberculosis culture
- Schistosomiasis stool or urine examination
- Autoimmune disease: antinuclear antibody (ANA), rheumatoid factor (RF), anti-dsDNA antibody, antiphospholipid antibodies, angiotensin-converting enzyme (with chest radiography) antithyroid antibodies, rheumatologic or paraneoplastic panel
- Prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), and coagulopathy panel
- Copper or B₁₂ serum levels
- Mitochondrial function serum testing

Imaging

- Inflammation of the spinal cord identified by imaging or CSF findings is required for a diagnosis of TM. Acute neurologic deficits referring to the spinal cord mandate emergent spinal imaging. An MRI scan with gadolinium enhancement of the whole spine is preferred; short inversion time inversion recovery (STIR) sequences are sensitive for identifying abnormalities. If patient cannot tolerate lengthy scan, or there is a time-critical concern, scanning segments where symptoms localize can suffice. Full spine and brain should be imaged later to establish presence of clinically silent lesions or baseline imaging.
- Longitudinally extensive TM (T2 hyperintense lesion spanning ≥ 3 segments) is typical of idiopathic TM or NMO, not MS.
- Selective enhancement of the nerve roots without cord involvement suggests GBS.
- All patients presenting with acute TM should have an ophthalmologic examination with ocular coherence tomography and visual-evoked potentials. Subclinical optic neuritis suggests a diagnosis of MS or NMO.
- MRI of the brain with contrast or dedicated optic nerve imaging is needed with encephalopathy/brain lesions or optic nerve involvement. Lesions in subcortical white matter suggest ADEM or MS.

Diagnostic Procedures/Other

An electromyogram and nerve conduction studies can be used in clinically ambiguous cases to differentiate GBS from TM.

DIFFERENTIAL DIAGNOSIS

- Infectious myelitis
- Postradiation myelopathy
- Compressive myelopathy
 - Trauma
 - Extramedullary: arteriovenous malformation, discitis, epidural abscess, vertebral osteomyelitis, tumor
 - Intramedullary: arteriovenous malformation, tumor
- Ischemic myelopathy
 - Spinal cord infarct, angiitis/vasculitis, fibrocartilaginous embolism
- Autoimmune
 - Acquired demyelination syndromes
 - Systemic autoimmune disease
 - Paraneoplastic syndrome

TREATMENT

MEDICATION

First Line

Methylprednisolone IV (dose: 30 mg/kg/day or a maximum dose of 1 g/day) or an oral equivalent is recommended initial treatment for noninfectious TM. Strong evidence exists in adults (not children) for efficacy in TM. Typical treatment length is 5–7 days followed by oral corticosteroid taper starting at dose of 1 mg/kg/day (maximum 60 mg/day prednisone equivalent) over 3–4 weeks.

Second Line

- If steroids are not effective or contraindicated, plasmapheresis is an alternative. Evidence exists for efficacy of plasmapheresis treatment in children. Typically, 5–7 exchanges are performed. Consider for NMO with progressive visual loss.
- Intravenous immunoglobulin G (IVIG; dose: 2 g/kg divided over 2–5

days) is an alternative or add-on treatment.

- Cyclophosphamide (dose: 500–750 mg/m²) administered once is reportedly effective in refractory TM cases.
- Immunomodulatory therapies for MS can begin after acute treatment. Rituximab is an option for TM due to NMO.

GENERAL MEASURES

- Most patients will have urinary retention and constipation, so appropriate bowel/bladder regimen should be implemented proactively.
- Short-term and long-term pain management plans are needed in almost all TM patients.

ADDITIONAL THERAPIES

- Physical, occupational, or speech/language therapists should be engaged as soon as possible to maintain function during hospitalization and assess needs for possible longer duration placement.
- Long-term neurologic follow-up (1–3 years) is necessary to assess for new symptoms, recurrence, and zenith of recovery.

ONGOING CARE

PROGNOSIS

- Complete recovery in 33–50% of pediatric cases. Up to 20% can have significant residual disabilities (not ambulatory, severe sensory loss, lack of sphincter control).
- Mortality due to acute TM is <5%.
- Infants may have extensive lesions and worse outcomes. Other factors associated with a poorer prognosis: rapid onset of symptoms (<24 hours to nadir), more sensory loss/weakness or length of time spent at symptom nadir, need for ventilation, longitudinal extent of lesion, higher sensory level, or diminished/absent reflexes at onset

CODES

ICD10

- G37.3 Acute transverse myelitis in demyelinating disease of central nervous system
- A89 Unspecified viral infection of central nervous system

FAQ

- Q: What is the typical clinical timeline of TM?
- A: TM symptoms typically begin over 2–3 days. Functional nadir can occur within hours to 1 month of onset. This nadir averages 7 days before recovery. Patient recovery can be rapid (within weeks) or span years.
- Q: What is the likelihood of recurrence?
- A: 60–80% of pediatric TM is monophasic. Approximately 15% of patients with TM will be diagnosed with MS or NMO and therefore would be at risk for a relapse.

TRICHINOSIS

Carolyn A. Paris • George Anthony Woodward

BASICS

DESCRIPTION

- Infection caused by ingestion of undercooked meat containing nematode (roundworm) larval cysts of the *Trichinella* genus
- Clinical disease in humans characterized by an intestinal phase followed by a muscular phase
- Extremely wide host range and geographic distribution

EPIDEMIOLOGY

- Historically, most U.S. infections are due to *Trichinella spiralis* in commercial pork.
- Currently, more U.S. infections are associated with wild game meat (especially bear) or through spillover to domestic animals.
- Occasional grouped outbreaks (e.g., families and communities with common exposure)
- Reservoir hosts include rodents, domesticated animals (e.g., dogs, cats), raccoons, opossums, and skunks.

Incidence

- Estimated 10,000 cases per year worldwide, with a mortality rate of 0.2% in main 55 countries reporting
- Between 2002 and 2007 in the United States, average of 11 cases annually
- Decreasing reported case numbers attributed to decline in prevalence of *Trichinella* in commercial swine (1.41% in 1900, 0.125% in 1966, and 0.013% in 1995), federal regulation preventing uncooked meat consumption by commercial swine, and increased public awareness regarding proper meat handling and preparation
- Likely underreported, particularly in developing countries with modest health controls

Prevalence

- ~4% of cadavers in 1970 study with evidence of previous infection (additional estimates range from 10 to 20% prevalence)

RISK FACTORS

- Consumption of inadequately cooked meat, even in small quantities
- Consumption of foreign meat (e.g., horse in France, dog in China) or wild game (e.g., bear, cougar, hyena, lion, panther, fox, horse, seal, walrus)
- Exposure to adulterated food (e.g., pork mixed in beef product)
- Traveling to underdeveloped countries
- Compromised immune status of host

GENERAL PREVENTION

- Consume only fully cooked meat, pork, and wild game; meat should reach >145°F internally, no pink color
- Freezing kills *T. spiralis* in pork (<6 inches thick) at –20°F for 6 days, –10°F for 10 days, and –5°F for 20 days.
- Freezing may not kill other *Trichinella* species, particularly in wild game.
- Curing, smoking, salting, and drying meat (including jerky) are not reliable sterilization methods.
- Routinely clean meat processing equipment.
- Irradiation may not kill *Trichinella* but should prevent replication.
- Avoid feeding swine uncooked meat scraps.
- Actively control reservoir hosts (e.g., rodents).

PATHOPHYSIOLOGY

- *Trichinella* are obligate intracellular parasites capable of infecting warm-blooded animals
- At least 8 *Trichinella* species identified: *Trichinella spiralis* (most common), *Trichinella britovi*, *Trichinella pseudospiralis*, *Trichinella papuae*, *Trichinella nativa*, *Trichinella nelsoni*, *Trichinella murrelli*, and *Trichinella zimbabwensis*
- Life cycle of all species comprises 2 generations in the same host (broad range of species—mammal, birds, and reptiles), but only humans become clinically affected.
- Disease not transmissible person to person

- Larvae in undercooked meat eaten by the patient are released after cyst wall digestion by gastric enzymes, pass to the small intestine, invade mucosa, then develop into adult worms.
- Incubation period is 1–2 weeks.
- Fertilized females release larvae (~500) over 2–3 weeks; adult worms do not multiply in human host and are expelled in feces.
- Newborn larvae travel the bloodstream to seed skeletal muscles, where they grow 10-fold, coil, encyst, and cause muscle fibers to enlarge and become edematous. Nonskeletal muscle may have granulomatous reactions, but larvae are found only in skeletal muscle.
- Cysts (hyaline capsules) may calcify over several months to years.
- Growing body of research on the ability of parasites to modulate the immune system and implications of this for immune-mediated diseases

ETIOLOGY

T. spiralis is the organism that causes trichinosis and is acquired by the consumption of raw or undercooked, infected meat.

COMMONLY ASSOCIATED CONDITIONS

- Rheumatic syndromes: polyarteritis nodosa–like systemic necrotizing vasculitis, symmetric polyarteritis, glomerulonephritis
- Immunocompromised hosts are at risk for more serious or prolonged infection.

DIAGNOSIS

HISTORY

- Ingestion of inadequately cooked meat (commercial and noncommercial pork, game animals, foreign meat)
- Others with similar symptoms and same dietary exposure
- Signs and symptoms
 - Clinical severity varies, from asymptomatic (most common) to fatal (rare); depends on *Trichinella* species and inoculum size
 - Children often have fewer and milder symptoms than adults.
 - Many signs and symptoms (i.e., periorbital and muscle edema, eosinophilia) due to allergic reaction to parasite antigens

- Nonspecific signs and symptoms may mimic other illnesses
- Enteral phase (24 hours–7 days after infection): symptoms due to intestinal ulceration from mucosal invasion by adult worms
 - Diarrhea, abdominal pain, nausea, vomiting, anorexia
 - May persist for weeks
- Parenteral phase (1–8 weeks after infection): symptoms due to systemic invasion
 - General: fever (begins at 2 weeks, peaks after 4 weeks, night spikes to 40–41°C), weakness, malaise, myalgias
 - Ocular: periorbital edema, subconjunctival hemorrhage, conjunctivitis, disturbed vision, ocular pain, chemosis
 - Muscular: myalgias, myositis (usually in extraocular muscles, then masseters, tongue, neck, limb flexors, lumbar muscles, intercostals, and diaphragm) with dyspnea, cough, hoarseness
 - Neurologic: headache, focal paralysis, delirium, psychosis
 - Skin: urticarial rash, subungual hemorrhages
 - Parenteral phase symptoms typically peak 2–3 weeks after infection.
 - Malaise and weakness may persist for weeks.
 - Cardiac: myocarditis, arrhythmias secondary to myocarditis
- Convalescent phase (begins 2nd month, may last months to years): myalgias, weakness

PHYSICAL EXAM

Fever, periorbital and generalized edema, muscular tenderness, urticaria, plus findings related to neurologic or cardiac involvement mentioned in “History” section

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool ova and parasite examination
- CBC and differential: leukocytosis (moderate) with eosinophilia (up to 70%, peaks 10–21 days postinoculation but prior to clinical symptoms)
- Elevation of muscle enzymes (lactate dehydrogenase [LDH], creatinine phosphokinase [CPK], aldolase)
- Specific anti-*Trichinella* antibody detection

- Serologic tests are available through the U.S. Centers for Disease Control and Prevention or state and some private labs.
- Detection of *Trichinella*-specific DNA by polymerase chain reaction (availability limited)
- *Trichinella* serology
 - 2 tests required to ensure accurate diagnosis: first to detect antigen (enzyme-linked immunosorbent assay [ELISA]) and the second to detect antibodies to parasite surface antigens (FA)
 - Bentonite flocculation (1:5- or 4-fold increase), latex flocculation test, ELISA, or immunofluorescence

Imaging

- X-ray: may show calcified cysts in muscle (6–24 months postinfection) or enlarged heart
- EKG: myocarditis may cause premature contractions, prolonged PR interval, small QRS with intraventricular block, and/or T wave flattening or inversion
- CT: small CNS lesions, IV enhancing ring calcifications
- Electromyography: Results resemble those of polymyositis and inflammatory myopathies.

Diagnostic Procedures/Other

- Skeletal muscle biopsy (especially deltoid or gastrocnemius muscle from the patient at least 17 days after infection)
 - Inflammatory cells surround encysted larvae in necrotic muscle fibers.
 - Granulomatous reaction present in nonskeletal muscle but not encysted larvae.
 - Usually unnecessary, negative result possible in infected patient due to sampling error
- Can test suspected meat if available

DIFFERENTIAL DIAGNOSIS

- Infection: viral syndromes, parasitic, spirochete, gastroenteritis, influenza, sinusitis, typhoid fever, measles, scarlet fever, meningitis, rheumatic fever, encephalitis, encephalomyelitis, poliomyelitis, tetanus, schistosomiasis, hookworm, strongyloides, or helminthic

infection

- Miscellaneous: fever of unknown origin, dermatomyositis, myocarditis, inflammatory bowel disease, angioneurotic edema, rheumatoid arthritis, glomerulonephritis, polyneuritis, eosinophilic leukemia, polyarteritis nodosa, nonabsorption syndromes

TREATMENT

MEDICATION

First Line

- Systemic corticosteroids for severe symptoms (not recommended as monotherapy, may prolong adult worm survival in intestines) plus
- Albendazole (Albenza)
 - 15 mg/kg/day divided b.i.d for 15 days
 - Max dose 800 mg/day
 - Teratogenic/embryotoxic in rats
 - Approved <2 years
- Mebendazole and albendazole are most efficacious during the enteric phase (active against intestinal worms, little effect on muscle-embedded larvae).

Second Line

Pyrantel pamoate (Antiminth)

- Used during pregnancy; not approved <2 years
- Effective only against adult worms, not encysted larvae

ADDITIONAL TREATMENT

General Measures

- Most patients recover without specific therapy.
- Symptomatic treatment: acetaminophen or NSAIDs, bed rest

ISSUES FOR REFERRAL

Cardiac, neurologic, pulmonary complications

INPATIENT CONSIDERATIONS

Admission Criteria

Cardiac, neurologic, or pulmonary complications indicate more severe

disease

Discharge Criteria

Resolution of cardiac symptoms

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Expect improvement over several weeks.
- At 3–4 weeks, retreatment may be indicated if symptoms persist or there are ova in the feces.

Patient Monitoring

Cardiopulmonary monitoring

DIET

- Avoid further exposures.
- Breastfeeding may continue; the single case report of cessation of milk production was associated with parenteral mebendazole.

PATIENT EDUCATION

If concern for trichinosis exposure or symptoms, seek medical care early. Treatment is most efficacious the 1st week after exposure.

PROGNOSIS

- Mild to moderate illness usually resolves spontaneously with minimal sequelae. Muscle swelling and weakness may persist.
- Poorer prognosis (can be fulminant and fatal) with cardiac, CNS, or pulmonary involvement
- Children usually are less symptomatic, have fewer complications, and recover more quickly.

COMPLICATIONS

- Cardiac: myocarditis (may result in death 4–8 weeks after infection), secondary arrhythmias, hypotension, pericardial effusion
- Neurologic: meningoencephalitis, CNS granulomas, headaches
- Pulmonary: pneumonia, pneumonitis, pleural effusion, pulmonary embolism or infarct

- Renal: glomerulonephritis
- Hepatic: fatty change
- Muscular: prolonged myalgias
- Ocular: retinal hemorrhages
- Complications rarely are permanent.

CODES

ICD10

- B75 Trichinellosis
- M63.80 Disorders of muscle in diseases classed elsewhere, unspecified site

FAQ

- Q: Is trichinosis contagious from person to person?
- A: No, except through infected breast milk.
- Q: Do special precautions need to be taken when treating a patient with presumed trichinosis?

- A: Only thorough hand washing. No isolation required.
- Q: What should we recommend for a patient who has eaten contaminated meat?
- A: Treatment with mebendazole or thiabendazole should be considered.
- Q: What are the classic hallmark signs of trichinosis?
- A: Diarrhea, abdominal pain, periorbital edema, myositis, fever, and eosinophilia, especially when combined with history of ingestion of potentially poorly cooked meat.

TRICHOTILLOMANIA

Ilse A. Larson, MD • Carol A. Mathews, MD

BASICS

DESCRIPTION

Trichotillomania (TTM) is the recurrent pulling out of one's hair resulting in hair loss. Pulling causes clinically significant distress or functional impairment, is accompanied by repeated efforts to stop, and is not due to another mental disorder or a general medical condition.

- Hair pulling can occur in any region of the body, but the most common sites are the scalp, eyelashes, and eyebrows. Other relatively common sites include the axilla, face, and pubic area. Sites may vary over time.
- Pulling can occur in brief episodes throughout the day or in sustained bouts.
- Automatic pulling is outside the patient's awareness.
- Focused pulling is in response to identifiable affective triggers.
- Some patients experience tension immediately before pulling or when attempting to resist the behavior, whereas others experience pleasure or relief when pulling.
- Patients may search for and pull hairs with specific qualities (e.g., thick hairs or short hairs).
- More than half of patients engage in a "ritual" with the hair before discarding it.
- TTM does not include habitual hair twirling.

EPIDEMIOLOGY

- Typical onset in childhood or adolescence: often coincides with the onset of puberty
- In childhood, girls and boys are equally affected.
- In adulthood, the ratio of affected females to males is 10:1.

Prevalence

1–3% lifetime prevalence

RISK FACTORS

TTM is more common in individuals with obsessive-compulsive disorder (OCD) and in their 1st-degree relatives.

Genetics

- One study of 34 twin pairs showed concordance in 38% of monozygotic and 0% of dizygotic twins, suggesting heritability.
- No specific genes implicated, although animal models of TTM exist.

COMMONLY ASSOCIATED CONDITIONS

- Trichophagia (ingesting hair), which can lead to trichobezoar. It is estimated that between 5 and 18% of patients with TTM ingest their hair.
- Psychiatric comorbidity is common (seen in 1/3–2/3 of children with TTM) and includes autism, pervasive developmental disorder (PDD), anxiety, mood, attention deficit, substance use, and eating disorders.
- Patients may also engage in nail-biting, skin-picking, or other pathologic grooming behaviors.

DIAGNOSIS

HISTORY

Patients may present with a complaint of hair loss or with concern regarding pulling behavior.

PHYSICAL EXAM

- Areas of hair loss do not show complete alopecia; instead, they contain hairs of different lengths, hairs with blunt ends, and remnants of hair bulbs. Hair density is normal in other areas.
- In some cases, pulling is widely distributed and hair loss may not be readily apparent.
- In children, patches of loss may be more prevalent on the side of the patient's dominant hand.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

Several instruments are available for clinical use; the Massachusetts General Hospital Hair Pulling Scale is one tool commonly used to monitor

symptom severity and response to treatment.

DIFFERENTIAL DIAGNOSIS

- Alopecia areata
- Tinea capitis
- Dermatologic conditions causing pruritus; normative hair removal (e.g., for cosmetic reasons)
- Other obsessive-compulsive or related disorders where pulling is part of a symmetry or other ritual
- Body dysmorphic disorder

TREATMENT

MEDICATION

- Few placebo-controlled randomized trials have included children or adolescents.
- N-acetylcysteine
 - A randomized controlled trial (RCT) of 50 adults demonstrated efficacy of N-acetylcysteine (56% of patients responded to treatment compared to 16% of patients on placebo).
 - A similarly designed study of 34 children showed no effect, with clinically modest but statistically significant improvements in symptoms in both treatment and control groups.
- Olanzapine
 - Has been shown to be efficacious in a study of 25 adults (85% of treatment group responded as compared to 17% of placebo group)
 - However, 84% of treatment group reported undesirable side effects.
- SSRIs do not reduce hairpulling but are efficacious for treating comorbid conditions and are used in some adults with TTM.

ADDITIONAL THERAPIES

- For mild cases in young children, reward systems or “home remedies” like a hat or Band-Aids on fingers may help.
- Behavior modification programs, habit reversal training methods, and cognitive behavioral therapy have all been used.
- One RCT of 24 children showed sustained effect of behavioral therapy

(75% in behavioral therapy group were responders as compared with 0% in minimal attention control group at 8 weeks; effect sustained over 8-week maintenance period).

GENERAL MEASURES

- Triggers should be identified and minimized with a focus on stress management strategies.
- Parent and family education about TTM and associated conditions is essential.
- The Trichotillomania Learning Center (www.trich.org) has valuable educational materials for patients, parents, and clinicians as well as a list of mental health providers with experience treating TTM.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patients with TTM should be referred to a mental health professional with training in behavioral therapy and, ideally, with experience treating patients with TTM.

PROGNOSIS

TTM often waxes and wanes, with symptoms reemerging at times of stress or transition.

COMPLICATIONS

- TTM can lead to significant academic, social, and developmental impairment.
 - 55% of children reported that TTM made it more difficult to study and 35% reported academic impairment as a direct result of pulling.
 - 55% of parents of children with TTM reported that their child avoided social events as a direct result of pulling.
 - 80% of parents of children with TTM felt that their child's pulling contributed to another psychiatric problem.
- Trichobezoar resulting from trichophagia can cause serious gastrointestinal complications including obstruction and perforation.

FAQ

- Q: What are signs and symptoms of trichobezoar?
- A: Patients can present with abdominal pain, nausea, vomiting, weight loss, or gastrointestinal bleeding. X-ray shows a characteristic abdominal mass, and hair may be present in the patient's stool.
- Q: Which patients with hairpulling behaviors should be referred for evaluation and treatment?
- A: Patients with patches of alopecia, distress related to their alopecia or pulling behavior, and those with deliberate pulling should be referred.
- Q: To whom should I refer patients with suspected or diagnosed TTM?
- A: Ideally, a psychologist or other mental health professional with training in behavioral therapy, cognitive behavioral therapy, or exposure-response management therapy.

TUBERCULOSIS

Andrew P. Steenhoff

BASICS

DESCRIPTION

- Pediatric tuberculosis (TB) is the disease state caused by *Mycobacterium tuberculosis*, an acid-fast bacillus (AFB). Pediatric TB should be regarded as a spectrum of exposure through infection to disease because progression from an infected person (exposure) to infection and disease can occur much faster (within 3–6 months) in children <2 years of age (occurring within the incubation of the disease stated below).
- Progression through this spectrum depends on age; such disease progression being 40–50% for children up to 2 years old, ~20% for those 2–4 years old, and 10–15% for those ≥ 5 years old. 5–10-year-old children are the most protected age group. Adolescence is another vulnerable age group.

EPIDEMIOLOGY

- Most common route of infection is via the respiratory tract. TB is spread from a person with disease by droplet nuclei that are inhaled by other people. Infection occurs after close and prolonged contact with an adult or adolescent who has active untreated infectious disease, usually pulmonary TB, in a poorly ventilated space. However, there are people who develop TB without knowledge of an infectious contact.
- Congenital infection occurs, although rarely, in the setting of an untreated mother in the last trimester of pregnancy.
- Infection with the tubercle bacillus needs to be differentiated from disease (i.e., TB).
- The interval between onset of infection and disease is usually 10–12 weeks.
- The greatest chance of disease occurring (i.e., of developing a positive result in tests using purified protein derivative [PPD], now renamed

tuberculin skin test [TST]) is within the 1st 2 years after infection. However, for infants and children <5 years of age, progression through the spectrum of pediatric TB (exposure–infection–disease) is age dependent (see “[Description](#)”).

- Postpubertal adolescents and immunosuppressed people including people with diabetes, with chronic renal failure, the malnourished, and those taking steroids for any reason have higher risks for progression of infection to disease.

GENERAL PREVENTION

- There are now several treatment regimens available for the treatment of latent TB infection. The reader is referred to the Centers for Disease Control and Prevention (CDC) Web site in the “Additional Reading” section.
- Preferred regimen is isoniazid (isonicotinic acid hydrazide-INH), 10–20 mg/kg/day PO for 9 months or, if compliance is not anticipated, 2 times a week as direct observed therapy at 20–30 mg/kg, with a maximum dose of 900 mg usually administered by a school nurse, child care worker, or the local TB control program, ideally without breaks in treatment, although the patient has 12 months to complete the course. If a break occurs near the end of treatment, it need not be restarted because such treatment is ~90% effective against development of active TB for 20 years in nonimmunosuppressed children. This recommendation prevents disease in the treated patient and, as a public health measure, interrupts transmission to contacts of that infected person with 90% efficacy.
- Other drugs for latent TB when INH cannot be tolerated or case-patient has INH-resistant but rifampicin-susceptible TB include 6 months of INH 10–20 mg/kg by direct observed therapy (for a total of 72 doses).
- For adults and children 12 years and older, a once-weekly 3-month course of INH and rifapentine can be considered via direct observed therapy (12 doses total).
- Bacille Calmette-Guérin (BCG) vaccine is recommended in the United States only for infants and children who test negative to PPD and who are continually exposed to contagious adults or to adults with TB that is resistant to both INH and rifampin and who cannot be kept away

from the contagious adult.

COMMONLY ASSOCIATED CONDITIONS

- HIV infection
- Lymphoma
- Diabetes
- Chronic renal failure
- Malnutrition
- Immunosuppression, including chronic daily steroid use, high-dose steroid use or tumor necrosis factor- α (TNF- α) agonists, cancer chemotherapy
- Social issues: incarcerated adolescents, infants, and children in homeless shelters

DIAGNOSIS

HISTORY

- Exposure: family member with TB or positive skin test
- Migrant farm workers
- Immigration from a TB-endemic geographic area (e.g., Haiti, Southeast Asia, Africa, South and Central America, Russia, and elsewhere in Eastern Europe, where greater concern about drug-resistant strains ought to be exercised); visit by individuals from those countries; or visited the above countries
- Higher incidence in Native Americans
- Contact with adults who have active TB
- HIV-positive people
- Immunosuppressed state
- Incarcerated adolescents and their relatives who visit
- Homeless people
- Poor people in urban areas
- Exposure to milk from untested herds
- Malnutrition
- Long-term steroid usage

PHYSICAL EXAM

- Cervical and/or axillary adenopathy
- May reflect underlying disease or state (e.g., HIV, malnutrition, long-term steroid use)
- Pulmonary rales or clear chest
- Enlarged liver or spleen
- Site-specific findings (e.g., gibbus [vertebral TB]) or focal neurologic signs (TB meningitis)
- Signs and symptoms:
 - Failure to thrive
 - Cervical or axillary lymphadenopathy without any other cause or that is prolonged
 - Cough >2 weeks
 - Weight loss
 - Change in sensorium
 - Fever in infants and adolescents, rarely in children 5–10 years of age
 - Decreased energy levels/playfulness >2 weeks

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Culture for TB: sputum, 3 gastric washings (early morning), pleural fluid, CSF, urine
- Culture may take 2–3 weeks by the radiometric method.
- Positive cultures are found in <50% of children.

Imaging

Chest radiographs may show hilar adenopathy with or without atelectasis. However, any infiltrate or pleural effusion in a child with a positive TST result and a risk factor for TB should be considered a TB suspect until proven otherwise. Infiltrates from bacterial or viral pathogens generally clear within 6–8 weeks; TB infiltrates tend not to clear so rapidly.

Diagnostic Procedures/Other

- Skin testing: TST
 - The Mantoux test comprises 5 tuberculin units with PPD administered intradermally. Details may be found at <http://www.cdc.gov/tb>.

- The CDC does not recommend routine skin testing in low-risk groups in communities with low prevalence of TB.
- Children at high risk should be tested annually:
 - Those in contact with adults from regions with high TB prevalence
 - Children who spend time in homeless shelters
- Those in contact with adults with TB, HIV, and other disease-producing immunosuppressed states: A skin test result may become positive 3–6 weeks after exposure; however, most commonly, it does not turn positive for 2–3 months—hence the rationale for treating an exposed child with INH and retesting with a PPD in 3 months.
- A positive TST is a SENTINEL public health event indicating TB transmission in a community even if all other tests and examinations are negative.
- Interferon gamma release assays (IGRA) are being used with more frequency to diagnose TB exposure in children. These tests can be used as an alternative to TST in screening high-risk children; they are most helpful in children who have received BCG vaccine in the past, as these tests are more specific for TB. There are limited data on the use of these tests in children younger than 4 years of age.
- A promising new molecular diagnostic test, Xpert MTB/RIF, is both simple and accurate but performs less well in children compared to adults.

DIFFERENTIAL DIAGNOSIS

- Malignancy
- Cervical or axillary adenopathy
- Pulmonary infiltrate: other chronic organisms, disorders, and conditions (e.g., Nocardia, histoplasmosis). Infiltrates owing to bacterial or viral pathogens resolve faster than TB; thus, reevaluation of a suspect in 8–12 weeks clarifies this differential.
- Hilar adenopathy: In TB is usually unilateral, but Epstein-Barr virus, adenovirus, pertussis, and malignancy may possibly mimic symptoms.
- GI disease: Most common differential diagnosis is Crohn disease.
- Meningitis: fungal meningitis, partially treated bacterial meningitis

(rarely)

TREATMENT

MEDICATION

- Initial treatment in areas with multidrug-resistant TB >4%: Until sensitivities are known, a 4-drug regimen should be started: INH, 10–15 mg/kg/day; rifampin, 10–20 mg/kg/day; pyrazinamide (PZA), 15–30 mg/kg/day; and either ethambutol, 15–20 mg/kg/day, or streptomycin, 20–40 mg/kg/day (depending on whether diagnosis is meningitis or miliary TB, for which a bactericide is desired); however, many cases in children of foreign-born parents are increasingly streptomycin resistant, making ethambutol a better choice.
- If the organism is sensitive to therapy, treatment with the initial 4 primary drugs should continue for the first 2 months; by then, all sputum specimens should have a negative result on culture, followed by 4 months of INH and rifampin. When this regimen is adhered to, prognosis and a complete cure are achieved in 97–98% of patients.
- If sputum specimens continue to test positive, the initiation phase is longer. For meningeal TB, the duration of treatment is always longer (12 months).

ADDITIONAL TREATMENT

General Measures

- Hospitalization (if the patient has disease)
 - In cases of extensive disease (e.g., miliary TB or meningitis), and when an adult source case is not known, aggressive attempts should be made to obtain an organism from gastric aspirates, sputum induction, bronchoalveolar lavage, CSF, pleural or joint aspirate, bone aspirate, liver or tissue biopsy, and, in some cases, blood cultures.
- Isolation policies
 - Unless the clinician can verify that the parent or any adult visitors are not themselves contagious, many infection control units require isolation of the child because the family members' state of

contagion remains unknown at admission.

- Nonpulmonary TB (e.g., GI TB, meningitis, bone TB, and TB with joint involvement) does not require isolation.
- Children >8 years of age and adolescents should be isolated until they have completed 10 days of therapy. Occasionally, immunocompromised children <8 years old also have cavitary disease and hence they, too, should be isolated.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Follow-up and contact tracing are key to making TB preventable.

PROGNOSIS

- Mortality for untreated TB is 40% over 4 years.
- For miliary TB and meningeal TB, prognosis depends on the stage of presentation as already discussed.
- For outbreaks of multidrug-resistant TB, death rates range from 70 to 90% within 4 months of diagnosis.

COMPLICATIONS

- Missed diagnosis: failure to consider TB in a child who is failing to thrive and whose TST is negative
- TB meningitis: Outcome depends on the stage at which anti-TB medication starts:
 - If pharmacotherapy is started at stage I, complete recovery occurs in 94%, with neurologic sequelae in 6%.
 - If delayed until stage II, complete recovery occurs in 51%, with neurologic sequelae in 40% and death in 7%.
 - If delayed until stage III, complete recovery occurs in 18%, with neurologic sequelae in 61% and death in 20%.
- Miliary TB: at least 2 organ systems involved
- Bone TB: most commonly spinal manifestation
- Renal TB: presents as a fever of undetermined origin (FUO), with or without urinary symptoms

- Congenital TB manifests with hepatosplenomegaly; may have CSF abnormalities and abnormalities on CSF testing and chest radiograph. Patients are too young for TST to be useful.
- Drug toxicity: Pediatric patients are much more tolerant of anti-TB medications than adults; thus, regular monitoring of liver function test results is not routinely required, although clinical monitoring for symptoms such as abdominal pain and loss of appetite on a monthly basis remains the cornerstone for identifying any toxicity.
- Hepatitis with INH, rifampin, and PZA; neurologic and hematologic complications with INH; skin rashes predominantly with rifampin and INH, but reports have occurred with all anti-TB medications; ototoxicity with streptomycin; but ocular toxicity with ethambutol in the pediatric age group has not been documented, and therefore it is a safe drug to use. Management of common side effects and drug interactions may be found in the 2006 American Thoracic Society/CDC/Infectious Disease Society of America statements (see “[Additional Reading](#)”).

- P37.0 Congenital tuberculosis
- A15.0 Tuberculosis of lung

FAQ

- Q: Should all children in close proximity to inner city areas with a prevalence of TB be screened annually with PPD?
- A: The AAP and CDC encourage targeted screening based on risk factors indicated earlier. The targeted screening questionnaire should be administered at every visit until age 2 years then annually thereafter. See tools at <http://www.cdc.gov/tb>.
- Q: Can the whole blood assay, IGRA (e.g. “QuantiFERON-TB Gold”), be used instead of the TST to differentiate children who were born in other countries and had BCG?
- A: Yes. The IGRA tests can be used as an alternative to TST, although additional larger studies are needed to evaluate the test characteristics of IGRAs in children. See www.cdc.gov/mmwr/pdf/rr/rr5905.pdf and Cruz et al. in the section “Additional Reading.”

TUBEROUS SCLEROSIS COMPLEX

Garrick A. Applebee

BASICS

DESCRIPTION

- Tuberous sclerosis complex (TSC) is a neurocutaneous syndrome characterized by a spectrum of signs and symptoms that present over a patient's lifetime, including neurologic disorders, multisystem tumor growth, and dermatologic manifestations.
- First described by Bourneville in 1880, the classic diagnostic triad of adenoma sebaceum, intellectual disability, and seizures has been revised to include other manifestations because many patients with tuberous sclerosis do not exhibit this triad.

EPIDEMIOLOGY

Incidence

Current estimates suggest an incidence of 1 in 5,000 to 1 in 15,000 births. 60–70% of cases reflect sporadic mutation; 30–40% of cases are familial.

RISK FACTORS

Genetics

- 2 clearly identified loci for familial and sporadic cases based on linkage analyses are 9q34 and 16p13, corresponding to TSC1 and TSC2 genes, respectively. TSC1 encodes the protein hamartin and TSC2 encodes the protein tuberin. Together, hamartin and tuberin join to form a regulatory complex of mTOR (the serine-threonine kinase, mammalian target of rapamycin). Permanent activation of mTOR through mutations in the genes coding for these proteins causes dysregulation of cellular growth, differentiation, and migration, leading to the clinical symptoms and multisystem cellular overgrowth seen in TSC.
- >1,000 mutations in these genes are known to exist, leading to highly variable phenotypes in this disorder.
- TSC2 mutations: more common in sporadic cases, associated with

more severe phenotypes

- 10–15% of cases meeting clinical criteria have no identifiable gene mutations.

ETIOLOGY

Tuberous sclerosis is either inherited in an autosomal dominant pattern or results from a spontaneous/sporadic mutation.

DIAGNOSIS

HISTORY

- Primary symptoms include seizures, intellectual disability, and skin lesions.
- All types of seizures are seen in TSC. Seizures may begin at any time and are present in 70–80% of patients. In infancy, infantile spasms are a common presenting seizure; 1/3 of patients develop infantile spasms.
- Intellectual disability and neurobehavioral abnormalities (e.g., autism, which is present in 25% of patients) may manifest as developmental delay, but some patients are without cognitive defect.
- Skin lesions may appear in infancy or during early childhood.
- It is important to obtain a full family history, reviewing involved systems.
- Inquire about history of seizures, mental retardation, skin lesions, and cardiac or renal disease/cancers.
- Screening for symptoms of hydrocephalus (headache, vomiting) is important: 10% of patients develop CSF obstruction from subependymal giant cell tumors.
- Women are primarily affected by pulmonary lymphangiomyomatosis, which may manifest as dyspnea or pneumothorax in early adulthood.

PHYSICAL EXAM

- Maintain a high level of suspicion for tuberous sclerosis in any patient presenting with the following:
 - Infantile spasms or childhood seizures
 - Autism
 - Intellectual impairment/developmental delay

- Peculiar skin lesions
- Ash leaf and café au lait spots are small (often <5 mm) but may be found anywhere on skin and are often present at birth. Examination with a Wood lamp may help to identify hypopigmented lesions (e.g., ash leaf spots).
- Cardiac rhabdomyomas (however, not all these patients will ultimately be diagnosed with TSC)
- Facial angiofibromas are typically found around the nose and cheeks and look like acne; they develop in later childhood to adolescence. They neither itch nor suppurate.
- Ungual fibromas appear around the nail bed.
- Shagreen patches are brownish, leathery skin patches near the sacrum.
- Fundusoscopic examination may reveal whitish-yellow areas in epipapillary and peripapillary regions around the optic nerve head. They rarely impair vision. Papilledema may be seen with hydrocephalus.
- Signs of heart failure or tachyarrhythmia may be seen in infants with cardiac tumors.
- Flank pain, nausea, vomiting, and hematuria may suggest renal involvement.
- Procedures: Dilated fundusoscopic examination may also aid in full visualization of the optic nerve head.
- Definite diagnosis requires 2 major or 1 major plus 2 minor features:
 - Major criteria: facial angiofibroma, unguinal fibroma, shagreen patch, hypomelanotic papule (ash leaf spot), cortical tuber, subependymal giant cell tumor, retinal hamartoma, cardiac rhabdomyoma, renal angiomyolipoma, lymphangiomyomatosis
 - Minor criteria: pitting in tooth enamel, hamartomatous rectal polyps, bone cysts, cerebral white matter radial migration lines, gingival fibromas, retinal achromic patch, “confetti” skin lesions (grouped lightly pigmented spots), multiple renal cysts
- As with other dominant, multisystem conditions, the findings in TSC have variable penetrance, and clinical manifestations may appear at different developmental points.
- Although seizures and intellectual disability are common in TSC, they

vary, are nonspecific, and so are not considered in the diagnostic criteria.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood and CSF lab test results are typically normal unless renal function is significantly compromised by renal cysts or renal angiomyolipomas.
- ECG may reveal cardiac dysrhythmias, present in 47% of persons with cardiac rhabdomyomas.
- In patients with intellectual disability or seizures, EEG helps to evaluate cerebral activity.
- In infants with suggestive history, an EEG may help diagnose infantile spasms, which are associated on EEG with a highly disorganized pattern of large-amplitude, asynchronous, sharp waves termed hypsarrhythmia.
- Later in childhood, patients with tuberous sclerosis may develop Lennox-Gastaut syndrome, which consists of developmental delays, seizures, and a characteristic EEG pattern of slow (i.e., ≤ 2.5 Hz), generalized spike-wave complexes.

Imaging

- Subependymal or other cerebral calcifications on CT, often found in the course of emergent evaluation of new seizures, suggest TSC—consider MRI.
- Guidelines suggest MRI of the brain with gadolinium administration yearly or in alternate years until age 21 years and every 2–3 years thereafter. Imaging will identify tubers, subependymal nodules, hydrocephalus, and giant cell tumors. These appear hyperintense on T-weighted images and may enhance with gadolinium.
- Echocardiogram can detect cardiac rhabdomyomas in infants with tuberous sclerosis; prenatal ultrasound commonly identifies these tumors.
- CT of the lungs is indicated in women with TSC to screen for lymphangiomyomatosis.
- Renal ultrasound (every 1–2 years) or CT will demonstrate renal

lesions.

Pathologic Findings

Findings reflect the primary tissue in which lesions are identified:

- Brain
 - 3 characteristic lesions are cortical tubers, subependymal nodules, and subependymal giant cell tumors.
 - In tubers, the cerebral cortical architecture is disrupted, and these regions may undergo calcification, which can be visible on skull radiographs or brain CT.
 - Subependymal nodules consist of large abnormal astrocytes emanating from the lateral ventricular surface.
 - Subependymal giant cell tumors are low-grade benign astrocytic neoplasms.
- Skin
 - Facial angiofibromas may be mistaken for acne and are highly suggestive of tuberous sclerosis; they appear as pinkish-yellow plaques on the malar regions and nasolabial folds.
 - Ash leaf spots are hypopigmented hypomelanotic macules occurring anywhere on the body.
 - Ungual fibromas are fleshy growths along the lateral borders of the nail bed.
 - Shagreen patches are areas of shaggy leathery skin typically in the lumbosacral area.
- Retina
 - Whitish-yellow angiomyolipomas or hamartomas occur near the optic nerve head or the retinal periphery and may calcify.
- Heart
 - Rhabdomyomas in the ventricular wall occur in infancy and contain abundant nodules of large eosinophilic cells; this is the most common type of cardiac tumor of infancy and early childhood which 4% of the time will occur in the absence of TSC.
- Kidney
 - Renal cysts, polycystic kidneys, angiomyolipomas, and, more rarely, renal carcinomas
- Other organ systems

- Less commonly affected are the lungs, GI tract, spleen, vascular bed, and lymphatic system.

DIFFERENTIAL DIAGNOSIS

Neurocutaneous syndromes in which skin lesions, intellectual disability, and seizures are characteristic features should be considered:

- Neurofibromatosis
- Sturge-Weber syndrome
- von Hippel-Lindau disease
- Neurocutaneous melanosis
- Albright syndrome
- Incontinentia pigmenti
- Linear sebaceous nevus

TREATMENT

MEDICATION

- Everolimus (a rapamycin analog) is an immunosuppressant agent that inhibits mTOR, thereby inhibiting the cellular proliferation seen in tuberous sclerosis patients. It has been approved by FDA for management of subependymal giant cell tumors, and its use in targeting other tuberous sclerosis complications is under investigation.
- Anticonvulsant therapy as needed. Infantile spasms may be treated with adrenocorticotrophic hormone or vigabatrin.
- Medical management of heart failure or cardiac dysrhythmias is indicated in tuberous sclerosis patients with cardiac rhabdomyomas.

ONGOING CARE

PROGNOSIS

Cognitive disability unfortunately will not improve unless the cognitive impairment results from uncontrolled seizures. Seizure control is medically refractory in up to 40% of cases, and some children require epilepsy surgery to remove cortical tubers or subependymal nodules. Cardiac tumors may also require surgical intervention. Renal

angiomyolipomas can be embolized angiographically or surgically corrected. Subependymal giant cell astrocytomas that cause hydrocephalus may require resection.

CODES

ICD10

Q85.1 Tuberous sclerosis

FAQ

- Q: Can tuberous sclerosis be transmitted in subsequent pregnancies?
- A: An affected patient with the tuberous sclerosis gene mutation has a 50% chance of transmitting the mutation to his or her children.
- Q: Is genetic testing available?
- A: Molecular genetic testing for mutations at the TSC1 and TSC2 loci are available but are not required for diagnosis because not all clinical cases of TSC have identifiable mutations.
- Q: Will my child need brain surgery?
- A: In the event of refractory seizures, removal of cortical tubers may help seizure control. Surgery may also be indicated in cases of

obstructive hydrocephalus. If a brain tumor is detected by MRI, neurosurgical evaluation is indicated.

TULAREMIA

Gordon E. Schutze

BASICS

DESCRIPTION

Tularemia is an infection caused by *Francisella tularensis*, a small, fastidious, nonmotile, gram-negative coccobacillus; 4 distinct subspecies have been described:

- *tularensis* (type A): found primarily in North America; causes the most severe cases of tularemia in humans
- *holarctica* (type B): subspecies found primarily in Europe and Asia; less virulent than *tularensis*
- *novicida*: rarely isolated but can be found worldwide
- *mediasiatica*: recovered from ticks and animals in Central Asia; not associated with disease in immunocompetent humans
- An additional species, *Francisella philomiragia* (formerly *Yersinia philomiragia*), has also been reported. This is a rare cause of human disease and is possibly associated with salt water exposure.
- Tularemia typically presents with fever, myalgias, and headache 3–6 days after initial exposure. The extent of the illness depends on infecting dose, subspecies, and route of entry.
- 6 clinical forms are typically described:
 - Ulceroglandular tularemia
 - Constitutes 75% of all cases
 - A papule, which ruptures and ulcerates, occurs at the site of entry.
 - Glandular tularemia
 - Identical to the ulceroglandular form
 - However, does not have an identified primary skin lesion
 - Oculoglandular tularemia
 - Occurs when the organism gains access via the conjunctival sac
 - Usually from the patient rubbing the eyes with contaminated fingers

- Yellow nodules and ulcers may appear on the palpebral conjunctiva associated with enlarged preauricular nodes.
- Oropharyngeal tularemia
 - Occurs after the ingestion of contaminated food or water
 - An ulcerative or membranous tonsillitis accompanies a painful sore throat.
 - Lower GI tract involvement with vomiting, diarrhea, and abdominal pain may be associated.
- Typhoidal tularemia
 - Presents with fever of unknown origin, without localizing lymphadenopathy or skin findings
 - Shock, pleuropulmonary findings, odynophagia, diarrhea, and bowel necrosis are often associated.
- Pneumonic tularemia
 - Occurs after inhalation of the organism
 - It can also be present in association with ulceroglandular and typhoidal tularemia.
 - Pulmonary tularemia is the most fulminant and lethal form.
 - Symptoms include fever, dry cough, and pleuritic chest pain.
 - Tularemia in this form is a feared potential biologic weapon because an exposure to only 1–10 colony-forming units can result in infection. Although not transmitted person to person, laboratory workers working with organism on an agar plate are at risk for this form of disease.

ALERT

- *F. tularensis* is currently listed as a class A bioterrorism agent because of its potential ease for dissemination and infection as well as potential for high case fatality rates.
- In the past, resistant forms of *F. tularensis* have been engineered, but the actual use of this organism as a bioterrorism agent has not been documented.
- The diagnosis of inhalation tularemia should raise the suspicion of bioterrorism.

EPIDEMIOLOGY

- *F. tularensis* is found primarily in the Northern hemisphere from the 30–70-degree latitudes. Wild mammals (e.g., rabbits, hares, squirrels, beavers, deer, and rodents) may be infected as well as invertebrates (e.g., ticks, deerflies, horseflies, and mosquitoes).
- Humans acquire tularemia after a bite by an infected arthropod or through contact with tissues or body fluids of an infected animal. The subspecies *holarctica* has been shown to persist in various water sources, and waterborne transmission to humans has been reported.
- Inhalational exposure can happen in the laboratory setting or after the organism is aerosolized during meat preparation.
- Most commonly reported during the summer months in children between 5 and 9 years of age and those >75 years old

RISK FACTORS

- Most frequently infected groups include hunters, trappers, farmers, and veterinarians.
- Activities involving wild animals or exposure to various arthropod vectors
- Infection has been linked to landscapers using lawn mowers and brush cutters.
- Laboratory personnel working with samples known to be or potentially infected with *Francisella*

GENERAL PREVENTION

- Isolation of the hospitalized patient
 - Standard precautions are recommended for protection against secretions. Human-to-human transmission has not been reported.
- Control measures
 - Protective clothing and insect repellent should be used to minimize insect bites.
 - Inspection for ticks and their immediate removal should be routine after outdoor activity in endemic areas.
 - Rubber gloves should be worn while handling or cooking wild animals (e.g., rabbits, lemmings) possibly contaminated with *Francisella*.
 - Laboratory workers should wear rubber gloves and masks in a

biosafety level 3 environment when working with specimens potentially containing *Francisella*.

- Vaccine
 - Significant research into various vaccine techniques continues to evolve given concerns of *F. tularemia* as an agent of bioterrorism.

PATHOPHYSIOLOGY

- Entry into the human is via skin, mucous membranes, or inhalational.
- A primary lesion develops at the site of exposure.
- Local tender lymph node swelling ensues.
- After skin inoculation or inhalation, the organism can spread via the bloodstream to various organs.

ETIOLOGY

Human infection can result from various modes of entry:

- Skin contact with infected animals
- Vector-borne infection described after the bite of a tick, mosquito, horsefly, or deerfly
- Inhalation of aerosolized organism seen in laboratory workers, crop harvesting, disturbance of contaminated hay, and grass cutting
- Ingestion of contaminated food products or water

DIAGNOSIS

HISTORY

- In the right clinical setting, a history that elicits any occupational exposure or recreational activity previously noted as risk factors should raise suspicion for tularemia.
- History of a recent tick or fly bite may be recalled among affected patients.
- A history of a papule that became ulcerated is classic for the ulceroglandular form.
- Fever $>101^{\circ}\text{F}$ for 2–3 weeks is common, with associated weight loss.

PHYSICAL EXAM

- A papule or ulcer may be seen at the inoculation site.

- Skin lesions should be sought, especially when lymphadenopathy is present.
- Lymph node swelling is typically tender with overlying erythema.
- After a 3–6-day incubation period, symptoms may include fever, myalgias, and headache.
- Hepatosplenomegaly, purulent conjunctivitis, adenopathy, an ulcerative skin lesion, and tonsillitis are other localized findings.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum tube agglutination titers of 1:160 or greater are generally considered positive.
- A 4-fold rise in titers over a 2-week period is necessary to define a current infection.
- Cultures of blood, skin, ulcers, lymph nodes, gastric washings, and respiratory secretions require special media containing cysteine.
- Laboratory personnel should be made aware of the infection risk from specimens. Growth of the organism requires a biosafety level 3 laboratory.
- Polymerase chain reaction (PCR) tests are available in some laboratories. They are more sensitive than culture and can be performed on tissue samples. Current PCR techniques do not differentiate subspecies, but such techniques are under development.
- Fluorescent in situ hybridization techniques have been used in the research setting to differentiate subspecies and may be clinically useful in the future.

DIFFERENTIAL DIAGNOSIS

Depending on the form of tularemia, the infection can mimic other illnesses such as streptococcal or staphylococcal infection, cat-scratch disease, mononucleosis, cutaneous anthrax, pasteurellosis, Q fever, legionellosis, typhoid fever, or mycobacterial disease. In general, tularemia should be considered in the following differential diagnoses:

- Fever of unknown origin
- Fever with purulent conjunctivitis
- Fever with hepatosplenomegaly

- Fever with skin ulcer

TREATMENT

MEDICATION

- IV/IM antibiotic therapy with gentamicin is considered 1st-line therapy.
- 2nd-line therapeutic options include streptomycin, ciprofloxacin, or doxycycline. Relapses have been associated with the latter two, and they are generally only used in adults or in specific situations.
- Duration of treatment is typically 7–10 days. In severe disease, some experts recommend combination therapy such as gentamicin with ciprofloxacin or doxycycline.

INPATIENT CONSIDERATIONS

Initial Stabilization

- If respiratory compromise is present, oxygen supplementation and/or assisted ventilation must be rapidly addressed.
- Recognition and prompt aggressive treatment of shock should be a major priority.

PROGNOSIS

- When recognized and treated with appropriate antibiotics, the course is generally <1 month.
- Mortality is low, except in cases of fulminant disease or are otherwise immunocompromised.
- The subspecies tularensis is thought to be more virulent than the others.
- Both typhoidal and pneumonic forms of tularemia are associated with the highest risk for mortality.

COMPLICATIONS

- Lymph node suppuration, meningitis, endocarditis, hepatitis, and renal failure have all been associated with tularemia. Lymph node suppuration despite adequate therapy may occur in up to 25% of patients with ulceroglandular or glandular disease.
- Infection with *F. tularensis* may be complicated by necrotic and

granulomatous lesions in the liver and spleen as well as parenchymal degeneration.

- A sepsis syndrome with shock, fever, myalgias, and severe headache can be seen. Recognition and prompt aggressive treatment of shock should be a major priority.
- Skin manifestations, including vesiculopapular rash, erythema nodosum, and erythema multiforme have been associated with tularemia.

CODES

ICD10

- A21.9 Tularemia, unspecified
- A21.0 Ulceroglandular tularemia
- A21.1 Oculoglandular tularemia

FAQ

- Q: If a tick is removed from my child, should antibiotics be started?

- A: No. Empiric antimicrobial therapy will not prevent tularemia.
- Q: Can my child get tularemia again?
- A: No. It appears once infection has occurred, the patient is protected from further new infections.

TURNER SYNDROME

John S. Fuqua

BASICS

DESCRIPTION

Presence of typical findings in a phenotypic female with complete or partial absence of the second sex chromosome

EPIDEMIOLOGY

Prevalence: 1:2,000–5,000 liveborn females

Genetics

- Frequency of genotypes
 - 45,X 55%
 - 46,Xi(Xq) 17%
 - 45,X/46,XX 13%
 - 46,Xr(X) 5%
 - 45,X/46,XY 5%
 - Other 5%
- Recurrence risk is low in subsequent pregnancies in the absence of familial defects of the X chromosome.

PATHOPHYSIOLOGY

Deletion of the SHOX gene at Xp22.33 is responsible for the majority of the height deficit in affected patients. Fetuses with Turner syndrome have accelerated loss of germ cells from the second half of gestation through the first few years of life, with eventual gonadal failure.

ASSOCIATED CONDITIONS

- Short stature (~100%)
- Hypogonadism (90%)
- ADHD (24%)
- Strabismus/hyperopia (17%)
- Conductive hearing loss (21%)
- Sensorineural hearing loss in adults (60%)

- Autoimmune thyroiditis (27%)
- Coarctation of the aorta (11%)
- Bicuspid aortic valve (16%)
- Hypertension (50%)
- Horseshoe kidney (10%)
- Renal collecting system abnormalities (20%)
- Celiac disease (6%)
- Glucose intolerance in adults (40–50%)

DIAGNOSIS

HISTORY

- Intrauterine growth retardation
- Slow postnatal growth, beginning in infancy
 - Eventual short stature
- Lymphedema, especially in infancy
- Frequent otitis media and middle ear effusions
- Normal overall intelligence, with performance IQ less than verbal IQ
 - Focused difficulties in math, visuospatial skills, executive functioning
- Decreased social cognition, with problems reading facial expressions, body language, and other nonverbal cues
- Lack of pubertal maturation for age

PHYSICAL EXAM

- HEENT
 - Down slanting palpebral fissures, ptosis, epicanthal folds
 - Low set, posteriorly rotated ears
 - Arched palate
 - Micrognathia
 - Neck webbing (pterygium colli)
 - Low set posterior hairline
- Musculoskeletal
 - Short stature
 - Wide carrying angle (cubitus valgus)

- Short 4th metacarpals
- Broad chest relative to height
- Scoliosis
- Genu valgum
- Madelung deformity of wrist
- Other:
 - Increased number of pigmented nevi
 - Absent breast development, normal pubic hair for age
 - Edema of feet and/or hands
 - Hyperconvex fingernails, dystrophic toenails

DIAGNOSTIC TESTS & INTERPRETATION

Laboratory diagnosis of Turner syndrome is based on karyotype. Once the diagnosis is established, additional tests should be performed to identify associated conditions or complications.

Lab

- If older than 4 years old: TSH, free T₄, screening for celiac disease
- If older than 10 years old: TSH, free T₄, celiac disease serologic screening, LFTs, fasting lipids, CBC, renal function, LH, FSH

Imaging

In all patients, regardless of age: renal ultrasonography and 2-D echocardiography with color Doppler or cardiac MRI

Diagnostic Procedures/Other

- EKG
- Audiologic evaluation
- Orthodontic assessment
- Educational/psychosocial evaluation
- Scoliosis screening

TREATMENT

GENERAL MEASURES

- Treatment of girls with Turner syndrome focuses on promoting linear growth and pubertal maturation as well as screening for and managing

other associated conditions.

- Spontaneous puberty, manifested as breast development, occurs in 14% of girls with a 45,X karyotype and 32% of girls with other Turner syndrome karyotypes. Up to 50% of those with spontaneous puberty may go on to have menses that persist into late adolescence or early adulthood.
- Nearly all girls with Turner syndrome eventually have ovarian failure.

MEDICATION

- Growth hormone administration is part of standard care for girls with Turner syndrome.
 - Treatment should start when growth failure is recognized.
 - Recommended dose for girls with Turner syndrome is 54 mcg/kg/24 h or 0.375 mg/kg/week.
- Addition of oxandrolone, a nonaromatizable androgen, may be considered in girls older than age 9 years to help promote growth.
 - This treatment may accelerate pubic and axillary hair growth, so oxandrolone is generally reserved for peripubertal patients.
 - The recommended dose is 0.05 mg/kg/24 h or less.
- Estrogen is required for pubertal-aged girls without spontaneous breast development who have elevated FSH levels.
 - Induction of puberty may be delayed to accrue additional linear growth, but early diagnosis and treatment with growth hormone may normalize height and allow for estrogen treatment at a physiologic age.
 - There are many estrogen treatment regimens available, including oral and transdermal routes. Treatment is usually initiated at doses that are 1/8–1/10 of the adult doses.
 - Doses are gradually increased to adult values over 2–4 years. After 2–4 years, intermittent progestin treatment is given to induce menstrual bleeding.

ADDITIONAL TREATMENT

Associated conditions may require treatment, including antihypertensives, SBE prophylaxis, levothyroxine, gluten-free diet, myringotomy tubes, and strabismus care.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Age 4–5 years
 - Assessment of social skills, psychoeducational evaluation prior to school entry
- Age 5–12 years
 - Every year: BP, TSH, LFTs, educational and social progress
 - Every 1–5 years: audiology and ENT
 - Every 2–5 years: celiac disease screening
 - As needed: dental and orthodontic evaluations
- Age 12 years–adult
 - Every year: BP, TSH, LFTs, fasting lipids, blood glucose
 - Every 1–5 years: audiology and ENT
 - Assessment of pubertal development and psychosexual adjustment
 - Every 5–10 years: cardiac MRI
 - As needed: celiac disease screening

PROGNOSIS

- Height percentile at diagnosis is highly predictive of adult height if not treated with growth hormone or estrogen, with a correlation coefficient of 0.95.
- Height loss in untreated girls with Turner syndrome is approximately 20 cm compared to the midparental target height.
- Mean adult height in untreated girls is 144 cm.
- The presence of webbed neck (pterygium colli) on physical exam is predictive of both aortic coarctation and ovarian failure.
- 90% of women with Turner syndrome have ovarian failure.
- 40–50% of adults with Turner syndrome have insulin resistance or abnormal glucose tolerance.
- Girls and women with Turner syndrome have an increased risk for depression, anxiety, and social withdrawal.

ALERT

Girls and women with Turner syndrome are at increased risk for aortic dissection, manifested as chest or back pain. Those with a bicuspid aortic

valve or with an ascending aortic size index $>2.5 \text{ cm/m}^2$ are at highest risk.

CODES

ICD10

- Q96.9 Turner's syndrome, unspecified
- Q96.0 Karyotype 45, X
- Q96.1 Karyotype 46, X iso (Xq)

FAQ

- Q: Are older parents at increased risk to have a child with Turner syndrome?
- A: No. Turner syndrome is not associated with either advanced maternal or paternal age.
- Q: Are there special precautions for girls with bicuspid aortic valve?
- A: Affected patients with bicuspid aortic valves should receive SBE prophylaxis.
- Q: Can assisted reproductive technology allow women with Turner syndrome to carry a pregnancy?
- A: In vitro fertilization of donor oocytes has been performed in women with Turner syndrome. However, pregnant women with Turner syndrome have a significantly increased risk for hypertension and gestational diabetes. Importantly, they also are at high risk for aortic dissection. Thus, pregnancy is controversial and usually discouraged at this time.

ULCERATIVE COLITIS

Naamah Zitomersky

BASICS

DESCRIPTION

Ulcerative colitis (UC) is a chronic, relapsing, inflammatory disease of the colon, which extends continuously from the rectum proximally to a varying extent. UC is categorized as an inflammatory bowel disease (IBD), along with Crohn disease (CD). Unlike CD, UC does not affect the small bowel.

EPIDEMIOLOGY

- The incidence of pediatric-onset UC is between 1 and 4/100,000 children/year in most North American and European regions.
- Roughly 15–20% of patients with UC develop the disease before the age of 18 years.
- Incidence peaks between 15 and 30 years of age.

ETIOLOGY

The precise cause of UC, as with IBD in general, is unknown, but is thought to involve both genetic predisposition and environmental triggers.

RISK FACTORS

Genetics

- Family history of IBD in ~15–20% of patients with UC
- There is an increased incidence of family history in patients diagnosed prior to 20 years of age.
- Higher concordance in monozygotic than in dizygotic twins
- Genome-wide association studies (GWAS) have identified multiple loci associated with UC. Mutations in genes involving intestinal barrier functions are seen in UC more often than healthy controls.
- Recent studies identified five new IBD susceptibility loci that are associated with early-onset disease.

DIAGNOSIS

Patients with UC typically present with bloody diarrhea, tenesmus, and lower quadrant abdominal pain. When symptoms become severe, weight loss, fatigue, and vomiting can be seen. Colonoscopy with histopathologic review of biopsies is the gold standard in diagnosis of UC.

HISTORY

A detailed history is important in making the diagnosis:

- Rectal bleeding (90%)
- Abdominal pain (90%)
- Diarrhea (50%)
- Weight loss (10%)
- Growth failure
- Recent travel (enteric infections)
- Antibiotic use (*Clostridium difficile*)
- Family history of IBD

PHYSICAL EXAM

- Fever, tachycardia
- Evidence of weight loss or poor growth
- Signs of anemia
- Uveitis
- Mouth sores
- Arthritis
- Abdominal tenderness typically in lower quadrants or abdominal distention
- Perianal/rectal examination (UC is not typically associated with perianal disease, but hemorrhoids or erythema can be seen.)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Iron deficiency anemia and anemia of chronic disease can be seen.
 - Thrombocytosis is another frequent finding.
- Iron studies (iron deficiency)

- ESR, CRP; disease activity
- Electrolytes (hydration), CMP. Serum albumin may be low, hypoalbuminemia may be present in fulminant colitis.
- Liver panel (hepatobiliary disease)
- Perinuclear antineutrophil cytoplasmic antibody (pANCA; positive in 80% of UC patients, 20% of CD patients)
- Stool for blood, white cells (colitis)
- Fecal calprotectin and fecal lactoferrin: may be elevated during times of active inflammation
- Stool cultures:
 - C. difficile, Salmonella, Shigella, Campylobacter, Yersinia, Escherichia coli (enterohemorrhagic), Aeromonas, amebiasis, cytomegalovirus

Imaging

- Plain abdominal radiograph
 - Important in diagnosing perforation, ileus, obstruction, and toxic megacolon
 - In toxic megacolon, the colon is dilated, and there are multiple air–fluid levels indicative of ileus. Serial x-rays are mandatory.
- An upper GI with small bowel follow-through (UGI/SBFT) may help to exclude small intestinal inflammation indicative of CD.
- New imaging modalities, such as MR enterography (MRE), CT enterography, are currently being performed in place of UGI/SBFT. MRE has the advantage of avoiding radiation exposure.
- MRI may have a role in differentiating transmural and mucosal inflammation and is useful for demonstrating perianal fistulas more consistent with CD than UC.
- Right upper quadrant ultrasound may be useful for evaluating associated hepatobiliary disease if it is suspected.
- Endoscopic retrograde cholangiopancreatography (ERCP) or MRCP are also useful in diagnosing primary sclerosing cholangitis (3% of UC patients).

Diagnostic Procedures/Other

- Colonoscopy (with biopsies) is the gold standard and is necessary to confirm the diagnosis of UC. It is critical to visualize and biopsy the

entire colon, including terminal ileum, to differentiate CD from UC.

- Upper endoscopy may increase chances of detecting CD and may detect chronic gastritis sometimes seen with UC.
- Video capsule endoscopy (VCE) is more sensitive than UGI/SBFT for diagnosing small bowel disease indicative of CD rather than UC.
- Pitfalls:
 - Infectious colitis (especially *C. difficile*) can mimic the findings of UC so this should first be ruled out with stool culture. Recurrent *C. difficile* occurs frequently in UC.
 - Differentiating Crohn colitis from UC: Small intestinal inflammation and perianal disease (fistula, abscess) are more indicative of CD.
 - Serum inflammatory markers and CBC may be normal in children with active colitis especially with mild disease.
 - The combination of positive pANCA and negative anti-*Saccharomyces cerevisiae* antibody (ASCA) has a reported sensitivity of 60–70% and a specificity of 95–97% for UC in adults. The sensitivity and specificity are lower for pediatric patients.
 - Toxic megacolon is a surgical emergency. It is characterized by a dilated colon at risk for breakdown of its barrier to toxins entering the systemic circulation. Signs and symptoms include peritonitis, mental status changes, and fluid and electrolyte imbalance. Plain abdominal radiograph shows a segment or total colonic dilatation. Risk factors include new diagnosis of UC, pancolitis, concurrent use of opiates and/or anticholinergics, and recent colonoscopy.

Pathologic Findings

- Chronic or chronic active colitis, with continuous inflammation limited to the mucosa
- Crypt architectural distortion, cryptitis (aggregation of inflammatory cells in the crypt epithelium), crypt abscesses
- Site of colon affected:
 - Rectum (virtually 100%)
 - Left side (50–60%)
 - Pancolitis (10%)
- Small intestine is technically not involved, but occasionally the

terminal ileum of patients with UC can be found to have mild inflammation on radiologic or histologic examination. This is thought to be from refluxed colonic contents (backwash ileitis).

- Skip lesions are not seen in UC.
- Chronic gastritis may be present in patients with UC.

DIFFERENTIAL DIAGNOSIS

- Infectious colitis: *C. difficile*, *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *E. coli* (enterohemorrhagic), *Aeromonas*, cytomegalovirus
- Crohn disease
- Congenital Hirschsprung enterocolitis
- Bleeding juvenile polyps
- Milk protein allergy especially in infants
- Immunodeficiency states (rare) onset of colitis within the first 2 years of life, often with perianal involvement; skin folliculitis, or eczema; other fungal or bacterial infections
- Eosinophilic colitis
- Autoimmune enteropathy
- Hemolytic-uremic syndrome
- Henoch-Schönlein purpura
- Trauma due to anal sex or sexual abuse

TREATMENT

MEDICATION

- Mild disease can be treated with oral mesalamine, topical corticosteroid enema or foam, or mesalamine enema/suppositories.
- For mild to moderate disease, Budesonide MMX is a once-daily, extended-release budesonide, which has been shown to induce remission in adults with mild to moderate UC and has fewer side effects than systemic corticosteroids.
- For moderate disease, mesalamine, a short course of oral corticosteroid and the addition of an immunomodulators such as azathioprine or 6-mercaptopurine may help to maintain disease remission and minimize the need for recurrent steroid use.

- Antibodies against tumor necrosis factor (TNF)- α include infliximab and adalimumab; both are used in the treatment of moderate to severe UC or steroid-resistant UC.
- Vedolizumab is an anti-integrin, which is a steroid-sparing agent used for induction and maintenance of moderate to severe UC in adults. $\alpha 4\beta 7$ integrins are expressed on B and T lymphocytes and facilitate binding to intestinal vasculature. Vedolizumab is a gut-selective antibody that blocks gut lymphocyte recruitment by blocking its interaction with mucosal addressin cell adhesion molecule-1.
- Fulminant disease: hospitalization, if concern for toxic megacolon—complete bowel rest with total parenteral nutrition, broad-spectrum antibiotics, discontinuation of anticholinergics and narcotics, avoidance of endoscopy, IV corticosteroids, serial abdominal radiographs, frequent examinations, stool monitoring (frequency, amount of blood, and volume of stool output); early surgical consult
- If treatment of acute symptoms with IV steroids fails (after 3–5 days), therapy with tacrolimus, cyclosporine, or infliximab can be started.
- Pediatric Ulcerative Colitis Activity Index (PUCAI): obtained on day 3–5; may identify patients with severe UC who will require escalation of therapy. Prevents unnecessary prolonged exposure to corticosteroids
- Short-term medications for severe colitis should be used as a bridge to surgery or to transition to another steroid-sparing agent, such as an immunomodulator or biologic.
- Tacrolimus (PO) 0.1 mg/kg/dose every 12 hours with goal trough levels of 10–15 ng/mL after 2 days.
- Cyclosporine (IV): 4 mg/kg/24 h for 2 weeks (therapeutic levels vary depending on the technique used in the laboratory)
- Cyclosporine (PO): 6–8 mg/kg/24 h for 6–8 months
- Tacrolimus and cyclosporine are both nephrotoxic. Should only be used by experienced clinicians
- Trimethoprim/sulfamethoxazole should be given for *Pneumocystis carinii* prophylaxis.
- 5-aminosalicylates:
 - Mesalamine (PO): 40–60 mg/kg/24 h (maximum 4.8 g/day)
 - Mesalamine (enema): 4 g at bedtime (for proctitis or isolated left-

sided disease)

- Mesalamine (suppository): 500 mg b.i.d.
- Corticosteroids:
 - Methylprednisolone (IV): 1–2 mg/kg/24 h (equivalent to prednisone 60 mg maximum)
 - Prednisone (PO): 1–2 mg/kg/24 h oral (up to maximum 60 mg/day)
 - For proctitis and isolated left-sided disease
 - Hydrocortisone enema: 100 mg once to twice daily
 - Hydrocortisone foam: 80 mg once to twice daily
 - Budesonide multimatrix system 9 mg/24 h orally
- Immunomodulators:
 - Mercaptopurine (6-MP) (PO): 1–1.5 mg/kg/24 h or azathioprine (PO): 2 mg/kg/24 h
 - Check thiopurine methyltransferase genetics or activity prior to initiation to avoid pancytopenia in those who lack this enzyme. Also monitor CBC and lipase every 2 weeks on initiation and with dosing changes to look for cytopenias or pancreatitis.
- Biologics:
 - Infliximab (IV): 5 mg/kg weeks 0, 2, 6, then every 8 weeks, dose and frequency can be increased to capture symptoms
 - Adalimumab (IM): for patients weighing 40 kg and greater, 160 mg on week 0, 80 mg on week 2, followed by 20 or 40 mg every 2 weeks starting on week 4. Reduce dosage by 50% for patients <40 kg.
- Anti-integrin
 - Vedolizumab (adult dosage) 300 mg IV weeks 0, 2, 6 weeks then every 8 weeks and can be increased to every 4 weeks to capture symptoms.

SURGERY/OTHER PROCEDURES

- Patients with fulminant disease who fail medical therapy should be referred for colectomy.
- Patients with chronically active disease unresponsive to medication, growth failure, or with corticosteroid dependence should also consider colectomy.
- Because UC is limited to the colon, colectomy is considered a curative

procedure. It also eliminates the elevated colon cancer risk.

- Sometimes surgery is urgently required for perforation, significant and persistent bleeding, toxic megacolon, and failure of medical treatment.
- Can be electively performed for chronic incapacitating disease, growth failure, corticosteroid dependence, dysplastic changes in the colon, or long-standing disease (usually after 10 years).
- Ileoanal anastomosis and pouch construction is surgery of choice for most pediatric patients and usually is performed in 3 stages over 6 months. 10% of cases are subsequently found to have Crohn disease after colectomy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Outpatient follow-up with a pediatric gastroenterologist should be arranged.
- Important parameters to follow routinely include abdominal symptoms, rectal bleeding, stool frequency/consistency, height/weight, hemoglobin, WBC count (for patients on immunosuppressives), ESR, albumin, bilirubin, and liver enzymes.
- There is ongoing debate about monitoring for mucosal healing in UC. Adult studies have shown better outcomes, reduction in disease progression, and fewer complications in individuals who achieve mucosal healing.
- Colon cancer screening with colonoscopy should be performed within 10 years of diagnosis.

COMPLICATIONS

- Bleeding
- Anemia
- Toxic megacolon
- Extraintestinal manifestations include hepatobiliary disease (3–5%), uveitis (up to 4%), arthritis affecting large joints (10%), spondylitis (6%), erythema nodosum (>5%), pyoderma gangrenosum (>1%), renal calculi (5%).

- Malignancy risk is 8% 10–25 years after colitis is diagnosed and it increases ~10% for every subsequent decade.
- Colonic stricture
- Thrombosis: Patients with IBD have a 3-fold higher risk of thrombosis compared to individuals without IBD. This risk rises further to 15-fold with disease flares. Presentation with calf pain or shortness of breath should prompt evaluation for deep vein thrombosis or pulmonary embolism.

CODES

ICD10

- K51.90 Ulcerative colitis, unspecified, without complications
- K51.80 Other ulcerative colitis without complications
- K51.311 Ulcerative (chronic) rectosigmoiditis with rectal bleeding

FAQ

- Q: Will my child have this disease forever?
- A: Some people will have only the initial attack and then be symptom-free, but usually and more often in pediatrics, individuals will have episodes of recurrences and remissions. Surgical removal of the colon represents a curative procedure, although some patients may develop inflammation in the pouch created out of the remaining bowel (pouchitis).
- Q: What is the cause of UC?
- A: Both genetic and environmental factors are important in the development of UC.
- Q: Where can I learn more about UC?
- A: The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition provides a Web site for children with IBD and their families (www.gastrokids.org). The Crohn's and Colitis Foundation of America (www.CCFA.org) is a nonprofit organization dedicated to the care and education of people with CD and UC.

UPPER GASTROINTESTINAL BLEEDING

Michael A. Manfredi

BASICS

DESCRIPTION

- Upper gastrointestinal bleeding (UGIB) is defined as bleeding in the GI tract that occurs proximal to the ligament of Treitz.
- The classic clinical symptom of UGIB is hematemesis, consisting of either bright red or “coffee grounds”-appearing blood.
- Other symptoms of UGIB include melena, occult blood loss, as well as hematochezia with rapid, severe bleeds.
- When hematemesis is suspected, a clinician must exclude non-GI causes, including hemoptysis (coughing up blood), nose bleeds, and bleeding from the mouth and pharynx.

EPIDEMIOLOGY

- Most large, prospective studies of UGIB in children have assessed the incidence in pediatric critical care settings to range from 6.4 to 25% of admissions.
- 80% of UGIB resolve spontaneously.

ETIOLOGY

- Neonatal period (birth to 1 month)
 - Swallowed maternal blood
 - Necrotizing enterocolitis
 - Duodenal or antral webs
 - Hemorrhagic disease of the newborn
 - Esophagitis
 - Gastritis
 - Stress ulcer
 - Foreign body irritation
 - Vascular malformation
 - GI malformation
- Infancy (1 month to 2 years)

- Esophagitis/gastritis
- Stress ulcer
- Mallory-Weiss tear
- Pyloric stenosis
- Vascular malformation
- Duplication cysts
- Metabolic disease
- Preschool age (2–5 years)
 - Esophageal varices
 - Esophagitis/gastritis/ulcer
 - Foreign body/bezoar
 - Mallory-Weiss tear
 - Vascular malformation
 - Meckel diverticulum
- School age (>5 years)
 - Esophageal varices
 - Infection
 - Esophagitis/gastritis/ulcer
 - Mallory-Weiss tear
 - Inflammatory bowel disease
 - Drugs: NSAIDs, α -adrenergic antagonists
 - *Helicobacter pylori*
- All ages: liver failure—coagulopathy, Henoch-Schönlein purpura

RISK FACTORS

- Liver disease may cause portal hypertension and/or coagulopathy.
- Renal disease may cause gastritis or angiodysplasia.
- Renal failure or cirrhosis may cause gastric antral vascular ectasia.
- Recent trauma or stress (e.g., burns, head trauma, surgery) may be associated with a stress ulcer or gastritis.

GENERAL PREVENTION

- Avoid or minimize the use of drugs that can lead to peptic ulcers, for example, NSAIDs and aspirin.
- In patients with chronic GI conditions, optimize therapy and monitoring.

- Correct coagulopathy.
- Prophylactic medical or endoscopic therapy is beneficial for patients with known variceal bleeding.

DIAGNOSIS

APPROACH TO THE PATIENT

- The initial evaluation of patients presenting with GI bleeding should focus on assessing vital signs, obtaining a history of present illness, as well as pertinent medical history, performing a physical examination, and lab testing.
- General goals: Determine location of the bleeding and etiology, begin stabilization, and start treatment.
 - **Phase 1:** Determine whether the emesis contains blood versus nonblood substances. Red food coloring, fruit-flavored drinks, juices, vegetables, and some medicines may resemble blood. A pH-buffered Gastrocult test can be used to identify blood in the vomitus.
 - **Phase 2:** Assess severity of bleeding. Is there a change in vital signs, hematocrit, BP, capillary filling, pulse?
 - **Phase 3:** Stabilize patient, and decide if emergency treatment or referral is needed.

HISTORY

- GI symptoms:
 - Emesis prior to hematemesis may suggest Mallory-Weiss tear.
 - Odynophagia and GERD may suggest esophageal ulcer.
 - Epigastric pain may suggest peptic ulcer.
- Characteristics of UGIB:
 - Color of blood: may help determine whether bleeding is active
 - Emesis: bright red blood versus coffee ground
 - Stool: melena versus maroon colored versus hematochezia
- Amount of blood
 - May indicate severity of bleeding (i.e., drops vs. 1 teaspoon vs. 1 tablespoon)

- Duration of symptoms
 - May help determine if this is an acute or chronic issue
- Medication history:
 - The patient's current or recently used medications may help determine the cause.
 - Gastrotoxic medications, such as NSAIDs and aspirin, as well as anticoagulant medication use may be implicated.
 - In addition, a history of medications in the house should also be obtained due to possible accidental ingestion in younger children.
- Prior history of UGIB
 - May help determine the location of current bleed
 - If the prior bleed was recent, this may facilitate timely specialty consultation with gastroenterology, surgery, and/or interventional radiology.
- Prior GI history
 - Gastroesophageal reflux, peptic ulcer disease, and/or previous GI surgery are risk factors for UGIB. May suggest symptoms are due to recurrence of disease
- Social history
 - A history of alcohol use could be associated with gastritis or Mallory-Weiss tear

PHYSICAL EXAM

- Immediately assess hemodynamic stability:
 - Heart rate: Tachycardia may be an early sign of intravascular volume depletion.
 - Blood pressure: Hypotension is a late sign of volume depletion and may not be present even with significant blood loss, as vasoconstriction maintains BP until decompensation occurs.
 - In the setting of normal blood pressure, obtain orthostatic BP.
 - Capillary refill: Delayed capillary refill suggests intravascular volume depletion.
 - Oxygen saturation: Decreased arterial saturation values may be due to decreased oxygen-carrying capacity.
 - Evaluate for signs of shock:
 - Vital sign derangement (as listed earlier)

- Cool clammy extremities
 - Poor mentation
- Abdomen
 - Evaluate bowel sounds for evidence of possible bowel obstruction.
 - Assess for abdominal tenderness, which may suggest peptic disease.
 - Evaluate for ascites, which may suggest liver disease.
 - Evaluate for signs of chronic liver disease of portal hypertension:
 - Hepatomegaly
 - Splenomegaly
 - Spider angioma
 - Caput medusa
 - Palmar erythema
 - Ascites
- Rectal examination
 - Heme-positive stool may or may not be present.
 - If positive, supports diagnosis of UGIB
- Skin
 - Petechiae, ecchymosis, or hemangiomas may suggest a coagulopathy or a vascular anomaly.
- HEENT
 - Evaluate for nasopharyngeal source of bleeding.
 - Evaluate the buccal mucosa for syndromic findings: freckles (Peutz-Jeghers syndrome) and telangiectasias (Osler-Weber-Rendu syndrome).

DIAGNOSTIC TESTS & INTERPRETATION

- NG tube lavage
 - No longer recommended in patients with suspected UGIB for diagnosis, prognosis, visualization, or therapeutic effect
- Gastrocult test for blood
 - If possible, confirm red substances are blood.
 - In neonates, may need to check for fetal hemoglobin with the Apt test, which identifies fetal hemoglobin versus swallowed maternal blood.
- CBC
 - Initial hemoglobin values may be unreliable because a time delay

between blood loss and hemodilution may occur and falsely produce near-normal values. Therefore, hemoglobin should be measured serially.

- If leukopenia or thrombocytopenia is present, consider chronic liver disease and portal hypertension.
- If anemia is present with normal erythrocyte indices, there is truly an acute cause for bleeding. If erythrocyte indices indicate iron deficiency anemia, consider varices or a mucosal lesion (i.e., chronic blood loss).
- Coagulation profile
 - If PT or PTT is abnormal, consider liver disease or disseminated intravascular coagulation (DIC) with sepsis.
 - If DIC screen is negative, consider liver disease. Important to avoid contamination of blood sample with heparin.
- Liver function test results may be abnormal in chronic liver disease.

Imaging

- Barium tests
 - Not useful in the acute setting
 - Barium can obscure view when performing esophagogastroduodenoscopy (EGD).
- Abdominal x-ray
 - If small bowel obstruction or foreign body is suspected
- Ultrasound
 - If portal hypertension is suspected
- Bleeding scan
 - Useful in the patient with significant bleeding that precludes endoscopy or in whom endoscopy is nondiagnostic
 - Technetium-99m–tagged erythrocyte scan detects rapid bleeding at a rate of 0.1–0.5 mL/min. Can be performed at 30-minute intervals for up to 24 hours
 - Meckel scan: Technetium-99m pertechnetate-tagged can detect a Meckel diverticulum that contains gastric mucosa.
- Angiography
 - Requires bleeding rate of 0.5–1 mL/min to detect location. Useful in detecting vascular causes of upper GI bleeding

- Can also be therapeutic (i.e., injection of coils into a vascular malformation)
- Upper endoscopy
 - Upper endoscopy is the prime diagnostic and therapeutic tool for evaluating UGIB in pediatric patients.
 - 90–95% sensitive at locating bleeding site

TREATMENT

GENERAL MEASURES

- Initial management:
 - Make patient NPO.
 - Obtain stable IV access.
 - Blood type and cross-match for PRBCs should be obtained.
 - Stabilize the patient with IV fluids and blood products as necessary (target hemoglobin ≥ 7 g/dL).
 - Target INR < 2.5
- Disease-specific therapy:
 - Peptic ulcer disease (medical therapy)
 - ▢ Proton pump inhibitors
 - ▢ H₂ blockers
 - ▢ Sucralfate
 - ▢ Prokinetic agents
 - ▢ H. pylori eradication
 - Peptic ulcer disease (endoscopic therapy)
 - ▢ Hemoclip
 - ▢ Thermal therapy (i.e., bipolar vs. argon plasma coagulation)
 - ▢ Injection therapy (i.e., 1:10,000 epinephrine)
 - Esophageal varices:
 - ▢ Octreotide infusion
 - ▢ Esophageal band ligation
 - ▢ Sclerotherapy
 - ▢ Sengstaken-Blakemore tube
 - ▢ Portosystemic shunts

ISSUES FOR REFERRAL

- Immediate referral if bleeding is profuse, if patient is hemodynamically unstable, or if bleeding will not stop
- Refer any patient with evidence of chronic iron deficiency anemia and heme-positive stools.

SURGERY/OTHER PROCEDURES

- Patients with significant UGIB should generally undergo endoscopy within 24 h of admission, following resuscitative efforts to optimize hemodynamic parameters.
- If rebleeding occurs after endoscopy or if endoscopy is unable to achieve initial hemostasis, then surgery or angiography should be considered.

ONGOING CARE

- Monitor hemoglobin in the hospital until patient's condition is stable.
- If bleeding has stopped, endoscopy should still be strongly considered to determine source of bleeding.
- Once patient is discharged, monitor patient's hemoglobin and stool for occult blood weekly until stable.
- More specific follow-up depends on the underlying condition.

- K92.0 Hematemesis
- K92.1 Melena

FAQ

- Q: When should you refer a patient for UGIB?
- A: You should refer patients immediately if there is evidence of significant and/or active bleeding, and or the patient is hemodynamically unstable. Patients with evidence of chronic iron deficiency anemia and heme-positive stools should be referred for elective, but timely evaluation.

URETEROPELVIC JUNCTION OBSTRUCTION

J. Christopher Austin • Michael C. Carr

BASICS

DESCRIPTION

Ureteropelvic junction (UPJ) obstruction is a partial blockage of the kidney at the point where the renal pelvis transitions into the proximal ureter.

EPIDEMIOLOGY

- 45% of all cases of significant prenatal hydronephrosis are due to UPJ obstruction.
- Occurs more commonly in males (M/F 2:1)
- Left-sided lesion more common (66%)
- Bilateral in 10–40%
- 50% of patients have an additional genitourinary malformation, most commonly
 - Vesicoureteral reflux
 - Contralateral UPJ obstruction
 - Multicystic dysplastic kidney
 - Renal agenesis
- Of patients with VATER association, 21% have UPJ obstruction and thus should be screened with renal ultrasound. (VATER stands for vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial and renal anomalies.)

PATHOPHYSIOLOGY

- The obstruction can cause varying degrees of hydronephrosis.
- Mild forms of UPJ obstruction result in dilation of the renal pelvis without loss of function.
- More severe forms result in dilation of the renal pelvis and calyces with loss of renal parenchyma and decreased function.
- In the most severe cases, the kidney may have cystic dysplasia and

very poor function.

- Congenital hydronephrosis owing to an intrinsic narrowing is nearly always asymptomatic.
- When the obstruction is intermittent owing to a crossing vessel, the renal pelvis becomes distended (most commonly owing to a transient increase in urine output), which drapes it over the vessel and kinks the ureter, resulting in an acute obstruction. The acute distention of the renal pelvis results in pain (renal colic).

ETIOLOGY

- Intrinsic: a congenital narrowing of the UPJ, which is most commonly owing to abnormal musculature and fibrosis of this area, resulting in an adynamic segment
- Extrinsic: kinking at the UPJ, which is most commonly owing to the renal pelvis draping over a lower pole crossing vessel. This type of obstruction can be intermittent.

DIAGNOSIS

HISTORY

- Antenatal
 - If unilateral, timing and severity of hydronephrosis and status of the contralateral kidney are factors.
 - When bilateral or affecting a solitary kidney, renal insufficiency is a concern.
 - The presence of oligohydramnios, increased renal echogenicity, and cystic changes are indicators of poor renal function and dysplasia.
- Postnatal
 - Feeding intolerance/respiratory distress (very rarely caused by UPJ obstruction)
- Older children
 - History of episodic abdominal (may not lateralize well), flank, or back pain
 - Length of episodes (usually 30 minutes to several hours); associated nausea and vomiting

- Relation of episodes to fluid intake; history of urinary tract infections or gross hematuria

PHYSICAL EXAM

- Newborn
 - Palpate kidneys.
 - Affected kidney may feel enlarged but should not be tense.
 - A tense mass can indicate a severe obstruction and should be imaged promptly.
- Older child
 - Careful abdominal exam for enlarged kidney and tenderness
 - Costovertebral angle tenderness

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Newborn
 - If bilateral or a solitary kidney, serial assessments of renal function are necessary (serum electrolytes and creatinine), starting at 24–48 hours of age.
 - With a normal contralateral kidney, no immediate laboratory testing is necessary.
- Older children
 - Urinalysis to detect hematuria or pyuria. Culture if infection is suspected

Imaging

Antenatally detected hydronephrosis: Infants with moderate to severe unilateral or bilateral antenatally detected hydronephrosis typically are evaluated with 3 imaging studies—renal/bladder ultrasound, voiding cystourethrogram (VCUG), and renal scan:

- Renal/bladder ultrasound: In most cases, immediate imaging is not necessary. Because of a period of relative oliguria of a newborn in the first 24–48 hours of life, an ultrasound may underestimate the degree of hydronephrosis. This should not preclude evaluating an infant during this time as long as any normal study is followed up with a repeat study in 4–6 weeks. Evaluation should reveal the severity of dilation of the renal pelvis and calyces, changes in the amount and

echogenicity of the parenchyma, and the presence of cortical cysts:

- The evaluation of the full bladder is important for excluding dilated distal ureters, thickening of the bladder wall owing to outlet obstruction, and ureterocele.
- In cases of bilateral hydronephrosis, a solitary hydronephrotic kidney, or a tense kidney on physical examination, imaging should be promptly performed.
- VCUg: This study will detect the presence of vesicoureteral reflux as well as exclude the presence of posterior urethral valves and other abnormalities of the bladder:
 - The test can be delayed until after discharge from the nursery unless there is concern about posterior urethral valves, in which case it should be performed early.
 - The presence of ureteral dilation on ultrasound strengthens the argument to perform a VCUg. The detection of vesicoureteral reflux, particularly in a circumcised male patient, may not confer benefit in their clinical management.
- Renal scan: This study can quantify the differential renal function or the amount each kidney contributes to overall renal function (the normal differential is $50\% \pm 5\%$ for each kidney):
 - The 2 most commonly used radionuclides are mercaptoacetyltriglycine (MAG-3) and diethylenetriamine penta-acetic acid (DTPA). In addition to the ability to detect diminished function, if there is poor drainage of the affected kidney, furosemide is given to wash out the radiotracer.
 - The time for washing out half of the accumulated radiotracer ($T_{1/2}$) is often given in the report.
 - A prompt $T_{1/2}$ (<10 minutes) is indicative of a nonobstructed kidney.
 - A slower $T_{1/2}$ may be indicative of obstruction when it is >20 minutes. An intermediate $T_{1/2}$ (10–20 minutes) is indeterminate for obstruction. Owing to effects of hydration, the amount of hydronephrosis, and variables in the timing of the diuretic administration, the $T_{1/2}$ may be unreliable.
- Intravenous pyelogram (IVP): This study is most useful for evaluating

the anatomy of the kidney and the ureters:

- It can also be used for evaluating an older child with intermittent symptoms if it can be done during a symptomatic episode.
- A normal study during a symptomatic episode of abdominal or flank pain excludes an intermittent UPJ obstruction as the cause of the child's pain.
- If a normal study is obtained while the child is asymptomatic, an intermittent UPJ obstruction remains a possible cause.
- Magnetic resonance urography (MRU): A new technique being studied that provides both anatomic and functional detail. Dynamic contrast-enhanced MRI requires sedation and placement of a bladder catheter. The images are obtained following infusion of gadolinium-DTPA. Furosemide is given 15 minutes before the start of the study. This technique is being studied for use instead of ultrasound and renal scans in the hope that it will be a more precise tool in deciding whether or not the child requires surgical repair.

DIFFERENTIAL DIAGNOSIS

- Vesicoureteral reflux: Higher grades of reflux will result in the dilation of the upper urinary tract.
- Distal ureteral obstruction: obstruction at the level of the bladder owing to ureterovesical junction obstruction, ureterocele, or an ectopic ureter
- Bladder outlet obstruction: dilation of the upper urinary tract secondary to obstruction of the lower urinary tract owing to posterior urethral valves, urethral atresia, or stricture
- Megacalycosis: congenital dilation and increased numbers of calyces without significant renal pelvis dilation or obstruction
- Multicystic dysplastic kidney: can be difficult to differentiate severe hydronephrosis from cysts by ultrasound. Renal scan will demonstrate no function in multicystic dysplastic kidneys.
- Triad syndrome: a triad of hypoplastic abdominal wall musculature, bilateral undescended testes, and dilation of the urinary tract (also known as prune belly syndrome or Eagle-Barrett syndrome)

TREATMENT

GENERAL MEASURES

- The decision to observe or surgically correct a UPJ obstruction depends on several factors. One must consider the age and overall health of the neonate, the amount of functional impairment of the kidney, whether it is a unilateral or bilateral process, the drainage pattern on renal scan, and whether or not it is symptomatic. There is no strict rule for who should be observed and who should undergo surgery. This decision should be made on an individual basis.
- Antibiotic prophylaxis
 - Newborns should be started on a once-a-day daily dose of amoxicillin or cephalexin at 1/4–1/2 the normal therapeutic dose.
 - The antibiotic can be switched to trimethoprim, trimethoprim/sulfamethoxazole, or nitrofurantoin at 2 months of age.
 - The duration that infants should be left on antibiotics is controversial among practicing pediatric urologists. Almost all agree that infants should be started on prophylactic antibiotics at birth.
 - They should be continued at least until the infant undergoes a VCUG to exclude reflux. Several factors including age, sex, and degree of hydronephrosis are taken into account when deciding whether or not to stop the prophylaxis.
- Observation
 - Infants with the hydronephrosis thought to be owing to a narrowing at the UPJ are typically observed when there is preserved function (>40%) in the affected kidney, and the contralateral kidney is normal.
 - The pattern of drainage is taken into account, and if there is prompt drainage and normal differential function ($50\% \pm 5\%$), these patients are followed with less frequent follow-up studies than those with less function or poor drainage.
 - Most patients have follow-up imaging studies done at 3–6-month intervals during their 1st year of life, and they are gradually spaced out as time goes by if the hydronephrosis remains stable or improves.
- Older children with hydronephrosis owing to a UPJ obstruction are

often detected during a symptomatic episode. If the UPJ obstruction is asymptomatic and the function of the kidney is preserved, the child may be observed as well.

SURGERY/OTHER PROCEDURES

- The gold standard for the repair of the UPJ obstruction has been a pyeloplasty:
 - During the procedure, the narrowed UPJ is most commonly excised, and the ureter is reanastomosed to the renal pelvis.
 - This procedure is successful 95% of the time.
- Less invasive approaches include endoscopically incising the narrowing (endopyelotomy) or balloon dilation:
 - These approaches have been used in adults with rates of success in the 50–70% range but are considerably less invasive.
 - Endoscopic procedures have not been routinely offered as a 1st-line therapy for the treatment of UPJ obstructions because of their limited experience in children and the lower rates of success.
- Laparoscopic pyeloplasty is being performed in older children and adolescents and will likely be more common in the next several years. Robotically assisted procedures are now being done, further enhancing the minimally invasive approach. Both offer a similar rate of success to a traditional pyeloplasty with decreased perioperative morbidity because of the small incisions for the laparoscopic instruments.

CODES

ICD10

- Q62.39 Other obstructive defects of renal pelvis and ureter
- Q62.11 Congenital occlusion of ureteropelvic junction
- N13.8 Other obstructive and reflux uropathy

FAQ

- Q: My unborn baby has hydronephrosis. My obstetrician told me that it is most likely a UPJ obstruction. Is my baby going to need surgery to correct this?
- A: Not necessarily; only ~1/3 of babies with significant hydronephrosis ultimately require surgical correction.
- Q: Will my child's kidney look normal after the surgery to fix it?
- A: Often the kidney has less dilation and an improved appearance but not completely normal. Of greater importance is that there is no longer obstruction and the function is preserved or improved.

URINARY TRACT INFECTION

Mercedes M. Blackstone

BASICS

DESCRIPTION

- Urinary tract infection (UTI) is defined by having pyuria and $\geq 50,000$ CFUs/mL of a single urinary tract pathogen from an appropriately collected specimen.
- Upper tract infection or pyelonephritis: infection of the renal parenchyma; most febrile babies with a positive culture have upper tract infection
- Lower tract infection or cystitis: infection limited to the bladder, not involving the kidneys; occurs more in older children and adolescents; usually no fever

EPIDEMIOLOGY

- Bimodal age distribution with peak incidence in infants <1 year of age (40 per 1,000)
- 2nd peak in adolescent females
- Overall prevalence of about 7% in febrile infants and young children; varies according to risk factors below
- Higher prevalence in Caucasian girls

RISK FACTORS

- Sex/age: Boys are most at risk for UTI during 1st year of life; girls until school age and again in adolescence.
- Circumcision status: Uncircumcised males <1 year of age have increased risk of UTI; prevalence is 10 times higher for uncircumcised males versus circumcised males <3 months of age.
- Race/ethnicity: Caucasian children are 2–4 times more likely than African-American children to have UTI:
 - May be due in part to differences in blood group antigens on the surfaces of uroepithelial cells, which affect bacterial adherence
- Abnormal urinary tract: Children with vesicoureteral reflux (VUR) and

obstruction are at higher risk for UTI.

- Bowel and bladder dysfunction
- Requiring frequent catheterization
- Sexual activity
- Clinical decision rule in febrile girls 2–24 months of age. Consider testing if ≥ 3 of following are present:
 - Temperature $\geq 39^{\circ}\text{C}$, fever for ≥ 2 days, non-African-American race, age < 1 year, absence of another potential source of fever

GENERAL PREVENTION

- Teach correct wiping—front to back—to young children.
- Consider prophylactic antibiotics for select children with recurrent infection, high-grade VUR, and urologic anomalies:
 - Existing evidence with 1-year follow-up does not support antibiotic prophylaxis for patients with low-grade VUR.
- Attention to good voiding and stooling habits; treat constipation
- Consider single-dose postcoital antibiotics for adolescents with recurrent UTI.
- Cranberry juice has not been shown to help.

PATHOPHYSIOLOGY

- Bacterial invasion of the urinary tract from ascending flora from skin or gut
- Shorter urethra in females puts them at increased risk.
- Poor bladder emptying (neurogenic bladder, obstructive uropathies) facilitates movement of pathogens into the upper tract.
- In young infants, can be from hematogenous spread

ETIOLOGY

Urinary tract pathogens

- *Escherichia coli* is responsible for about $>80\%$ of UTIs in children.
- Other fairly common microbes include *Klebsiella* species, *Enterococcus*, and *Proteus mirabilis*.
- Less common: *Enterobacter cloacae*, group B hemolytic streptococci, *Citrobacter*, *Pseudomonas* species, *Staphylococcus aureus*, *Serratia* species, and *Staphylococcus saprophyticus* (teenage girls)
 - Can also have viral or fungal causes of UTI

COMMONLY ASSOCIATED CONDITIONS

- ~5–10% of babies with febrile UTIs (pyelonephritis) are bacteremic, but the clinical course is likely unchanged.
- VUR, urinary abnormalities, bowel and bladder dysfunction

DIAGNOSIS

HISTORY

- Babies
 - Nonspecific symptoms, often fever alone
 - Can have vomiting, irritability, poor feeding, and lethargy
 - Rarely, failure to thrive or jaundice
- Older children
 - Classic symptoms of the lower tract include urgency, frequency, dysuria, hesitancy, suprapubic discomfort, hematuria, and malodorous urine. Classic symptoms of the upper tract include fever, chills, nausea, and flank pain.
 - May have history of constipation
 - Can also present with secondary enuresis
 - Ask older children about sexual activity.
- Special question
 - Has the young child had a history of UTI, unexplained fevers, or urinary tract anomaly?

PHYSICAL EXAM

- Temperature and blood pressure should be documented.
- Babies and toddlers: often no physical findings or fever alone
 - Less common: abdominal pain or distention, poor growth or weight gain, malodorous urine
 - Associated findings: may see evidence of foreign body, phimosis, labial adhesions, or midline abnormality of the lower back, which could indicate a neurogenic bladder
- Older children
 - Lower tract: suprapubic tenderness; may see evidence of constipation

- Upper tract: fever; costovertebral angle tenderness to percussion
- Evaluation for sexually transmitted infections

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urine culture collected sterilely is the gold standard for diagnosis:
 - Bladder catheterization in young children (or less commonly, suprapubic aspirate)
 - Midstream clean-catch method for older cooperative children
 - A specimen should not be obtained by applying a bag to the perineum; contamination rates are too high.
- False positives
 - Contaminated urine by perineum or stool organisms
- Cultures take 24–48 hours, so several rapid screening tests are available:
 - Conventional urinalysis: ≥ 5 WBC/HPF (uses centrifuged urine) and bacteria suggests UTI.
 - Enhanced urinalysis (combines microscopy on uncentrifuged urine with Gram stain): ≥ 10 WBC/mm³ and positive Gram stain consistent with infection
 - High sensitivity and specificity; helpful in neonates
 - Urine dipstick alone equivalent to conventional microscopy
 - Leukocyte esterase (LE) indicates presence of urinary leukocytes.
 - Remember that conditions other than UTI may also present with pyuria.
 - Nitrites are formed by nitrate-splitting bacteria (high rate of false negatives because urine has to sit in the bladder for ≥ 4 hours for nitrites to be detected).
 - Moderate or large LE and nitrites alone suggest UTI; together they are highly specific.
- Serum testing is not routinely indicated in the patient with suspected UTI.
 - Blood culture: not indicated in the well-appearing patient ≥ 2 months because bacteremia does not alter management
 - Inflammatory markers: White blood cell (WBC) count, C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and

procalcitonin (PCT) may all be elevated in UTIs but are not particularly helpful in predicting diagnosis or distinguishing between upper and lower tract disease.

- Serum creatinine: not necessary for routine UTI but should be obtained in patients with recurrent disease or renal anomalies

ALERT

Pitfalls

- 10–25% of infants will have a negative urinalysis despite culture- or nuclear scan–documented UTI, so a culture should always be obtained in this population.
- Conversely, there are very high rates of asymptomatic bacteriuria in the pediatric population, so a mildly positive urinalysis should be weighed in the context of the pretest probability for UTI.
- Failure to culture by sterile means: leads to a contaminated culture that is difficult to interpret
- Failure to screen a young child with another possible source of fever; children with otitis media, upper respiratory infections, and gastroenteritis can have a concurrent UTI.

Imaging

- There is controversy surrounding indications for imaging in routine febrile UTIs. UTI without fever does not require radiologic evaluation.
- Ultrasound (US): identifies hydronephrosis, congenital anomalies, and abscesses. Not good at detecting scars or VUR:
 - Recommended by the American Academy of Pediatrics (AAP) clinical practice guideline for febrile children 2–24 months of age with first UTI; however, use of US in females with first febrile UTI has been questioned.
 - Normal prenatal US beyond 32 weeks' gestation substantially reduces the likelihood of an abnormal US.
- Voiding cystourethrogram (VCUG): test of choice to detect and characterize VUR
 - No longer routinely recommended by the AAP after first febrile UTI
 - Indicated for young children with recurrent febrile UTIs or an

abnormal renal US

- In addition to the children covered by the AAP parameter, consider imaging for UTIs in boys, children with recurrent infections, and children with persistent voiding dysfunction, urinary abnormalities, poor growth, hypertension, or concerning family history.
- Renal cortical scan: detects acute pyelonephritis and renal scarring. Unclear use in clinical setting; consider in febrile children if diagnosis is unclear.

DIFFERENTIAL DIAGNOSIS

- True UTI can easily be confused with asymptomatic bacteriuria.
- The differential diagnosis of isolated or prolonged fever is very broad.
- Infants: gastroenteritis, occult bacteremia, occult pneumonia, meningitis, viral syndrome
- Older children and adolescents
 - Common: vaginal foreign body, vulvovaginitis/urethritis, epididymitis, gastroenteritis, sexually transmitted infection, pelvic inflammatory disease
 - Less common: excessive drinking, urinary calculi, diabetes mellitus or insipidus, appendicitis, Kawasaki disease, tubo-ovarian abscess, ovarian torsion, group A streptococcal infection
 - Rare: mass adjacent to bladder, spinal cord process (tumor, abscess), hypercalcemia

TREATMENT

MEDICATION

First Line

- Empiric antibiotic therapy should be initiated in febrile children with suspected UTI in order to prevent scarring.
- E. coli is the most common pathogen associated with first UTI; it is typically sensitive to multiple antimicrobials.
- Gram staining, when available, can help guide empiric therapy as can local patterns of susceptibility.
- Empiric inpatient therapy: IV therapy with a 3rd-generation

cephalosporin such as cefotaxime (120 mg/kg/day divided t.i.d.) or ceftriaxone (75 mg/kg/day) or the combination of ampicillin (100 mg/kg/day divided q.i.d.) and gentamicin (7.5 mg/kg/day divided t.i.d.)

- High-risk patients who are immunocompromised, have indwelling catheters, or have recurrent UTIs should initially receive broad-spectrum antibiotics that cover the organisms involved in prior infections.
- Empiric outpatient therapy: Options include cefixime (8 mg/kg/day once daily), cefdinir (14 mg/kg once daily), amoxicillin-clavulanate (45 mg/kg of amoxicillin component per day divided b.i.d.), co-trimoxazole (6–12 mg TMP/kg/day divided b.i.d.), or cephalexin (50–100 mg/kg/day divided q6–8h).
 - Many communities have high rates of resistance to amoxicillin and co-trimoxazole; resistance to amoxicillin-clavulanate and cephalexin is also on the rise.
- Antibiotic duration (IV/oral)
 - Children ≤ 2 years of age with a febrile UTI, UTI, or urinary tract abnormalities should receive a total of 7–14 days of antibiotic therapy.
 - Older children without fever or significant history likely have an uncomplicated cystitis are eligible for a short course of antibiotics (5–7 days).
- Antibiotic prophylaxis after UTI
 - Benefit somewhat unclear; AAP no longer recommends prophylactic antibiotics after first febrile UTI
 - Consider prophylaxis for patients with high-grade VUR in consultation with an urologist.

INPATIENT CONSIDERATIONS

ADMISSION CRITERIA

- The majority of patients with UTI can receive outpatient therapy with close follow-up.
- Consider hospitalization for young infants (consider hospitalization under 6 months, hospitalize under 2 months).
 - Ill patients with concern for development of urosepsis

- Complex or immunocompromised host
- Concern for dehydration or inability to tolerate medications
- Social concerns, lack of follow-up
- Failed outpatient management

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Consider a repeat urine culture after 2 days of therapy if the patient is not improving on an appropriate antibiotic regimen.
- Such patients should also receive imaging.
- Urinalysis and urine culture for subsequent febrile illnesses

PROGNOSIS

Prompt treatment of febrile UTIs reduces the risk for scarring and its sequelae. These children generally have a very good prognosis.

COMPLICATIONS

- Repeated febrile UTIs in young children may lead to renal scarring.
- Renal scarring in childhood carries a risk of hypertension, preeclampsia, and end-stage renal disease as an adult.

CODES

ICD10

- N39.0 Urinary tract infection, site not specified
- N12 Tubulo-interstitial nephritis, not spcf as acute or chronic
- N30.90 Cystitis, unspecified without hematuria

FAQ

- Q: Which children should have a radiologic evaluation after a UTI?
- A: Boys. Febrile children younger than age 2 years, and anyone with recurrent febrile UTIs, hypertension, or family history of urinary tract abnormalities.
- Q: Does a urine culture need to be done if the catheterized dipstick or urinalysis is negative?
- A: >10% of febrile infants with pyelonephritis will have a false-negative screening test (dipstick, urinalysis). A sterile urine culture should be done in these young patients.

UROLITHIASIS

Kara N. Saperston • Michael DiSandro

BASICS

DESCRIPTION

- Urolithiasis is the occurrence of calculi (stones) within the urinary tract, including the kidney, ureter, or bladder.
- Stones may be composed of calcium oxalate, calcium phosphate, uric acid, cystine, magnesium ammonium phosphate, xanthine, indinavir, and triamterene.

EPIDEMIOLOGY

The incidence of stones in children of both sexes has increased over the last 25 years.

RISK FACTORS

- Poor fluid intake
- Immobility
- Urinary tract obstruction
- Urinary tract infection (*Proteus mirabilis* or *Escherichia coli*)
- Bladder augmentation
- Dumping syndrome
- In children, 50% have a metabolic syndrome associated with urolithiasis.
- 75% have a metabolic predisposition to forming stones.

PATHOPHYSIOLOGY

- The urine contains multiple solutes; some help prevent crystallization and some contribute to crystal formation.
- The likelihood of a solute crystalizing varies with the pH of the urine (e.g., uric acid crystal formation is more likely at lower pH).
- When enough crystals form in the urine and urine flow out of the kidney is slow or obstructed
- Crystals then coalesce into a small nidus upon which more crystals will

form. This process then leads to stone formation.

COMMONLY ASSOCIATED CONDITIONS

Children who present with urolithiasis younger than age 6 years are more likely to develop hypertension (HTN) and diabetes mellitus (DM) later in life.

DIAGNOSIS

HISTORY

- Sudden or gradual onset of flank pain
- Location of stone is guided by the pain.
 - Midabdominal or suprapubic pain may indicate ureteral location of stone.
 - Testicular or labial pain indicates the stone is near the ureteral orifice.
 - Younger children are more likely to have nonspecific and/or nonlocalized pain.
- Nausea and/or vomiting
- Vague midabdominal pain
- Gross or microscopic hematuria is seen in only 50% of patients.
- Urinary tract infection (UTI) or fever
- Recent furosemide exposure
- Immobilization (postsurgical, wheelchair use)

PHYSICAL EXAM

- +/- Costovertebral angle (CVA) tenderness
- Abdominal tenderness, without rebound tenderness. Patient will have peritonitis only if a stone is accompanied by severe pyelonephritis.
- +/- Restless and unable to find a comfortable position
- +/- Blood in the urine

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urinalysis and urine culture
- 24-hour urine collection for calcium, citrate, creatinine, magnesium,

oxalate, pH, phosphate, and uric acid

- Basic metabolic panel including calcium, phosphorus, and uric acid
- If hypercalcuria, then obtain vitamin D and PTH levels.
- CBC: if infection suspected

Imaging

- Renal ultrasound: limited ability to visualize ureteral stones
- Plain abdominal radiograph
- CT scan of abdomen and pelvis, only if absolutely necessary
 - Remember radiation ALARA goal (as low as reasonably achievable).

DIFFERENTIAL DIAGNOSIS

- UTI, upper or lower tract
- Appendicitis
- Gastroenteritis
- Congenital ureteropelvic junction (UPJ) obstruction
- Henoch-Schönlein purpura
- Tumor
- Papillary necrosis
- Trauma
- Renal artery/vein thrombosis
- Nutcracker phenomenon

ALERT

A stone causing urinary obstruction with an associated urinary tract infection is high risk and a surgical emergency.

TREATMENT

MEDICATION

- Fluid
- Watchful waiting
- Consider expulsion therapy.
 - Alpha-blockers: Flomax (may cause headache and hypotension) (not FDA approved)

ADDITIONAL THERAPIES

- Surgical removal
 - Ureteroscopy
 - Extracorporeal shock wave lithotripsy (ESWL)
 - Percutaneous nephrolithotomy (PCNL)

GENERAL MEASURES

- After diagnosis, referral to pediatric urology for surgical management and to pediatric urology or pediatric nephrology for complete metabolic evaluation and treatment
- Stones <3 mm may pass without surgical intervention.
- Regardless of the size, further metabolic evaluation by a specialist should occur.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- All stones passed should be sent for chemical analysis.
- Increase fluid intake: Urine should be clear.
- Avoid vitamin D and C supplementation until metabolic workup is complete.
- Avoid high cranberry intake.
- Minimize sodium intake and reduce animal protein intake.
- Targeted reduction of specific foods such as oxalate-containing foods if with hyperoxaluria

PROGNOSIS

- 1/2–1/3 of children with metabolic abnormality will form another stone.
- Severe hyperoxaluria is associated with primary hyperoxaluria that can cause early renal failure and may require kidney transplant to correct renal failure and simultaneous liver transplant to correct the hereditary metabolic defect.
- Cystinuria: Treatment with Thiola and D-penicillamine can be associated with myelosuppression.

CODES

ICD10

- N20.9 Urinary calculus unspecified
- N20.0 Calculus of kidney
- N20.1 Calculus of ureter

FAQ

- Q: When should a child with a stone be admitted for management?
- A: If the stone has obstructed a solitary kidney, if the child has an elevated white blood cell count or UTI in the setting of obstruction, and if the child is immunocompromised and shows signs of a UTI.

URTICARIA

Christopher P. Raab

BASICS

DESCRIPTION

- Urticarial lesions are best described as raised, pruritic, circumscribed erythematous papules.
 - Single lesions may coalesce as they enlarge, forming generalized, raised, erythematous areas.
 - Transient, typically lasting several hours
 - Also known as “hives” or “nettle rash”
 - Acute: <6 weeks’ duration
 - Chronic: >6 weeks’ duration
- Other similar but non-urticarial entities:
 - Angioedema
 - Urticarial-like lesions
 - Form in the deep dermal, subcutaneous, and submucosal layers
 - Anaphylaxis
 - Hypersensitivity reaction after exposure to an antigen
 - Producing respiratory compromise secondary to airway edema, urticarial rash, pruritus, and hypotension; can lead to shock

EPIDEMIOLOGY

- Female-to-male ratio of 3:2
- No variation in race

Incidence

Lifetime incidence of 15–25%

GENERAL PREVENTION

When a trigger is identified, avoidance is the main preventive measure.

PATHOPHYSIOLOGY

- Immune mediated
 - Antigen is cross-linked to IgE on a mast cell.

- This causes mast cell activation, leading to the release of vasoactive mediators, such as histamine, leukotrienes, prostaglandin D2, platelet-activating factor, and other vasoactive mediators.
- These vasoactive mediators cause pruritus, vasodilatation, and capillary leak, which lead to the characteristic findings.
- Common triggers include some medications such as penicillins, foods such as milk or eggs, and envenomations.
- Non-immune mediated
 - Degranulation of mast cells secondary to other non-IgE reactions such as physical changes, chemicals, some medications such as beta-lactams and sulfa-containing drugs, and some foods
- Autoimmune mediated
 - Degranulation of mast cells caused by cross-linking of IgE by IgG or IgG binding to the high-affinity IgE (FcεRI) receptor on mast cells

ETIOLOGY

Acute urticaria

- Viral infections are thought to make up ~80% of all cases of acute urticaria in children. Most commonly isolated causes include the following viruses:
 - Epstein-Barr
 - Coxsackievirus A and B
 - Hepatitis A, B, and C
- Parasitic infections
- Bacterial infections (especially group A strep)
- Medications: most frequently reported include the following:
 - NSAIDs
 - Opiates
 - Vancomycin
- Radiocontrast
- Foods
- Transfusion of blood products
- Food additives and dyes
- Natural remedies including cranberry, feverfew, glucosamine, and ginger

- Insect venom including bees, wasps, hornets

Chronic urticaria

- Idiopathic: Most have an unknown cause, but many feel that an association with an autoimmune mechanism is likely.
- Physical (~20–30%)
 - Dermatographism (9%): Stroking of skin using mild to moderate pressure with fingernail or hard object causes linear urticaria at site of contact.
 - Cholinergic (5%): diffuse erythema and elevated but pale urticarial lesions; intense pruritus; associated with sweating reflex, so often associated with overheating or exertion; may be worsened in combination with other triggers in specific combinations
 - Cold (3%): Urticarial lesions present at areas of skin exposed to low temperatures; familial and nonhereditary forms
 - Aquagenic: Urticarial lesions arise when the patient is exposed to water (e.g., bathtub, swimming pool).
 - Delayed pressure/vibratory: Deep or prolonged pressure on skin produces significant urticaria and often angioedema. Vibratory urticaria is a form of delayed pressure urticaria caused by repetitive vibration (e.g., use of a jackhammer).
- Mast cell disease
 - Urticaria pigmentosa: excessive number of mast cells in skin, bone marrow, lymph nodes, and other tissues; flares characterized by pruritus, flushing, tachycardia, nausea, and vomiting
 - Systemic mastocytosis
- Systemic disease
 - Rheumatologic
 - Urticarial vasculitis: erythematous wheals that resemble urticaria but histologically appear as leukocytoclastic vasculitis; often presents with systemic symptoms and lasts >24 hours
 - Cryopyrin-associated periodic syndromes can present with urticaria, such as Muckle-Wells syndrome: chronic recurrent urticaria, deafness, amyloidosis, and arthritis.
 - Neoplasms
 - Infections: parasites especially noted to cause chronic urticaria

- Autoimmune: antibodies to IgE or IgE receptor (FcεRI)

DIAGNOSIS

HISTORY

- Description of rash: Lesions may not be present at time of exam due to transient nature. Digital photos are often useful.
- Duration of symptoms, acute versus chronic:
 - If acute (<6 weeks), ask about
 - Viral symptoms including rhinorrhea, cough, fever, congestion, malaise
 - Any medications (prescription or over the counter) or any herbal remedies
 - Any new foods or beverages
 - Any new exposures to perfumes, chemicals, or other skin products
 - If chronic (>6 weeks)
 - History of previous episodes including timing, exposures, any past history of urticaria or angioedema
 - Other symptoms or variations in presentation
 - Symptoms of systemic diseases, such as hyperthyroidism, systemic lupus erythematosus (SLE), juvenile idiopathic arthritis, myositis, amyloidosis, infections, and lymphoma
 - Duration of lesions

PHYSICAL EXAM

- Appearance of rash: classic wheal and flare appearance
- Respiratory: Look for evidence of stridor, wheezing, or dyspnea. If present, be concerned for airway compromise or lower airway edema from an anaphylactic reaction.
- Facial or neck swelling: concern for possible airway compromise
- A full physical exam should be performed to look for signs of systemic disease or malignancy, such as
 - Upper respiratory tract infections
 - Thyromegaly

- Lymphadenopathy or splenomegaly to suggest lymphoma
- Joint examination for any evidence of connective tissue disease, arthritis, or SLE

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Testing is often fruitless unless indicated by history and physical examination.
- Skin testing may be performed if the causative agent is thought to be 1 of several food items.
- If symptoms are difficult to handle or persist >3 months, consider
 - CBC with differential
 - ESR
 - Thyroid studies (thyroid-stimulating hormone [TSH], free T₄, antithyroglobulin, and antiperoxisomal antibody)
- If symptoms are atypical, last >1 year, or are suggestive of urticarial vasculitis
 - Complement studies
 - ANA titer
 - Liver function tests
 - Skin punch biopsy

DIFFERENTIAL DIAGNOSIS

- Viral exanthema
- Atopic dermatitis
- Contact dermatitis
- Insect bites
- Maculopapular drug rash
- Erythema multiforme
- Plant-induced eruptions
- Henoch-Schönlein purpura
- SLE
- Autoinflammatory disease
 - Systemic onset juvenile idiopathic arthritis
 - Cryopyrin-associated periodic syndromes: familial cold autoinflammatory syndrome, Muckle-Wells syndrome, neonatal

onset multisystem inflammatory disease (NOMID)

- Mevalonate kinase deficiency
- Tumor necrosis factor-receptor–associated periodic syndrome (TRAPS)

TREATMENT

Emergent treatment: If with any difficulty breathing, stridor or wheezing, or other signs of anaphylaxis, give epinephrine 0.01 mL/kg of the 1:1,000 solution SC/IM.

MEDICATION

- Acute urticaria
 - Usually self-resolving but can treat with 2nd-generation nonsedating antihistamines
 - 1st-generation antihistamines: diphenhydramine 1 mg/kg/dose or total 5 mg/kg/d divided PO q6h or hydroxyzine 2 mg/kg/day PO divided q6h for pruritus
- Chronic urticaria: See below.

First Line

- Antihistamines/H₁ antagonists:
- Less sedating, longer acting, and should be mainstay of therapy
 - Cetirizine (Zyrtec): Dosing varies by age from 2.5 to 10 mg daily.
 - Loratadine (Claritin): 5 mg daily
- Fexofenadine (Allegra): 6 months to <2 years of age, 15 mg twice daily; 2–11 years of age, 30 mg twice daily; and >12 years of age, 60 mg twice daily. 1st-generation antihistamines are effective but more sedating:
 - Diphenhydramine (Benadryl): 5 mg/kg/day divided q6h
 - Hydroxyzine (Atarax): 0.5 mg/kg/dose q6h
 - Cyproheptadine (Periactin): 2 mg up to 3 times a day: primary treatment for cold urticaria

Second Line

Increase 2nd-generation H₁ antagonist dose to maximum for age. In adult

guidelines, increasing the dose up to 4-fold is more effective.

Third Line

- Addition of a second nonsedating 2nd-generation H₁ antihistamine
- Leukotriene inhibitors: minimal additive response noted in clinical studies
 - Montelukast (Singulair): 5 mg daily
- Combined H₁ and H₂ antagonists
 - H₂ antagonists: added as 2nd agent because skin cells have both H₁ and H₂ receptors and a synergistic effect can be achieved by addition of an H₂ blocker
 - Ranitidine (Zantac): 2–4 mg/kg/day divided twice daily
- Doxepin (Sinequan): a tricyclic antidepressant. >12 years of age, 10–50 mg/day and can slowly titrate up to 100 mg/day; potent antihistamine but poorly tolerated due to sedation, hypotension, anticholinergic side effects, and massive weight gain
- Other immune-modifying agents used in chronic urticaria:
 - Other nonstandard therapies have been tried in small case studies: cyclosporine, colchicine, dapsone, IV immunoglobulin (IVIG), plasmapheresis, methotrexate, cyclophosphamide, calcium channel blockers, ephedrine
 - Corticosteroids: Titer to lowest effective dose. Start with standard dose of 0.5–1 mg/kg/day of prednisone; often poorly tolerated secondary to substantial side effects including hypertension, immunosuppression, hyperglycemia, physical changes
 - Omalizumab: Anti-IgE antibody has been shown to reduce signs and symptoms of chronic urticaria in those at maximum standard therapies.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Watch for signs and symptoms of anaphylaxis; this is the major complication.

- Patients with chronic urticaria should follow up with their physician on a regular basis to monitor symptoms and response to therapies.

PROGNOSIS

- Chronic urticaria
- Resolution in 50% by 12 months
- Another 20% resolve by 5 years
- 10–20% >20 years; many of those who continue to have symptoms are felt to have an autoimmune etiology.
- May have recurrences; physical urticaria subtypes are more likely to recur.

COMPLICATIONS

Anaphylaxis with resulting edema of the upper airway is the major life-threatening complication. The patient should seek immediate medical attention.

CODES

ICD10

- L50.9 Urticaria, unspecified
- L50.0 Allergic urticaria
- L50.6 Contact urticaria

FAQ

- Q: When should I refer patients to a specialist, and to what specialty should I send them?
- A: Often, referral is made when a trigger cannot be identified, if it is felt to be a food or medication trigger, and/or the symptoms persist for >6 weeks. Refer to a dermatologist or allergist–immunologist experienced in the evaluation and workup of urticaria.
- Q: When should treatment with corticosteroids or other nonstandard therapies be used to treat chronic urticaria?
- A: Typically, these medications carry significant side effects and should be reserved for those patients in whom the urticaria is causing significant alterations in activities of daily living.
- Q: When does a patient need to be hospitalized or observed during an episode of urticaria?
- A: Concerning signs include extensive angioedema, respiratory symptoms such as stridor or wheezing, or nausea/vomiting. Symptoms of anaphylaxis should be treated with epinephrine and the patient observed for several hours to ensure that symptoms do not recur.

VACCINE ADVERSE EVENTS

Kristen A. Feemster

BASICS

ALERT

Adverse events after immunization may be a true vaccine-associated event or may be a coincidental event that would happen without immunization. Epidemiologic studies are important to establish causation.

DESCRIPTION

- A clinically significant event that occurs after administration of a vaccine and has been causally related to the vaccine
- All suspected adverse events should be reported; however, reporting does not imply causation.
- Contraindication to immunization: condition that increases risk of a serious adverse reaction
- Precaution for immunization: condition that might increase risk of an adverse event or may decrease effectiveness of vaccine to mount an immune response
 - Usually a temporary condition
 - Immunization indicated with a precaution if benefits outweigh risk

EPIDEMIOLOGY

- Adverse events monitored prelicensure to establish safety and postlicensure to identify rare adverse events that would not be detected in prelicensure studies. Reporting is guided by the following:
 - National Childhood Vaccine Injury Compensation Program
 - Established by National Childhood Vaccine Injury Act of 1986 to establish a no-fault mechanism to manage claims of vaccine injury outside of the civil law system and provide compensation
 - Petitioners can file claims based on the Vaccine Injury Table (see “[Patient Education](#)”) created by the program or can attempt to prove causation for an injury that is not listed.
 - Program also mandates reporting of adverse events by health care

- professionals and creation of vaccine information materials.
- Vaccine Adverse Event Reporting System (VAERS)
 - Passive surveillance system to monitor all vaccines licensed in the United States
 - All reports reviewed by FDA medical officers.
 - Can detect possible unrecognized adverse events but limited ability to determine true causal relationships
 - Reporting to VAERS mandated by the National Childhood Vaccine Injury Compensation Program
- Vaccine Safety Datalink
 - Active surveillance system formed by CDC in partnership with managed care organizations covering 9 million people
 - Can perform better observational studies to help determine causation
- Clinical Immunization Safety Assessment (CISA) Network
 - Network of 7 academic centers established by CDC in 2001 to develop research protocols to diagnose, evaluate, and manage adverse events
 - Develops evidence-based guidelines for immunizing people at risk for serious adverse events after vaccination

Incidence

- Difficult to measure incidence owing to current reporting systems for adverse events
- There are ~30,000 reports each year to VAERS.
 - 13% considered serious adverse events.
- As of July 2013, ~15,000 claims filed under the National Childhood Vaccine Injury Compensation Act since 1988, and ~3,400 families compensated.

DIAGNOSIS

HISTORY

- Common mild adverse events after vaccination include the following:
 - Fever

- Local erythema, swelling, and/or tenderness
- Sleepiness and decreased appetite
- Increased fussiness
- Mild rash: occurs in 1 of 25 people up to 1 month after varicella vaccination
- Moderate to serious adverse events to currently recommended vaccines are rare but include the following:
 - Syncope, particularly among adolescents
 - Febrile seizures (MMR, varicella, and DTaP vaccines)
 - Temporary joint pain or stiffness (MMR)
 - Temporary thrombocytopenia (MMR)
 - High fever
 - Shoulder injury related to vaccination
- To minimize the possibility of vaccine adverse events and to maximize the effectiveness of vaccination, the following contraindications and precautions should be followed.

DIFFERENTIAL DIAGNOSIS

Allergic reaction to an unrelated exposure

Intercurrent illness

ONGOING CARE

APPROACH

- Before vaccination
 - Discuss benefits and potential adverse events so that families know what to expect.
 - Actively review vaccine information sheets.
 - Solicit concerns so that they can be addressed.

General **contraindications** for vaccination include the following:

- History of an **anaphylactic** reaction to a vaccine component
 - History of egg allergy no longer contraindication to influenza vaccination unless documented history of anaphylaxis.
- Pregnancy for **live virus vaccines** unless mother is at high risk for the vaccine-preventable condition

- Primary T-cell immunodeficiencies (i.e., severe combined immunodeficiency)
 - No live vaccines
 - Inactivated vaccines can be safely administered but may not generate an adequate immune response.
- Primary B-cell immunodeficiencies
 - If severe (i.e., X-linked agammaglobulinemia), no live bacterial vaccines, live-attenuated influenza vaccine (LAIV), or yellow fever vaccine
 - Less severe antibody deficiencies can receive live vaccines except for OPV.
- Phagocyte dysfunction
 - No live bacterial vaccines
 - All live virus and inactivated vaccines probably safe and effective
- Secondary immunosuppression (transplant, malignancy, autoimmune disease)
 - No live vaccines depending on degree of immunosuppression
 - Can achieve adequate response to vaccination within 3 months to 1 year after stopping immunosuppressive therapy
- HIV/AIDS
 - Can give MMR and varicella vaccine unless severely immunocompromised
 - No OPV or LAIV
- High-dose corticosteroids >14 days
 - No live virus vaccines until therapy discontinued for at least 1 month
- Vaccine-specific contraindications
 - DTaP/Tdap:
 - Encephalopathy within 7 days of previous DTP, DTaP, or Tdap dose not attributable to another cause
 - Rotavirus
 - Severe combined immunodeficiency
 - Previous history of intussusception
 - Hib conjugate vaccine should not be given to infants <6 weeks of age.

- LAIV: Advisory Committee on Immunization Practices (ACIP) recommends against use in multiple groups (please see “[Influenza](#)” chapter).

General **precautions** for receiving a vaccine include moderate to severe acute illness with or without fever. Vaccine-specific **precautions** include the following:

- DTaP/DTP
 - Fever $\geq 104^{\circ}\text{F}$ or shock-like state within 48 hours of previous DTaP/DTP dose
 - Persistent, inconsolable crying >3 hours within 48 hours of previous DTaP/DTP dose
 - Seizure within 3 days of previous DTaP/DTP dose
- Any tetanus toxoid–containing vaccine
 - Guillain-Barré within 6 weeks of a previous tetanus toxoid–containing vaccine dose
 - Progressive neurologic disorder (infantile spasms, poorly controlled epilepsy)
 - Children with stable neurologic conditions can be vaccinated.
 - History of Arthus hypersensitivity reaction after previous tetanus toxoid–containing dose
 - Wait 10 years between doses of tetanus toxoid–containing vaccines.
- Hepatitis B
 - Infants $<2,000$ g in weight
- Hepatitis A, IPV, and HPV vaccines
 - Pregnancy
- Inactivated influenza and LAIV
 - Guillain-Barré within 6 weeks of a previous tetanus toxoid–containing vaccine dose
 - LAIV only: antiviral receipt within 48 hours of vaccination (avoid antivirals for 14 days)
- Varicella
 - Receipt of antibody-containing blood product within past 11 months
 - Immunocompromised household contacts are not a contraindication or precaution, but if rash develops 7–25 days after vaccination,

- should avoid direct contact with immunocompromised individual.
- Antiviral receipt within 24 hours of vaccination (avoid antivirals for 14 days)
 - MMR
 - Receipt of antibody-containing blood product within past 11 months
 - History of thrombocytopenic purpura
 - Need for tuberculin skin test
 - Rotavirus
 - Immunosuppression
 - Receipt of antibody-containing blood product within 6 weeks
 - Chronic gastrointestinal disease
 - Previous history of intussusception
 - The following are NOT precautions or contraindications to vaccine receipt:
 - Mild or recent illness
 - History of a mild to moderate local reaction to a vaccine
 - Concurrent antimicrobial therapy
 - Recent exposure to an infectious disease
 - Breastfeeding
 - History of other nonvaccine allergies
 - Stable neurologic conditions (e.g., cerebral palsy, developmental delay)

MANAGEMENT

- If a patient presents with a potential adverse event:
 - Take thorough history and perform exam to characterize symptoms and determine timing of symptom onset.
 - Evaluate for other potential causes of symptoms.
 - Determine likelihood of causality.
 - Report all adverse events to VAERS.
 - If the family would like to file a claim, refer to National Childhood Vaccine Injury Compensation Program.
- Addressing safety concerns
 - >10% of parents delay or refuse certain vaccines for their children.
 - Growing prevalence of misinformation about vaccines challenge provider–parent communication.

- Despite increasing vaccine safety concerns, health care professionals are one of the most trusted sources of information regarding vaccines.
- Provide tailored information emphasizing benefits of vaccination and potential consequences of not accepting vaccination.
- Apply principles of risk communication.
- Actively solicit concerns before vaccination.
- If parents have specific concerns, refer to additional sources for reliable and accurate information (see references in “[Patient Education](#)”).
- Document vaccine discussions.
- Reporting adverse events
 - VAERS is the primary reporting site for suspected adverse events. Health care providers, vaccine recipients, or parents of vaccine recipients and vaccine manufacturers can all report.
 - Health care providers are required to report
 - Any adverse event listed by vaccine manufacturer as a contraindication for the receipt of additional doses of the vaccine
 - Any adverse event included on the VAERS reportable event table that occurred within the specified time period
- Vaccine Injury Compensation Program
 - Covers all vaccines recommended for routine administration for children by the ACIP
 - To qualify for compensation, must prove there was an injury listed in the Vaccine Injury Table that occurred within prescribed time period, prove that a vaccine caused an injury not listed on the Table, or prove that a vaccine aggravated a preexisting condition
 - Effects of injury must last >6 months after vaccination and result in hospitalization, surgery, or death.

- T80.52XA Anaphylactic reaction due to vaccination, initial encounter

FAQ

- Q: Many parents request spacing vaccines. Is there evidence that giving multiple vaccines at a time is too much for a child's immune system?
- A: Recommended vaccines have a very small amount of antigen compared to natural infection, and they activate a small proportion of immune system memory. Additionally, all vaccines given together have been tested when given at the same time to make sure they remain safe and effective.
- Q: What is the bottom line regarding autism and vaccines?
- A: Multiple studies including a recent Institute of Medicine (IOM) report have not shown any causal relationship between thimerosal-containing vaccines and autism or MMR and autism. Additionally, the U.S. court system through the Omnibus Autism Proceeding has recently ruled that there is insufficient evidence to show any causal relationship between thimerosal-containing vaccines or MMR and autism.

VAGINITIS

Sara M. Buckelew

BASICS

DESCRIPTION

- Vaginitis is inflammation or irritation of the vagina causing typical symptoms of vaginal discharge, burning, and itching.
 - May be due to infection such as trichomoniasis, candidiasis, or bacterial vaginosis (BV); see [Appendix, Table 7](#).
 - Noninfectious causes include foreign body or exposure to an irritant or allergen.
- Vulvovaginitis is irritation or inflammation of both the vulva and the vagina; most often due to *Candida albicans*
- In postpubertal females, BV is the most prevalent cause of vaginal discharge and typically causes a fishy odor.
- Physiologic leukorrhea (i.e., “physiologic discharge”) is usually associated with pubertal onset and frequently precedes menarche. It is typically thin, white, and mucoid.

EPIDEMIOLOGY

- Vaginitis affects females of all ages.
- In prepubescent girls, 25–75% of vaginitis is nonspecific in etiology.
- Approximately 75% of women have had at least one episode of vulvovaginitis due to candida in their lifetime.
- The most common causes of postpubertal vaginitis are as follows:
 - BV (22–50%)
 - Vulvovaginal candidiasis (17–39%)
 - *Trichomonas vaginalis* (4–35%)

RISK FACTORS

- For prepubertal females, poor hygiene is a common risk factor.
- For BV: vaginal douching, smoking, intrauterine device usage, non-white race, prior pregnancy, unprotected sexual intercourse, usage of spermicide, homosexual relationships

- For trichomoniasis: multiple sexual partners, other sexually transmitted infections, lack of condom usage, smoking
- For vulvovaginal candidiasis: use of systemic antibiotics, uncontrolled diabetes mellitus, diet high in refined sugars
- Irritant risk factors often include soaps, tampons, topical products and medications, extreme cleansing, clothing, and douching.

PATHOPHYSIOLOGY

- In prepubescent female, with prepubertal hormones, the vagina has a neutral pH, atrophic mucosa, and a warm environment that easily allow for bacterial overgrowth.
- Physiologic leukorrhea
 - Estrogen levels; the volume of discharge varies with the menstrual cycle and is especially heavy at the time of ovulation.
- Candida vulvovaginitis
 - Use of antibiotics increases the occurrence of candidiasis by eliminating competitive organisms.
- BV
 - Caused by shift in vaginal flora
 - Normal Lactobacillus species decrease and overgrowth of bacteria, including Gardnerella vaginalis, Mycoplasma hominis, and anaerobes such as Prevotella and Mobiluncus species

ETIOLOGY

- All ages:
 - Chemical, irritant, allergy
 - Nonspecific vaginitis (may be associated with hygiene)
 - Foreign body or material such as rolled up toilet paper
 - Candidiasis associated with antibiotic use
 - Trauma, mechanical irritation
 - Sexual abuse
- More common in prepubertal females:
 - Group A β -hemolytic Streptococcus
 - Haemophilus influenzae
 - Shigella
 - Pinworms or scabies

- Congenital abnormalities
- More common in postpubertal females:
 - Physiologic leukorrhea (may cause discharge but not irritation)
 - BV
 - Trichomoniasis
 - STIs such as gonorrhea and chlamydia
 - Pubic lice

DIAGNOSIS

HISTORY

- For many adolescent girls, vaginal symptoms may be uncomfortable to talk about. Important to meet alone with an adolescent.
- Symptoms alone cannot distinguish between the different causes of vaginitis but can assist the clinician.
- Describe the discharge including color (white, green-yellow, gray?), consistency (frothy? thick?), amount, odor, and duration of symptoms.
- Is there pain? Pain with intercourse? Burning?
- Bladder symptoms: Is there dysuria? Frequency? Urgency?
- Is there itching? Is it worse at night? Is it present in other family members?
- Exposure to any new possible irritants (e.g., new soap, spermicides, douching)
- Anything that makes symptoms better or worse?
- Prior history of similar symptoms? Prior treatment for past vaginitis?
- Sexual history including number of partners, use of barrier methods, history of STI
- Any medications, such as systemic antibiotics
- STI risk factors
- Any chronic diseases such as diabetes or other immunocompromised conditions

PHYSICAL EXAM

- Vital signs, including height, weight, BMI, and temperature
- Inspect pubic hair for sexual maturity rating (tanner scores) and also

evidence of infection or irritation.

- External genital or vaginal evidence of erythema, excoriation, and discharge. In younger children, this can be done in the “frog-leg” position.
- Discharge should be sampled.
- Examination of other evidence for irritation or inflammation such as warts, injury, and ulceration
- Consistency, color of discharge
- If patient is sexually active, speculum exam may need to be performed to evaluate the cervix. “Strawberry cervix” can be a sign of inflammation seen in trichomoniasis.
- Bimanual exam also should be considered if symptoms suggest risk for pelvic inflammatory disease.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

In order to best evaluate etiology, a sample of discharge should be collected. The sample can be obtained by the clinician or by the patient typically using a cotton-tipped applicator.

- Odor/”whiff” or “amine” test:
 - Slide prepared with drop of 10% KOH
 - The examiner should whiff the slide for presence of a fishy odor suggestive of BV, also seen in trichomoniasis, negative in candida.
- Wet mount of the vaginal discharge mixed with saline for microscopy
 - This slide is examined for evidence of trichomonads, clue cells, and yeast.
 - Clue cells are vaginal epithelial cells with adherent coccobacilli seen on wet mount and when >20% of epithelial cells suggestive of BV.
- Wet mount with 10% KO
 - May demonstrate budding yeast (“spaghetti with meatballs” appearance) suggestive of candida
- Nitrazine paper
 - Measures pH of sample
 - Vaginal pH >5 seen in BV, >5.4 seen in trichomoniasis, <4.9 candidiasis

- Urinalysis may be helpful if patient complains of dysuria.
- STI testing as warranted based on risk factors. Chlamydia PCR can be obtained by cervical or vaginal swab or urine; gonorrhea PCR or culture (cervical or vaginal swab)
- Consider a pregnancy test as indicated.

DIFFERENTIAL DIAGNOSIS

- Physiologic leukorrhea
- Candidiasis
- BV
- Trichomonas
- Other STIs including chlamydia, gonorrhea, herpes simplex virus infection, HPV
- Skin conditions including psoriasis
- Lichen sclerosis (hypotrophic dystrophy of the vulva)
- Congenital abnormalities, such as ectopic ureter
- Sexual abuse
- Mechanical irritation from lack of lubrication, trauma
- Pinworm infection

TREATMENT

MEDICATION

- Medication management depends on the etiology.
- Vulvovaginal candidiasis
 - Topical antifungals such as clotrimazole, butoconazole, miconazole, or terconazole are available over the counter.
 - Oral fluconazole 6 mg/kg up to a maximum of 150 mg as a single dose can also be given.
 - Longer treatments may be necessary for recurrent or severe infections.
- BV
 - Antibiotics are treatment of choice.
 - Oral metronidazole 500 mg twice daily for 7 days or intravaginal metronidazole gel for 5 days or clindamycin cream (7 days) or

- suppository (100 mg ovules for 3 days)
- Higher rates of recurrence are seen with single-dose therapy for BV.
 - Relapse may require longer courses of treatment.
 - Trichomonas
 - Metronidazole 2 g orally in a single-dose
 - Sexual partners should be treated simultaneously if possible to avoid reinfection.
 - Chlamydia
 - Azithromycin 1 g orally for 1 dose or doxycycline 100 mg orally twice daily for 7 days
 - Gonorrhea
 - Ceftriaxone 125 mg intramuscular for one dose
 - PLUS azithromycin 1 g orally for 1 dose or doxycycline 100 mg orally twice daily for 7 days
 - HSV
 - For initial outbreak: acyclovir 400 mg orally 3 times daily for 7–10 days or 200 mg 5 times daily for 7–10 days; can use valacyclovir or famciclovir alternatively
 - Suppressive therapy for recurrent infections can use acyclovir, valacyclovir, or famciclovir.
 - Lichen sclerosus
 - Mild pruritus consider mild emollient
 - More severe symptoms consider topical steroids
 - Group A β -hemolytic Streptococcus and H. influenzae
 - Amoxicillin 40 mg/kg/day to max 500 mg divided twice daily for 7 days
 - Shigella
 - Trimethoprim/sulfamethoxazole
 - Pinworm infestations
 - Mebendazole 100 mg orally, repeat dosage 2 weeks later
 - Consider treatment of entire family

ADDITIONAL TREATMENT

General Measures

- Good hygiene and avoidance/removal of irritants includes hand

washing following toileting, encourage wiping from front to back, clean with a mild nonscented soaps or lotions, wear cotton underwear, and avoid bubble baths and douching.

- Warm bath/Sitz baths followed by air-drying
- Use of topical emollients, zinc creams, or topical low-potency steroids to assist with itching and/or inflammation

COMPLEMENTARY & ALTERNATIVE TREATMENTS

Probiotics may be helpful in preventing recurrence in BV and candida vulvovaginitis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- If symptoms persist following over the counter or other treatment, patients need to be reevaluated by a clinician as may be another etiology.
- Patients with an STI such as trichomonas, gonorrhea, or chlamydia should make certain that all sexual partners receive treatment in order to prevent reinfection.

ALERT

Patients taking metronidazole for trichomonas or BV should be told explicitly to avoid alcohol.

PATIENT EDUCATION

- In prepubescent females: Encourage good hygiene to prevent recurrence.
- In sexually active adolescents: Encourage regular condom usage. Consider discussion of contraceptive options.

PROGNOSIS

With treatment, vaginitis typically resolves quickly with no complications.

COMPLICATIONS

- BV is associated with premature labor and preterm birth, premature

rupture of membranes, and increased risk of acquiring STIs.

- Trichomonas
- Gonorrhea and chlamydial infections that are not treated can lead to pelvic inflammatory disease.

CODES

ICD10

- N76.0 Acute vaginitis
- N89.8 Other specified noninflammatory disorders of vagina
- B37.3 Candidiasis of vulva and vagina

FAQ

- Q: How do you diagnose BV?
- A: BV is a clinical diagnosis based on having 3 out of 4 Amsel Criteria:
 - Thin, homogenous discharge
 - Vaginal pH >4.5
 - Positive “whiff” test

- >20% clue cells on wet mount or Gram stain
- Q: Should sex partners of patients with vaginitis be treated?
- A: Depends on the etiology of the vaginitis. For BV and candida, there are no treatment recommendations for sex partners. For patients with trichomonas, partners should be treated, and to reduce recurrence, partners should avoid sexual intercourse until both have been treated and are asymptomatic.
- Q: In prepubescent females, is a positive culture definitive for infection?
- A: One common issue in prepubertal females is how to distinguish between normal vaginal flora and potential pathogens. Growth of normal pathogens even in girls who are symptomatic are not diagnostic.

VARICOCELE

Sophia D. Delpe • Adam B. Hittelman

BASICS

DESCRIPTION

A varicocele is an abnormal tortuosity and dilation of the testicular veins and the pampiniform venous plexus of the spermatic cord.

EPIDEMIOLOGY

Incidence

- Rare in prepubertal boys, increases with age to approximately 15% in late adolescence and healthy adult population
 - 2–10 years old, <1%
 - 11–14 years old, 7.8%
 - 15–19 years old, 14.1%
- Based on World Health Organization observational study (1992), 15–20% of adult varicocele patients have fertility problems.
 - Varicocele presents in 25% of men with abnormal semen analysis and 12% of men with normal semen parameters.
 - Present in 35–40% of males with primary infertility
- Left-sided predominance, 90%
- No racial predilection

RISK FACTORS

- Exact mechanisms have not been fully elucidated.
- May be related to physiologic changes in puberty, such as rapid testicular growth and increased testicular blood flow
- Associated with increased height and low body mass index
- Increased risk in 1st-degree relatives of patients with a varicocele

PATHOPHYSIOLOGY

- Association between varicocele and testicular dysfunction/fertility compromise
 - Impaired spermatogenesis: decreased motility, decreased density,

and increased number of pathologic sperm forms

- Ipsilateral testicular hypotrophy
 - Recent data demonstrates correlation between varicocele grade and testicular hypotrophy, although not observed in prior studies.
 - Testicular “catch-up growth” after varicocelectomy
 - Catch-up growth in 30–50% of patients managed conservatively
- Potential field defect, affecting growth of bilateral testicles
- Exact mechanisms not clearly elucidated—multiple theories:
 - Hyperthermia: Varicocele increases intratesticular temperature, likely by interfering with the pampiniform plexus’ ability to provide countercurrent cooling system.
 - Potential reflux of renal and adrenal metabolites, causing testicular damage
 - Increased production of nitric oxide and reactive oxygen species correlate with severity of varicocele.
 - Endocrine abnormalities are found in subset of patients with varicocele, including low testosterone, abnormal response to gonadotropin-releasing hormone (GnRH), and impaired Leydig cell function.

ETIOLOGY

- Associated with anatomy of left testicular vein
 - Inserts into renal vein at right angle (right testicular vein drains into vena cava)
 - Incompetent or absent valves
 - Left testicular vein 8–10 cm longer than right, with increased pressure
 - Increased venous pressure from “nutcracker phenomenon”: compression of left renal vein as it passes between aorta and superior mesenteric artery

DIAGNOSIS

HISTORY

- Often asymptomatic and incidentally noted on routine physical exam

- Infertility not common issue in adolescent population
- Associated pain/heaviness/dull ache in 2–11% of cases
- Laterality
- Age of onset
- When and how testicular abnormality first detected
- Change in size of varicocele with positioning or Valsalva
- Prior surgery or trauma
- Prior imaging

PHYSICAL EXAM

- Examine in warm room when patient is supine and standing.
- Palpate at rest and with Valsalva.
- Para- and supratesticular mass; feels like a “bag of worms”
- Assess size and consistency.
- Estimate testicular volume with orchidometer, calipers, or color Doppler ultrasound.
 - Right testicle serves as control for left.
 - >2 mL or >20% size discrepancy, right > left, is significant.
- Varicocele grade
 - Grade 1 (small): palpable only with Valsalva
 - Grade 2 (medium): easily palpable but not visible
 - Grade 3 (large): visible through scrotal skin
- Varicocele should decompress in supine position.
- Solitary right varicocele or failure of vessels to decompress in supine position raises concern for potential retroperitoneal or abdominal mass.

DIAGNOSTIC TESTS & INTERPRETATION

- Color Doppler scrotal ultrasound to diagnose varicocele and estimate testicular volume
- Semen analysis in age-appropriate patients
- GnRH simulation test leads to increased FSH and LH response.
 - Has not conclusively been shown to be good predictor of postsurgical improvement in adolescents

DIFFERENTIAL DIAGNOSIS

- Epididymal cyst/spermatocele
- Testicular mass

- Epididymal mass
- Paratesticular mass
- Inguinal hernia
- Hydrocele
- Cord lipoma

ALERT

Secondary varicocele, especially right-sided, can be a clinical indicator of retroperitoneal mass or venous obstruction. It is important to do physical exam standing and in supine position to assess for decompression of varicocele in supine position.

TREATMENT

- Treatment is not indicated in all children/adolescents with varicocele.
- Annual ultrasound assessment of testicular volume recommended.
 - Potential for interobserver variability for imaging
 - Spontaneous catch-up growth in some patients managed conservatively.
- 80–85% of men with varicocele do not exhibit effect on fertility.
- Definitive treatment is recommended for the following:
 - Size discrepancy between right and left testicle of >2 mL or 20%
 - Adolescents with abnormal semen analysis and high-grade varicocele
 - Adolescents with symptoms: pain, heaviness
 - Adolescents with bilateral varicocele
- Treatment options
 - Surgical ligation and division of testicular veins (laparoscopic vs. subinguinal approach)
 - Testicular artery- and lymphatic-sparing reduces risk of secondary hydrocele.
 - Intravenous embolization of testicular veins

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Persistence should be assessed by surveillance ultrasound 6 months after repair.
- Trans-scrotal US to assess for testicular catch-up growth
- Semen analysis to see if improvement in semen parameters

PROGNOSIS

After repair, recurrence can occur in 1–16% of patients (depending on surgical technique).

COMPLICATIONS

- Recurrent/persistent varicocele
- Secondary hydrocele
 - May require surgery if symptomatic
- Testicular hypotrophy/atrophy
- Persistent fertility compromise

FAQ

- Q: What are long-term benefits of surgical repair of varicoceles?
- A: If varicocele is corrected, testicular catch-up growth can occur when performed in adolescents, as well as decreased risk for infertility. In adult population, 2/3 of patients will have improvement in semen analysis, and 40% of their partners will become pregnant.
- Q: Is there benefit of surgical repair of varicocele after puberty? Will this improve fertility?
- A: Testicular hypotrophy does not improve after adult varicocelectomy. Although it appears to be a progressive process, studies have not clearly demonstrated clear benefit in fertility improvement if corrected in adolescence versus when fertility compromise is diagnosed.
- Q: What happens if a varicocele is left untreated?
- A: There is good evidence to show that when left untreated, a varicocele will continue to affect testicular growth with loss of volume and progressive deterioration in semen analysis.
- Q: What is the risk of recurrence after repair?
- A: Recurrence can occur in 1–16% of adolescents, depending on surgical technique.

VASCULAR BRAIN LESIONS (CONGENITAL)

Daphne M. Hasbani • Sabrina E. Smith

BASICS

DESCRIPTION

- Developmental venous anomalies (DVAs) are the most common vascular malformation of the brain, representing 60% of all central nervous system vascular malformations. Also known as venous angiomas, DVAs are made up of a cluster of venous radicles that drain into a collecting vein. They occur in 2.5–3% of the general population.
- DVAs are associated with cavernous malformations (see below) in 8–40% of cases, and 20% of patients with mucocutaneous venous malformations of the head and neck have DVAs. They are also associated with sinus pericranii, a communication between intracranial and extracranial venous drainage pathways in which blood may circulate bidirectionally.
- Cavernous malformations (CMs), also known as cavernous hemangiomas or cavernomas, are multilobulated, low-pressure, and slow-flow vascular structures filled with blood, thrombus, or both. They do not contain elastin or smooth muscle. There is no intervening brain tissue except at the periphery of the lesion.
- Arteriovenous malformations (AVMs) are abnormal clusters of vessels that connect arteries and veins without a true capillary bed and have intervening gliotic brain tissue.
- Vein of Galen malformations (VOGMs) are a specific type of congenital AVM that involves the vein of Galen, which flows into the straight sinus after draining the internal cerebral veins and basal veins.
- Sturge-Weber syndrome (SWS), also known as encephalotrigeminal angiomatosis, is characterized by leptomeningeal angiomatosis, facial port-wine stain (capillary malformation), and glaucoma. Some patients have all 3 findings, although others have just 1 or 2 features.

PATHOPHYSIOLOGY

- DVAs are an extreme variation of normal venous development.

Typically, venous drainage in the brain occurs through a superficial system and a deep system. DVAs result when a deep venous territory drains toward the surface or when a superficial territory drains to the deep venous system instead of draining in the expected direction. Intervening brain tissue is normal. The mechanism responsible for DVA formation is unknown.

- The pathogenesis of CMs is unknown, although the report of cases of new cavernoma development adjacent to a DVA suggests that DVAs may lead to CM formation. Most CMs occur sporadically, although familial syndromes exist. Several genes have been associated with familial CMs.
- The cause of AVM formation is unknown. A failure of normal capillary development with dysplastic vessels forming between primordial arteriovenous connections has been suggested.
- VOGMs are embryonic AVMs consisting of choroidal arteries draining into the precursor of the vein of Galen. They develop between weeks 6 and 11 of fetal life.
- SWS occurs sporadically in 1/40,000–50,000 births and is associated with a somatic mosaic mutation in guanine nucleotide-binding protein G(q) subunit alpha. The pathophysiology is thought to be venous dysplasia, in which the primordial venous plexus that is normally present at 5–8 weeks of gestation fails to regress. The location of this plexus around the cephalic end of the neural tube and under the ectoderm destined to form the facial skin accounts for the clinical features. Venous stasis occurs due to the absence of normal cortical venous structures, and hypoperfusion of brain tissue occurs. These findings are unilateral in the majority but can be bilateral in up to 20% of cases.

DIAGNOSIS

HISTORY

- DVAs are usually benign and asymptomatic, coming to clinical attention as an incidental finding on a neuroimaging study.
- Headache, seizure, and intracerebral hemorrhage are common in

patients with CMs and AVMs. Focal neurologic deficits may result from intracerebral hemorrhage or compression of underlying brain structures by the vascular malformation.

- 95% of newborns with VOGMs present with CHF. Others present with hydrocephalus, subarachnoid hemorrhage, intraventricular hemorrhage, or failure to thrive.
- Infants and older children usually present with hydrocephalus, headache, seizures, exercise-induced syncope, or subarachnoid hemorrhage.
- Facial port-wine stain, seizures, and glaucoma are common in SWS. Other neurologic symptoms include hemiparesis, developmental delay, mental retardation, and strokelike episodes presenting with hemiparesis and visual field defects.

PHYSICAL EXAM

- Physical exam is normal in children with DVAs and children with CMs or AVMs that have not ruptured. Focal neurologic deficits may persist following intracerebral hemorrhage associated with CMs or AVMs.
- In newborns with VOGMs, signs of congestive heart failure such as tachycardia, respiratory distress, and hepatomegaly may occur. A continuous cranial bruit heard may be heard over the posterior skull, and bounding carotid pulses and peripheral pulses may be present. Scalp veins may be dilated.
- Older infants and children with VOGMs also may present with CHF but more often demonstrate increased head circumference, focal neurologic signs, and failure to thrive. Proptosis may be noted.
- Children with SWS often have a facial port-wine stain, most often in the V1 distribution. Glaucoma is also common. Hemiparesis or seizures may develop.

DIAGNOSTIC TESTS & INTERPRETATION

Routine blood studies are usually normal. Chest x-ray studies and electrocardiogram may reveal typical changes of high-output CHF in patients with VOGMs.

Imaging

- Neuroimaging studies are required for definitive diagnosis.

- DVAs can be visualized on contrast-enhanced CT or MRI. Diagnosis is made by visualization of the typical “caput medusa” appearance of the radially arranged veins draining into a collecting vein, seen as a linear or curvilinear focus of enhancement. They can also be visualized with conventional angiography, although this is not required unless a patient presents with an acute hemorrhage.
- MRI is better than CT at demonstrating CMs, which have a mulberry appearance. On MRI, they are well-circumscribed lesions of mixed signal intensity on T1- and T2-weighted sequences. Contrast enhancement is variable. They are best seen on gradient-echo T2-weighted images or susceptibility-weighted images, which are sensitive to hemosiderin or deoxyhemoglobin.
- AVMs can be seen with CT/CTA, MR/MRA, and conventional angiography. Dynamic sequences are required to characterize the anatomy of feeding and draining vessels. Conventional angiography is the gold standard.
- VOGMs can be diagnosed on fetal ultrasound or MRI. In newborns, cranial ultrasound shows a large, hypoechoic structure in the region of the vein of Galen. CT shows a high-density mass that enhances with contrast. MRI shows an area of decreased signal intensity or signal void because of high flow within the malformation. CT and MRI also show areas of cerebral ischemia or hemorrhage. Conventional angiography is required before intervention.
- In SWS, CT may show calcifications or atrophy. Gadolinium-enhanced MRI is the most sensitive study, showing leptomeningeal enhancement due to pial angiomatosis. Initial CT and MRI are often normal in the newborn period, so follow-up imaging is required.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for headaches and seizures, common presenting symptoms of brain vascular malformations, is broad. CNS infection, vascular malformation, hydrocephalus, and mass lesion can result in both. Other causes of seizure include dysplasia and remote brain injury, both genetic and idiopathic. Other causes of headache include benign conditions such as migraine and tension headaches and structural abnormalities such as Chiari I malformations.

- VOGMs must be considered in any newborn with unexplained CHF (especially high-output failure), hydrocephalus, or intracranial hemorrhage. Other causes of high-output CHF in the newborn include anemia, hyperthyroidism, and other AVMs.
- Intracranial hemorrhage may result from AVMs, CMs, aneurysms, bleeding diatheses, hypertension, or trauma in neonates and children. In older children, sickle cell disease, vasculopathies including moyamoya syndrome and vasculitis also can lead to hemorrhage.

TREATMENT

GENERAL MEASURES

- DVAs do not typically require treatment.
- Anticonvulsants should be used to treat seizures.
- Surgical resection is the only treatment option for CMs, although conservative management may be indicated if the risk of surgery outweighs the potential benefit.
- Treatment options for AVMs include resection via microsurgery, embolization, stereotactic radiosurgery, and conservative management. Risk of hemorrhage ranges 0.9–34% per year, so decisions about treatment should be guided by symptoms at presentation and structural features of the AVM.
- Treatment of choice for VOGMs in all ages is endovascular embolization. Direct surgical intervention has unacceptable risks and is no longer recommended. Radiosurgery has been used in a small number of clinically stable older patients. Refractory CHF prompts intervention in neonates. Treatment in older infants and children is indicated to prevent cerebral ischemia (from arterial steal or from venous infarction) and to prevent hydrocephalus. Embolization can be completed in stages over a few months after CHF is controlled.
- Ventriculoperitoneal shunts may be required in patients who develop hydrocephalus following intracerebral hemorrhage related to CM or AVM or in patients with VOGMs.
- Treatment in SWS is targeted to symptoms, using anticonvulsants for seizures and eye drops or ocular shunts for glaucoma. Low-dose

aspirin is recommended at the time of diagnosis to prevent further brain injury due to impaired cerebral blood flow. Seizures can lead to ongoing brain injury by increasing metabolic demand in brain tissue that has abnormal perfusion at baseline, so aggressive seizure management is recommended. Some children with intractable epilepsy may be good candidates for epilepsy surgery.

ONGOING CARE

- Generally, no specific follow-up is required for patients with DVAs.
- Follow-up with a neurologist is indicated for patients with CMs, AVMs, VOGMs, and SWS.
- Neurosurgical consultation is indicated for patients with CMs, AVMs, and VOGMs.
- A follow-up CT or MRI is indicated to evaluate patients with new neurologic signs or symptoms.
- Ophthalmologic follow-up is indicated for patients with SWS and most patients with VOGMs, especially prior to treatment when hydrocephalus may develop.

PROGNOSIS

- Prognosis is excellent for patients with isolated DVAs.
- Prognosis for patients with CMs and AVMs depends on the size, location, presenting symptoms, and specific characteristics of the lesion. Patients who have experienced an intracerebral hemorrhage have worse prognosis than those who have not.
- For patients with VOGMs, earlier age of symptoms is associated with worse prognosis. Mortality in neonates with symptomatic lesions is 36%. In a recent meta-analysis of 337 patients treated with endovascular embolization between 2001 and 2010, 84% had a good or fair clinical outcome, and mortality was 16%.
- Prognosis in patients with SWS depends on the extent and location of involvement. Seizures occur in the majority (~85%), with low normal intelligence or mental retardation in ~35%.

COMPLICATIONS

- Death can occur in patients with intracerebral hemorrhage due to CMs or AVMs.
- Mortality approaches 100% in untreated patients with VOGMs.
- In severe case of VOGMs, 80% of cardiac output may be delivered to the head because of the low vascular resistance within the malformation. Cardiac ischemia may occur because of decreased coronary artery blood flow.
- Intracerebral hemorrhage may occur as a result of CMs, AVMs, and VOGMs or as a complication of treatment.
- Longer term complications from CMs, AVMs, and VOGMs include mental retardation, seizures, hydrocephalus, and chronic motor impairment.
- In patients with SWS, visual impairment can result if glaucoma is difficult to control. Persistent hemiparesis can develop.

PATIENT MONITORING

- Serial neuroimaging should be performed in patients with CMs, AVMs, and VOGMs to guide the timing of treatment and to assess for recurrence.
- Head circumference should be monitored in patients with VOGMs as a marker of hydrocephalus.

CODES

ICD10

- Q28.3 Other malformations of cerebral vessels
- Q85.8 Other phakomatoses, not elsewhere classified
- D18.02 Hemangioma of intracranial structures

FAQ

- Q: Can the AVM recur after treatment?
- A: AVMs have a propensity to recur. Imaging studies give a good indication of the likelihood of recurrence.
- Q: How does a vascular malformation cause seizures?
- A: Seizures can result from ischemia, hemorrhage, or acute hydrocephalus associated with the malformation.

VENTRICULAR SEPTAL DEFECT

Shabnam Peyvandi

BASICS

DESCRIPTION

- A ventricular septal defect (VSD) is an opening in the ventricular septum, resulting in a communication between the left ventricle (LV) and the right ventricle (RV). The ventricular septum can be divided into 4 major areas:
 - Inlet/canal septum
 - Membranous/conoventricular septum
 - Muscular septum (largest)
 - Conal/infundibular/outlet septum (includes conal septal hypoplasia and malalignment types)
- There are several corresponding types of VSDs that have different natural histories and associated problems:
 - Inlet/canal VSDs: usually part of an atrioventricular (AV) canal defect, 5–7% of all VSDs
 - Membranous/conoventricular VSDs: 80% of all VSDs by classic teaching; fewer than muscular VSDs by echo data
 - Muscular VSDs: usually single and small but can be multiple and of variable size; 5–20% of all VSDs by classic teaching, but a large percentage are inaudible
 - Conal septal hypoplasia VSDs: usually large and unrestrictive; associated with aortic valve (AoV) cusp prolapse and aortic insufficiency
 - Anterior malalignment VSDs: usually associated with RV outflow tract obstruction. Paradigms: tetralogy of Fallot, double outlet RV
 - Posterior malalignment VSDs: usually associated with LV outflow tract obstruction. Paradigms: subaortic stenosis with coarctation or interrupted aortic arch
- There may also be multiple VSDs of different types in a single patient. Many complex forms of congenital heart disease include a VSD.

EPIDEMIOLOGY

- VSDs are the most common form of congenital heart disease.
 - ~1.5–5.7 per 1,000 term births
 - ~4.5–7.0 per 1,000 preterm births, by classic teaching
- Echo data show a higher incidence of ~50 per 1,000 live births, mostly asymptomatic muscular VSDs.

RISK FACTORS

Genetics

- Sibling and offspring recurrence risk for VSDs is estimated to be ~3–4%.
- VSD is the most common lesion in trisomies 21, 13, and 18, but >95% of children with VSDs have normal chromosomes.

COMMONLY ASSOCIATED CONDITIONS

- Congenital heart disease that includes a conal septal malalignment VSD (e.g., tetralogy of Fallot) or VSD with a conotruncal malformation (e.g., truncus arteriosus or interrupted aortic arch type B) has a 13–50% incidence of microdeletion of chromosome 22 (22q11.2 deletion syndrome).
- In a recent series, 7% of patients with an isolated membranous/conoventricular VSD had a 22q11.2 deletion.

PATHOPHYSIOLOGY

- Both the size of the VSD and the ratio of pulmonary vascular resistance (PVR) to systemic vascular resistance (SVR) determine the direction and amount of shunting.
 - Small VSD: The VSD imposes high resistance to flow with a large LV-to-RV pressure gradient, usually resulting in normal RV pressures. The restrictive size results in a small left-to-right shunt. The VSD size is usually $\leq 1/4$ the size of the AoV annulus. The workload of the ventricles is normal.
 - Moderate VSD: The VSD imposes modest resistance to flow, usually resulting in mildly elevated RV pressures. The amount of shunting can still be large and is determined by the PVR/SVR ratio. The VSD size is usually $1/3$ – $2/3$ the size of the AoV annulus. The workload of the ventricles is increased.

- Large VSD: The VSD imposes no resistance to flow and is unrestrictive, resulting in systemic RV pressures and RV hypertension. The workload of the ventricles is markedly increased.
- The lower the PVR/SVR ratio, the greater the degree of left-to-right shunting. A large left-to-right shunt leads to pulmonary vascular congestion, tachypnea, tachycardia, and hepatomegaly, all signs of congestive heart failure (CHF). The amount of CHF correlates directly with shunt size and usually peaks at 6–8 weeks of age, timed with the nadir of PVR and physiologic anemia. Lack of significant CHF in patients with a large VSD signifies elevated PVR and requires careful evaluation. Cardiac catheterization may be required in these patients to provide additional data.
- If a large VSD is left untreated, pulmonary vascular obstructive disease will eventually develop, leading to reversal of the shunt, cyanosis, and RV failure (Eisenmenger syndrome).

DIAGNOSIS

HISTORY

- Small VSD: The child is usually asymptomatic, with normal growth and development. Most commonly, a murmur is detected at 1–6 weeks of age.
- Moderate VSD: The child is usually symptomatic with slow weight gain and sparing of longitudinal growth. There is often an increased incidence of respiratory infections. Sweating and fatigue with feeding may be present.
- Large VSD: The child is usually quite symptomatic, especially with a larger shunt, showing signs of CHF and marked failure to thrive.
- Children with Eisenmenger syndrome have cyanosis, fatigue, and symptoms of right heart failure.

PHYSICAL EXAM

- Small VSD
 - The child usually appears healthy with normal growth.
 - The heart action is quiet, but there is often an associated systolic

thrill along the left sternal border with a membranous VSD, in contrast to a small muscular VSD.

- Heart sounds are normal. A high-frequency, pansystolic murmur is present in membranous VSDs, whereas in muscular VSDs, the murmur is not pansystolic.
- The murmur is loudest over the region of the VSD.
- Moderate VSD
 - The child usually appears in mild distress with tachycardia and tachypnea.
 - The heart action is increased and there is often still an associated thrill.
 - The P_2 component of S_2 may be normal or accentuated.
 - A medium frequency, pansystolic murmur is present over the location of the VSD.
 - A mid-diastolic rumble is present over the mitral listening area (apex) as a result of a significant shunt and indicates $\geq 2:1$ pulmonary-to-systemic flow ratio. Hepatomegaly may be present.
- Large VSD
 - The child usually appears ill with marked distress and marked tachycardia and tachypnea, proportional to the size of the left-to-right shunt.
 - The heart action is markedly increased without a thrill. The P_2 component of S_2 is loud and narrowly split as a result of pulmonary hypertension.
 - A soft, low-frequency pansystolic murmur is present over the VSD.
 - The loudness of the mid-diastolic rumble is proportional to the size of the left-to-right shunt.
 - CHF physical exam signs are proportional to the size of the left-to-right shunt but are usually present to a significant degree.
- If significant aortic insufficiency develops, a high-frequency, early diastolic murmur is heard along the left sternal border.
- In newborns whose PVR has not yet fallen, the increased heart action remains the key to diagnosis, as auscultation may be unimpressive.
- Likewise, in children with elevated PVR, the increased heart action remains the key to diagnosis. Auscultation shows a narrowly split S_2

with a loud P₂. The murmur loudness depends on VSD size and shunt but often is soft or absent and unimpressive.

- Once Eisenmenger syndrome develops (secondary to pulmonary vascular obstructive changes), patients manifest cyanosis, clubbing, an increased RV impulse, a narrowly split S₂ with a loud P₂ component and a soft or absent VSD murmur. There may be a systolic murmur of tricuspid insufficiency at the left lower sternal border (LLSB), a high-frequency early diastolic murmur of pulmonary insufficiency, or an S₃ at the LLSB. There is usually associated jugular venous distention and hepatomegaly, indicating high right-sided filling pressures.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- ECG
 - Small VSD: normal
 - Moderate VSD: left ventricular hypertrophy (LVH)
 - Large VSD: biventricular hypertrophy (BVH) and left atrial enlargement (LAE)
 - Eisenmenger syndrome: right ventricular hypertrophy (RVH) and right atrial enlargement (RAE)
- Cardiac catheterization
 - Generally reserved for patients with difficult VSD anatomy, associated lesions, or for the assessment of the ratio of pulmonary to systemic flow and pulmonary vascular reactivity

Imaging

- Chest radiograph
 - Small VSD: normal
 - Moderate VSD: hyperinflation, cardiomegaly, increased pulmonary vascular markings
 - Large VSD: cardiomegaly, markedly increased pulmonary vascular markings, Kerley B lines
 - Eisenmenger syndrome: normal heart size, prominent central pulmonary arteries, and decreased peripheral vascular markings
- Echocardiogram
 - All children with a murmur consistent with a VSD should undergo

an echocardiogram to define the location, size, and number of VSDs and any associated defects. Color/spectral Doppler allows visualization of the shunt direction and the amount of restriction to the VSD, if any.

TREATMENT

GENERAL MEASURES

- Small VSD: no intervention; continued observation
- Moderate VSD: If signs of CHF develop, digoxin, diuretics, afterload reduction, and increased caloric intake are indicated.
- Large VSD: CHF often develops and requires aggressive therapy as noted above.
- Membranous and muscular VSDs often become smaller or close spontaneously. Generally, observation and/or medical therapy is indicated for a few months.
- Conoseptal hypoplasia and malalignment VSDs do not close spontaneously and therefore require surgical closure, often in infancy.
- After 1 year of life, a significant left-to-right shunt ($Q_p:Q_s \geq 2:1$) or elevated pulmonary artery pressures are an indication for surgery.
- Children with elevated pulmonary artery pressures ($\geq \frac{1}{2}$ systemic) should undergo repair before 2 years of age, even if CHF symptoms are controlled.
- Development of complications, including aortic insufficiency, subaortic membrane, and double-chamber RV, is usually an indication for surgical repair.
- Surgical correction may be contraindicated if the PVR is >8 Wood units/ m^2 .
- Recent series of surgical VSD closure report a mortality of 0.6–2.3%.
- Complete heart block occurs in $<2\%$ of patients postoperatively but requires pacemaker therapy when it occurs.

ONGOING CARE

PROGNOSIS

- Spontaneous closure: usually by age 2 years; 90% of small muscular VSDs and 8–35% of small conoventricular VSDs
- Prognosis with surgical closure is excellent.
- The risk of Eisenmenger syndrome is considered minimal if large VSDs are surgically closed by 2 years of age.
- Caveat: Despite timely VSD surgical closure, a very small percentage of patients still go on to develop Eisenmenger syndrome.

COMPLICATIONS

- All VSDs: endocarditis—overall rate of 15 cases per 10,000 person-years of follow-up
- Moderate-to-large VSDs: LV volume overload, left atrial hypertension, CHF, poor growth, Eisenmenger syndrome
- Specific types
 - Inlet/canal VSDs: often associated with cleft mitral valve with possible AV valve insufficiency
 - Membranous/conoventricular VSDs: risk for development of aortic insufficiency typically due to prolapse of the right aortic cusp, subaortic membrane, or double-chamber RV
 - Muscular VSDs: isolated—near-zero risk for the development of subsequent lesions
 - Conal septal hypoplasia VSDs: risk for development of aortic insufficiency
 - Malalignment VSDs: usually associated with outflow tract obstruction and distal great artery hypoplasia/obstruction

PATIENT MONITORING

Subacute bacterial endocarditis (SBE) prophylaxis is recommended for 6 months after complete closure (surgical or catheter based) of a VSD.

ICD10

- Q21.0 Ventricular septal defect
- Q24.8 Other specified congenital malformations of heart

FAQ

- Q: Should children with a murmur consistent with a VSD undergo echocardiogram?
- A: Yes, to define the location, size, and number of VSDs and any associated lesions.
- Q: Should children with VSD have SBE prophylaxis?
- A: Based on the revised 2007 American Heart Association Guidelines, isolated VSD does not warrant SBE prophylaxis. However, SBE prophylaxis is recommended for 6 months following complete surgical or interventional catheterization closure (no residual defect) of a VSD.
- Q: Should asymptomatic children with a small VSD have activity restrictions?
- A: No, if there are no other problems.

VENTRICULAR TACHYCARDIA

Arvind Hoskoppal

BASICS

DESCRIPTION

- Ventricular tachycardia (VT) is a series of 3 or more repetitive beats originating from the ventricle at a rate faster than the upper limit of normal for age. It usually is a wide complex rhythm but can appear narrow in infants, and the QRS complex is always different from sinus rhythm. VT may, but not always, have atrioventricular (AV) dissociation.
- Sustained VT: lasts >30 seconds
- Nonsustained VT: lasts from 3 beats to 30 seconds
- VT may be monomorphic or polymorphic.
- Torsades de pointes: a polymorphic variant
 - The QRS complexes gradually change shape and axis throughout the tachycardia.
 - Associated with congenital long QT syndrome, acquired long QT, and Brugada syndrome
- Premature ventricular contractions (PVCs) have been reported in 0.8–2.2% of otherwise healthy children.

Genetics

- Long QT syndrome may be inherited in an autosomal recessive or autosomal dominant pattern. It is related to a variety of cardiac ion channel defects and may be associated with hearing loss and/or a family history of sudden death.
- Brugada syndrome is most commonly related to a defect in the cardiac sodium channel (SCN 5A) and appears to be inherited in an autosomal dominant pattern.

PATHOPHYSIOLOGY

VT may result from a reentrant mechanism, triggered mechanism, or abnormal automaticity.

ETIOLOGY

- Diverse and often overlapping
- Idiopathic
- Myocarditis or dilated cardiomyopathy
- Long QT syndrome (LQTS)
- Right ventricular dysplasia
- Brugada syndrome
- Before and after surgery for congenital heart disease (e.g., tetralogy of Fallot, transposition of the great arteries, aortic stenosis, hypertrophic cardiomyopathy, myocardial tumors, Ebstein anomaly, and pulmonary vascular occlusive disease)
- Metabolic disturbances (hypoxia, acidosis, hypo/hyperkalemia, hypomagnesemia, hypothermia)
- Drug toxicity (e.g., digitalis toxicity, antiarrhythmic agents)
- Substance abuse (cocaine, methamphetamine)
- Myocardial ischemia (e.g., Kawasaki disease, congenital coronary anomalies)
- Trauma
- Invasive lines or catheters
- Pericardial effusion
- Catecholaminergic polymorphic VT

DIAGNOSIS

Based on electrocardiogram (ECG), rhythm strip, Holter, or event monitor

HISTORY

- Varies widely, ranging from asymptomatic to sudden cardiac arrest/death
- Other symptoms include palpitations, presyncope or syncope, exercise intolerance, and dizziness.

PHYSICAL EXAM

- Can be normal; occasional heart rhythm irregularity secondary to frequent PVCs
- Acute, sustained VT may have signs of hemodynamic compromise,

including lack of pulse.

- Signs of underlying heart disease, if any, are present.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum electrolytes, including magnesium and potassium levels, blood gas, and serum drug levels as appropriate
- Urine toxicology screen
- ECG
 - ≥ 3 consecutive ventricular complexes faster than the upper limit of normal for age
 - Bundle branch morphology (right or left) may indicate the site of origin of the VT. May have AV dissociation
 - Typically, repolarization (T-wave) abnormalities are present.
 - The QTc interval should be measured in lead II during sinus rhythm.
 - Evaluate for Brugada syndrome in leads V₁ and V₂ (right bundle branch block, coved-type ST elevation, and T-wave inversion in the right precordial leads). Brugada syndrome ECG findings may be more obvious when the patient is febrile.
- Echocardiogram
 - Rule out congenital heart disease (CHD), pericardial and pleural effusions, tumors, and hypertrophic cardiomyopathy and assess ventricular function.
 - Cardiac magnetic resonance imaging may be helpful in addressing abnormalities that are beyond the resolution of echocardiography.
- Ambulatory Holter monitor
 - Quantitative assessment of ventricular ectopy, and frequency of VT
 - Less frequent episodes may need an event monitor or loop recorder.
- Exercise stress test (>5 years old)
 - Benign PVCs are characteristically suppressed with exercise and return in the immediate recovery period.
 - Exacerbation or worsening of ventricular arrhythmias is concerning.
- Cardiac catheterization: assessment of hemodynamics, endomyocardial biopsy, and coronary artery angiography
- Electrophysiologic study indications

- Confirm diagnosis and mechanism of a wide complex rhythm.
- Evaluate suspected VT in the setting of structural or functional heart disease, syncope, or cardiac arrest.
- Evaluate nonsustained VT in patients with CHD.
- Determine appropriate medical therapy in a patient with inducible VT.
- Evaluate syncope in the setting of palpitations (SVT vs. VT).
- Characterize VT with consideration for catheter ablation.
 - Note: Electrophysiologic studies are generally not helpful in individuals with LQTS.

DIFFERENTIAL DIAGNOSIS

Wide complex tachyarrhythmia

- Should always suspect VT until proven otherwise
- Supraventricular tachycardia (SVT) with aberrancy
- Antidromic tachycardia (antegrade conduction down an accessory pathway during an AV reciprocating tachycardia (e.g., Wolff-Parkinson-White syndrome)
- Atrial flutter or fibrillation with rapid antegrade conduction over an accessory pathway

TREATMENT

- **Acute**
 - If the patient is hemodynamically compromised, prompt synchronized direct-current (1–2 joules/kg; adult, 100–400 joules) cardioversion is indicated.
 - Asynchronous cardioversion for ventricular fibrillation or pulseless VT
 - Cardiopulmonary resuscitation as necessary
 - Lidocaine (1 mg/kg bolus over 1 minute, followed by an infusion at 20–50 µg/kg/minute, assuming normal liver and kidney function)
 - If torsades de pointes, MgSO₄ may be given
 - Overdrive ventricular pacing may terminate the tachycardia; however, pacing may accelerate the VT or induce ventricular

fibrillation.

- IV amiodarone (side effect: hypotension, responds to volume)
- **Chronic**
 - Medications
 - Class IB (mexiletine and phenytoin). β -Blockers (propranolol, atenolol, nadolol) are used in LQTS and may be effective in exercise-induced VT and postoperative CHD.
 - Class III agents (amiodarone and sotalol) should be avoided in patients with LQTS.
 - Class IC agents (flecainide) may be proarrhythmic, and sudden death has been reported in patients with structural heart disease who were taking class IC agents.
 - Verapamil for right ventricular outflow tract VT and verapamil-sensitive left ventricular VT
 - Atrial pacing at rates slightly faster than VT rates may suppress tachycardia.
 - Catheter ablation using radiofrequency energy or cryoenergy
 - Implantable cardioverter defibrillators

ONGOING CARE

PROGNOSIS

- Generally very good in patients with idiopathic VT and a structurally normal heart.
- Suppression of ventricular ectopy with exercise has a favorable prognosis.
- In patients with heart disease (congenital or acquired) or LQTS, VT may increase the risk of presyncope, syncope, and possibly sudden death.

COMPLICATIONS

- Cardiovascular compromise (sudden death)
- Acquired cardiomyopathy (from long-standing VT and a lack of AV synchrony)

PATIENT MONITORING

- Depends on the underlying cause
- ECG, Holter monitor, and exercise stress test

CODES

ICD10

- I47.2 Ventricular tachycardia
- I45.81 Long QT syndrome
- Q24.8 Other specified congenital malformations of heart

FAQ

- Q: Do frequent single PVCs require treatment?
- A: In an otherwise healthy child with a structurally normal heart, normal QT interval, and PVCs that suppress with exercise, no

treatment is indicated.

- Q: Should siblings of patients with LQTS be evaluated?
- A: Yes. Siblings and parents (even if asymptomatic) should have an ECG, Holter monitor, and exercise stress test for definitive evaluation of the QT interval. Commercial genetic testing is currently available to detect mutations in some of the most common genes that cause the LQTS. The test will positively identify ~75% of patients with the LQTS. Genetic testing may be considered in patients in whom there is a high suspicion of LQTS.

VESICoureTERAL REFLUX

Michael H. Hsieh

BASICS

DESCRIPTION

Vesicoureteral reflux (VUR) occurs when urine passes backward from the bladder to the ureters or kidneys.

EPIDEMIOLOGY

Prevalence

VUR occurs in ~1% of children. There are 2 different groups of patients:

- Those who were detected prenatally without any history of urinary tract infection (UTI)
 - ~20–30% of patients with prenatal hydronephrosis have VUR. Screening this population for VUR is controversial.
 - The ratio of males to females in this group is 3:1. This ratio is believed to be caused by a period of high-pressure voiding in boys, which resolves by 18 months.
- Those who were detected after an acute UTI
 - ~30–50% of children with a febrile UTI will have VUR.

RISK FACTORS

Genetics

- 30% of siblings will have VUR (usually low-grade), and the great majority will have been asymptomatic with only rare renal scarring.
- Parents with VUR have a 60% chance of having children with VUR:
 - Whether or not to screen siblings is controversial as low-grade VUR usually resolves without treatment or sequelae.
 - One may elect to screen siblings with a history of recurrent febrile illnesses even in the absence of definitely diagnosed UTIs.

PATHOPHYSIOLOGY

- VUR in combination with UTI can lead to pyelonephritis, renal scarring, and possibly end-stage renal disease.

- Primary VUR is classified into 5 grades by the International Reflux Study based on the voiding cystourethrogram (VCUG):
 - Grade I: reflux into ureter
 - Grade II: reflux into renal pelvis without dilation of calyces
 - Grade III: blunting of calyces, mild dilation of ureter
 - Grade IV: grossly dilated ureter, moderate calyceal dilation with maintained papillary impressions
 - Grade V: grossly dilated ureter with loss of papillary impressions
- The grading scale is important because spontaneous resolution rates are very different between grades I–III and grades IV–V.

ETIOLOGY

- A combination of abnormal anatomy and abnormal voiding pressure:
 - Primary VUR results from either a short ureteral tunnel through the bladder wall or transient high-pressure voiding, which occurs normally in the first 18 months of life.
 - Patients with primary low-grade VUR can expect improvement and even resolution of the VUR with time as the ureteral tunnel grows or when bladder pressures decrease.
- Secondary VUR occurs when there is an associated lesion responsible for the abnormal anatomy or increased intravesical (bladder) pressure:
 - Patients with secondary reflux require treatment of their primary problem and still may require surgery to treat their secondary reflux.
 - Secondary reflux may occur in neurologically normal patients with bladder and bowel dysfunction, ureterocele, posterior ureteral valves, and prune belly syndrome or in neurologically abnormal patients with spina bifida.
 - The distinction between primary and secondary reflux is important because large prospective trials have been conducted on patients with primary reflux and it is not appropriate to extend those findings to patients with secondary reflux.
 - Another important distinction is whether the diagnosis of VUR was made as a result of a prenatal diagnosis of hydronephrosis or whether the child presented with UTI.

DIAGNOSIS

HISTORY

- Prenatal dilation of the urinary tract or UTI as presentation
- Family or sibling history of VUR
- Family history of UTI, suggestive of infection-susceptible uroepithelium
- Family history of renal failure
- Voiding history: age at toilet training
- Daytime or nighttime incontinence
- Frequency of urination
- Sensation of emptying the bladder completely
- Signs of bladder and bowel dysfunction:
 - Urgency
 - Frequency
 - Damp underwear
 - Associated constipation: frequency of bowel movements, suggestive of pelvic floor immaturity
- Evidence of holding urine during a bladder contraction:
 - Squatting, crossing legs
 - Compressing urethra with heel (Vincent curtsy)

PHYSICAL EXAM

- Abdominal palpation (primarily to check for hard stool)
- Check for labial adhesions in girls
- Phimosis in boys
- Inspection and palpation of spine (possible neurogenic bladder)
- Blood pressure

DIAGNOSTIC TESTS & INTERPRETATION

Lab

A serum creatinine and urinalysis for proteinuria may be obtained if the renal ultrasound suggests significant renal scarring or in severe bilateral VUR.

Imaging

- Renal/bladder ultrasound
 - Ultrasound is usually obtained following a febrile UTI, or if the patient had a prenatal diagnosis of hydronephrosis, between the 2nd day and 1st week of life. The ultrasound is not as sensitive as dimercaptosuccinic acid (DMSA) scan for renal scarring.
 - The lack of hydronephrosis does not mean that the patient does not have VUR. However, renal bladder ultrasound is a useful tool for following renal growth.
- VCUG
 - A contrast study is necessary for the 1st VCUG to delineate the urethral anatomy in boys and to accurately grade the reflux in both sexes.
 - An age-appropriate volume should be instilled in the bladder. The voiding portion of the study is important because ~20% of VUR can be missed if voiding is not observed.
 - Follow-up VCUGs can be performed using radionuclide to decrease the radiation dose to the child.
 - Whether to routinely perform a VCUG for a “first” febrile UTI in children aged 2 months to 2 years is controversial
- DMSA renal scan
 - The most accurate way to diagnose pyelonephritis and renal scarring
 - It is not possible to predict which patients will develop scarring after an acute episode (unless they have prior scarring, which is a risk factor for future scarring).
 - If the diagnosis of upper tract infection versus cystitis is important, then the DMSA scan during an acute episode is useful.
 - DMSA is not usually helpful with afebrile UTI.
 - Some advocate using DMSA to identify high-risk patients requiring VCUG.

DIFFERENTIAL DIAGNOSIS

In the prenatally detected group, hydronephrosis can also be due to ureteropelvic or ureterovesical junction obstruction. The important task is to differentiate primary from secondary VUR so that the parents can be appropriately counseled.

TREATMENT

GENERAL MEASURES

- Four randomized controlled trials suggest that medical management (prophylactic antibiotics) and surgery have essentially equal outcomes in regard to hypertension, growth, and renal scarring. Surgery was more effective at preventing pyelonephritis.
- The rate of renal scarring was equal in the medical and surgical arms of the International Reflux Study. However, the timing of renal scarring was different: In the medically treated arm, new renal scars continued to form during 5 years of follow-up, whereas in the surgical arm, the renal scars stopped within 10 months of surgery. Surgery was 95% successful in correcting reflux with a 4% complication rate. Surgery involves creation of a longer muscular backing for the ureter to create a flap-valve mechanism.
- Patients with low-grade reflux should be maintained on prophylactic antibiotics and surgery delayed because grades I–III have a significant rate of spontaneous resolution. Patients with high-grade reflux (grades IV–V) should be initially maintained on prophylactic antibiotics, but earlier consideration for surgical correction should be given due to the lower rate of spontaneous resolution. Likewise, patients with reflux and renal scarring should be considered for earlier surgery because they have already shown a propensity toward UTI and renal damage.
- Antibiotic prophylaxis does not mean treatment-dose antibiotics. The antibiotics chosen are highly concentrated in the urine, and the use of high doses only selects out resistant organisms and leads to complications such as yeast infections. Amoxicillin at 10–15 mg/kg/24 h is used for the first 2 months of life, then trimethoprim/sulfamethoxazole (40 mg/200 mg/5 mL) at 0.25 mL/kg/24 h (equivalent to 2–3 mg/kg daily of trimethoprim) or nitrofurantoin at 1–2 mg/kg/24 h.
- Patients who are detected with VUR in infancy should probably have a contrast VCUG at 18 months to 2 years to determine if VUR has resolved.
- In toilet-trained children, maintenance of a regular voiding pattern and

regular bowel movements decreases the risk of febrile UTI and increases the chance of VUR resolution.

- Patients being managed on antibiotic prophylaxis undergo annual follow-up nuclear VCUG to document improvement or resolution of VUR. Grading is less precise with nuclear VCUG, but the radiation dose is lower. A renal ultrasound is also obtained to follow renal growth and check for gross renal scars.
- Indications for crossing over to surgery are as follows:
 - Patient or parent wishes
 - Nonadherence with medical therapy
 - Breakthrough infections while on medical therapy if a careful review of voiding habits demonstrates that bladder and bowel dysfunction is not responsible for the UTI. Lack of new renal scarring may also suggest that continued medical management is appropriate.
 - New renal scarring
 - Persistence of grades IV or V reflux after an appropriate period of antibiotic prophylaxis
- The use of injectable bulking agents has a 80–85% success 1 year after 1 treatment of low-grade VUR, with progressively decreasing success rate as the grade of VUR increases. Centers with more experience with injection have higher success rates. The minimally invasive nature of these treatments is balanced with a lower success rate. Deflux (dextranomer/hyaluronic acid) is the most commonly used injectable in the United States and is widely used in treating grades I–III VUR. Deflux treatment in higher grades of VUR and robotic and laparoscopic ureteral reimplantation are being explored in select patients.
- The use of continuous antibiotic prophylaxis has been questioned because although it decreases the risk of UTI for higher grade VUR, it has not been shown to decrease renal scarring compared to placebo. An NIH multi-institutional trial to determine the benefits of continuous prophylaxis versus placebo treatment is ongoing. The Swedish Reflux Trial showed a decreased rate of febrile UTI in girls with grades III–IV VUR who underwent injection therapy or prophylaxis, compared to

those on surveillance. New renal scarring was less frequent in girls on prophylaxis compared to those on surveillance.

- The management of patients who continue to have VUR after several years of prophylactic antibiotics is controversial. Although most feel comfortable discontinuing antibiotics for boys with VUR after age 6 years because the risk of renal scarring is decreased and boys are at low risk for UTI, the adolescent girl is at increased risk for complications during pregnancy if she has a past history of UTI. The few studies on this subject seem to indicate that the patients with VUR and recurrent UTI are at risk for pregnancy-related complications whether or not the VUR has been surgically corrected, suggesting that the propensity toward UTI plays a more important role.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Patients with renal scarring should have annual BP checks and urinalysis for proteinuria through adolescence.

PROGNOSIS

- In primary VUR, 80–90% of grades I and II reflux, 70% of grade III, 40% of grade IV, and 25% of grade V resolve over a 5-year period.
- The annual rate of spontaneous resolution is between 15% and 20% for grades I–III.
- Bilateral reflux is less likely to resolve than unilateral reflux.
- Patients age 5 years or older at presentation are less likely to resolve than those who present at <5 years of age.
- Reflux that appears in the filling phase of VCUG (“passive reflux”) may be less likely to resolve than reflux that only appears during voiding phase.
- Ultimately, the goal is prevention of renal scarring rather than resolution of the reflux because low-pressure sterile reflux does not lead to renal scarring.
- Chronic kidney disease is very unlikely in the absence of bilateral

grade III or higher VUR.

CODES

ICD10

- N13.70 Vesicoureteral-reflux, unspecified
- Q62.7 Congenital vesico-uretero-renal reflux
- N13.71 Vesicoureteral-reflux without reflux nephropathy

FAQ

- Q: How soon after a UTI should the VCUG be performed?
- A: Once the patient is clinically stable and afebrile and sterile urine has

been documented, the VCUG can be performed.

- Q: Why not operate immediately to repair the reflux when it is diagnosed?
- A: Depending on the grade of reflux, many cases will resolve in time.

VIRAL HEPATITIS

Scott Elisofon

BASICS

DESCRIPTION

- Viral hepatitis is defined as a systemic viral infection, in which the predominant manifestation is that of hepatic injury and dysfunction.
- It is primarily caused by hepatotropic viruses, which include hepatitis A–E.
- 10% of cases are caused by other viruses, such as Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex virus (HSV), varicella-zoster virus (VZV), rubella, parvovirus, adenovirus, enteroviruses, and others.

EPIDEMIOLOGY

Incidence

- Hepatitis A: ~17,000 cases per year in the United States. 8% occur in day care centers.
- Hepatitis B: 140,000–320,000 infections per year worldwide. ~40,000 U.S. cases per year
- Hepatitis C: 20,000 infections per year in the United States
- Hepatitis E: Common in poorly developed countries but rare in the United States.

Prevalence

- Hepatitis B: United States has a low prevalence with <1% of the population infected; higher rates in certain subgroups such as immigrants from endemic areas, homosexuals, and parenteral drug users
- Hepatitis C: United States has prevalence of 1.8%, representing ~3.9 million people (85% chronically infected).

RISK FACTORS

- Hepatitis A (transmission: fecal–oral)
 - Day care attendance, household exposure, travel to endemic areas,

- men who have sex with men
- Maximum infectivity 2 weeks before jaundice
- Hepatitis B and C (transmission: blood, body fluids, and sexual contact)
 - Recipients of blood or blood products
 - IV drug users
 - Multiple sexual partners
 - Homosexual males
 - Body piercing and tattoos
 - HIV-positive status
 - Infants born to a mother with hepatitis B or C
 - Household contacts with hepatitis B or C

GENERAL PREVENTION

- Good sanitation, hygiene, vaccination, screening blood products, condom use, safe disposal of needles
- Hepatitis A
 - Vaccination of all children between the ages of 1 and 18 years, especially those travelling to endemic regions or those with liver disease
 - Vaccine (Havrix, Vaqta): 0.5-mL dose IM and 2nd dose 6–12 months later
 - Prior to travel to an endemic region, immune globulin 0.02 mL/kg should be given to children younger than 1 year of age and considered for children who are immunocompromised or have liver disease.
 - Infected patients should avoid return to day care center for 2 weeks after illness subsides.
 - Postexposure prophylaxis for children >1 year of age: hepatitis A vaccine
 - Postexposure prophylaxis for <1 year of age and immunocompromised individuals: immune globulin 0.02 mL/kg IM
- Hepatitis B
 - Screen all pregnant women.
 - Hepatitis B vaccine to all infants at birth; complete 3-vaccine series 0.5-mL dose IM during infancy.

- Vaccine and hepatitis B immunoglobulin to high-risk infants
- Mother's with previous vertical transmission should consult a high-risk obstetrician and hepatitis B expert at least 3–6 months prior to delivery of another infant.
- Hepatitis C
 - Elective C-section has not been shown to reduce vertical transmission.
 - During vaginal delivery, avoid fetal scalp monitoring and prolonged rupture of membranes >8 hours.
 - Avoid sharing of toothbrushes, nail clippers, and razors.
 - Breastfeeding is allowed, unless the mother has active bleeding from nipples.

PATHOPHYSIOLOGY

- Acute viral hepatitis tends to affect the liver parenchyma, whereas chronic viral hepatitis affects portal and periportal areas.
- Chronic viral hepatitis (B or C) is defined by continuing viral replication and inflammation of the liver for >6 months.
- Worsening injury leads to extensive fibrosis that occurs between portal tracts (portal bridging), nodular changes, and finally, cirrhosis.

DIAGNOSIS

HISTORY

- History should focus on risk factors for viral exposure, sick contacts, travel history, and high-risk behaviors.
- Family history of liver or autoimmune disease, medications, or drug and alcohol use should also be explored.

PHYSICAL EXAM

- Jaundice, hepatomegaly, or tenderness over the liver may or may not be present during acute infection.
- Signs and symptoms during acute infection:
 - Fever
 - Malaise and fatigue
 - Nausea and vomiting, anorexia

- Jaundice: in hepatitis A, seen in 88% of adults but only 65% of children
- Hepatomegaly
- Right upper quadrant (RUQ) abdominal pain
- Dark urine and pale stools
- Arthralgias/arthritis
- The vast majority of affected patients are minimally symptomatic or asymptomatic, especially with chronic infection.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Liver tests
 - Marked elevation of aspartate aminotransferase/alanine aminotransferase (AST/ALT) during acute infection
 - May be normal to mildly elevated in chronically infected individuals
 - Bilirubin from mild to marked elevation
 - In severe hepatitis, monitor PT/INR, albumin, electrolytes, glucose, and CBC.
- Biochemical markers for each virus for diagnosis, management, and monitoring
 - Hepatitis A
 - ▢ Virus (HAV) IgM: recent infection
 - ▢ Anti-HAV IgG: past exposure or immunization-acquired
 - Hepatitis B
 - ▢ Surface antigen (HBsAg): current infection, acute or chronic
 - ▢ Surface antibody (HBsAb): immunized or resolved infection
 - ▢ “e” antigen (HBeAg): active viral replication; “infectious”
 - ▢ “e” antibody (HBeAb): end of severe infectivity (except in precore mutants). End point for many hepatitis B therapies and studies
 - ▢ Core antigen (HBcore) IgM: early phase of acute infection, not present in chronic HBV
 - ▢ Core total Ab: exposed to HBV
 - ▢ HBV DNA: quantification useful to assess viral load

- HBV mutations: useful to assess resistance to treatment
 - HBV genotyping can sometimes be helpful in determining if interferon therapy would be beneficial (genotype D unfavorable for interferon use).
- Hepatitis C
 - HCV Ab: exposure to HCV
 - HCV RNA: Quantitative, assess viral load; qualitative, assess presence/absence of virus.
 - HCV genotype: useful to determine duration of treatment and likelihood of response
- Hepatitis D
 - HDV Ab: exposure to hepatitis D

Diagnostic Procedures/Other

Liver biopsy is often needed to determine type and extent of liver damage. It is usually indicated prior to initiation of antiviral therapy in children with hepatitis B or C.

Pathologic Findings

A wide array of histologic features is possible on liver biopsy, including inflammation, necrosis, and fibrosis, based on the severity and chronicity of disease.

DIFFERENTIAL DIAGNOSIS

- Many disorders give rise to elevated transaminases, and clues to a viral origin are based on the history, serology, and histologic findings.
- The diagnosis of “non A–E hepatitis” is often used when the cause is almost certainly viral, but no virus is isolated.
- Other possibilities include drug-induced, ischemic, alcoholic, autoimmune hepatitis, as well as Wilson disease or α_1 -antitrypsin deficiency.

TREATMENT

MEDICATION

- Hepatitis A

- No specific therapy is necessary for previously immunized or infected patients.
- Postexposure prophylaxis is recommended for nonimmunized patients household contacts, intimate exposure contacts, and children and staff in nursery or day care centers with outbreaks.
- Hepatitis A vaccine for children >1 year of age. Children <1 year of age or immunocompromised individuals should receive immune globulin 0.02 mL/kg IM \times 1.
- Hepatitis B
 - Postexposure prophylaxis with hepatitis B vaccine and hepatitis B immunoglobulin (HBIG) is indicated for neonates born to mothers who are hepatitis B carriers and for unvaccinated individuals after sexual contact with carriers or accidental exposure to infected blood products.
 - Persons previously vaccinated with known titer >10 mIU/mL do not require any intervention, and children vaccinated with low titer need only a booster HBV vaccine.
 - There is no treatment for acute hepatitis B, although lamivudine is reported to be effective in fulminant HBV hepatitis.
 - Treatment is not usually considered when patients are immune tolerant (normal ALT, (HBeAg)-positive, with high HBV DNA).
 - Children should be monitored every 6–12 months with ALT, HBeAg, and HBeAb. When ALT is elevated, treatment is considered by hepatitis B experts.
 - Some pediatric studies suggest that antiviral therapy hastens but does not increase the rate of HBeAg seroconversion.
 - Medications that have been used for chronic hepatitis B include the following: interferon, peginterferon, lamivudine, adefovir, tenofovir, or entecavir.
 - Lamivudine is no longer routinely recommended in chronic HBV due to a high rate of resistance with prolonged treatment.
 - Adefovir dipivoxil and tenofovir are approved for children >12 years of age and entecavir for children >16 years of age.
 - The factor most predictive of treatment response in children with chronic hepatitis B is an elevated pretreatment ALT.

- Each year, approximately 5% of children spontaneously clear HBeAg, at which point the disease usually becomes inactive, although a few will later reactivate.
- Hepatitis C
 - For acute hepatitis C, treatment with interferon in first 3 months after acquiring infection has been quite successful in adults and should be considered in children.
 - Antiviral therapy for chronic infection can be initiated at any time after 3 years of age, and is indicated for children with progressive or advanced disease
 - Pegylated interferon and ribavirin is currently the treatment of choice for chronic hepatitis C in children >3 years of age.
 - Treatment duration depends on genotype:
 - Genotypes 1 and 4: 1 year (type 1 most common in United States)
 - Genotypes 2 and 3: 6 months (types more likely to respond to therapy)
 - Several protease inhibitors, telaprevir and boceprevir, have recently been approved for treatment of chronic HCV in adults in combination with peginterferon and ribavirin.

General Measures

- Most cases of acute hepatitis do not require hospitalization.
- Dehydration, coagulopathy, or severe cases need inpatient care; monitor and correct coagulation defects and fluid, electrolyte, and acid–base imbalances.
- Report acute cases to public health department.
- Patients with acute liver failure should be transferred to a pediatric transplant center.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- For hepatitis B and C, serial measurement of serum AST/ALT, viral markers, α -fetoprotein, and ultrasound of the liver

- Liver biopsy pretreatment and for evaluation of disease progression

PROGNOSIS

- Hepatitis A
 - Mild disease usual
 - Rarely results in relapsing, fulminant, or cholestatic disease
 - No chronic liver disease
 - Mortality <1%
 - Protective antibodies develop in response to infection and persist for life.
- Hepatitis B
 - Fulminant hepatitis 1–2%
 - Mortality 0.8%
 - Chronic sequelae: Rate of chronicity is inversely proportional to age of acquisition: 90% in infants, 25% in ages 1–5 years, and 6–10% in older children; cirrhosis <5%, hepatocellular carcinoma
- Hepatitis C
 - Fulminant hepatitis 1%
 - Chronic sequelae: Infants infected via vertical transmission have 60–80% chance of chronic infection. Cirrhosis is uncommon, and hepatocellular carcinoma is rare in children and adolescents. If untreated, HCV can lead to advanced liver disease in adults.
 - HCV is the most common indication for liver transplantation in adults.

COMPLICATIONS

- Patients with advanced liver disease due to chronic hepatitis B or C are at risk of complications associated with cirrhosis and portal hypertension.
- Patients with chronic hepatitis B or with cirrhosis due to hepatitis C are at increased risk of hepatocellular carcinoma.
- Hepatitis B
 - Hepatitis D coinfection: Acute hepatitis B and D virus infection occur simultaneously.
 - Hepatitis D superinfection: Acute hepatitis D occurs in a chronic carrier of hepatitis B.

Pregnancy Considerations

Hepatitis E: mortality of 20% caused by acute liver failure in pregnant women

- B19.20 Unspecified viral hepatitis C without hepatic coma

FAQ

- Q: Why do infants who acquire HBV at birth have a higher incidence of chronicity?
- A: The immaturity of the neonatal immune system contributes to the higher incidence of chronicity in this population.
- Q: Should a mother with HCV positivity breastfeed?

- A: Transmission of HCV via breast milk is unlikely.

VOLVULUS

Jeffrey R. Lukish

BASICS

DESCRIPTION

Volvulus represents an abnormal rotation (torsion) of the viscera that results in ischemia. Gastric, cecal, and midgut volvulus can occur. Midgut volvulus is the most common form in infants and children.

EPIDEMIOLOGY

- Malrotation with midgut volvulus occurs in 1 in 6,000 live births.
- Slightly more common in boys
- Most children with midgut volvulus present in the 1st month of life.

RISK FACTORS

- Children with malrotation have a narrow mesenteric vascular pedicle and are predisposed to volvulus.
- Familial associations can occur.
- The risk of volvulus in patients with malrotation does not decrease with age.

ETIOLOGY

Volvulus occurs due to failure of the fetal gut to undergo normal in utero rotation and fixation (malrotation), resulting in a narrow mesenteric vascular pedicle.

COMMONLY ASSOCIATED CONDITIONS

Up to 30% of children with malrotation have congenital heart disease. Additionally, 30–60% of patients with other congenital gastrointestinal (GI) malformations (gastroschisis, omphalocele, intestinal atresia, Hirschsprung disease) have malrotation.

DIAGNOSIS

HISTORY

- The primary presenting sign is the sudden onset of bilious vomiting.

ALERT

Infants and children with bilious emesis require evaluation to rule out malrotation and volvulus.

- Recurrent colicky abdominal pain
- Feeding intolerance
- Chylous ascites and/or protein-losing enteropathy due to lymphatic congestion and bacterial overgrowth
- In older children, recurrent abdominal pain and emesis and constipation
- Bloody stools or blood-tinged mucus per rectum can occur and can be late manifestations of ischemic bowel.

PHYSICAL EXAM

- Infants with volvulus may manifest complaints of severe pain without significant physical exam findings (out of proportion to physical exam).
- Abdominal tenderness (mild to severe)
- Irritability, lethargy
- Palpable abdominal mass
- Edema of abdominal wall (late finding)
- Flexion of legs
- Tachypnea and tachycardia
- Hypotension (late finding)

ALERT

Pitfalls in management include the following:

- Delay in diagnosis
- Failure to recognize the key sign of bilious emesis
- Failure to recognize colicky pain (in infants) or cyclic bilious emesis (in older children) as possible manifestations of malrotation
- Failure to order the diagnostic study (a limited upper gastrointestinal series ["upper GI"]) to evaluate the duodenal sweep

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Laboratory analysis is unpredictable. May see elevated acute phase reactants, leukocytosis, metabolic acidosis, and thrombocytopenia

Imaging

- No imaging modality is 100% sensitive.
 - The goal is to delineate whether the duodenum follows a normal sweep to the right of the vertebral bodies before transition to the jejunum.
 - The 3rd portion of the duodenum crosses behind the superior mesenteric artery to the left of the vertebral body at L1 and rises to the level of the pyloric bulb before transition into the jejunum.
- Plain radiographs
 - Can be normal or show a paucity of bowel gas
 - A dilated stomach and duodenum (double bubble) can be present.
- Abdominal ultrasound
 - May show inversion of normal position of superior mesenteric artery (SMA) and superior mesenteric vein (SMV)
 - If SMA is to the right of the SMV, malrotation may be present.
 - The ultrasound has a sensitivity of 80%.
- Upper GI tract (contrast) radiography
 - May show abnormal position of the ligament of Treitz and, if volvulus is present, a corkscrew appearance of the midgut
 - The upper GI is approximately 95% sensitive for identifying malrotation.
 - False positives may occur in children with a distended stomach or ileus. In these cases, the ligament of Treitz is then pushed into an abnormal position.
- Barium enema (BE)
 - Can be useful in evaluating the position of the colon and cecum
 - The sensitivity of BE for diagnosing malrotation and volvulus is 75%.
 - In cases of cecal, sigmoid, or transverse colonic volvulus, contrast enema shows a beak deformity at site of volvulus.

DIFFERENTIAL DIAGNOSIS

- Ileus
- Intestinal atresia
- Perforated viscus
- Necrotizing enterocolitis
- Meconium ileus or meconium plug syndrome
- Hirschsprung enterocolitis
- Appendicitis
- Intussusception
- Pyelonephritis

TREATMENT

GENERAL MEASURES

- Any child who presents with bilious emesis and an acute abdomen may require emergent surgical exploration. The concern for midgut volvulus is paramount, and delays for further workup may not be warranted.
- Intravenous fluid resuscitation is indicated, until normal urine output is established.
- Nasogastric decompression and intravenous antibiotics are indicated.

SURGERY/OTHER PROCEDURES

- Laparotomy with reduction of the torsion and inspection of the bowel for necrosis or ischemia
- The Ladd procedure consists of 4 components:
 - Reduction and untwisting of the volvulus by a 360-degree counterclockwise rotation of the midgut
 - Division of abnormal adhesions extending over the duodenum (Ladd bands) that are transfixing the cecum in the right upper quadrant
 - Division and opening of the mesenteric attachments to provide a wider vascular base to the midgut and appendectomy
 - Removal of the appendix: The appendix is removed because it is in a highly unusual place and would result in a diagnostic dilemma should the child develop appendicitis.

- Many surgeons can perform the Ladd procedure laparoscopically.
- Second-look operations may be indicated if a large portion of the midgut is ischemic; the volvulus may be reduced with reexploration in 12–24 hours.
- On rare occasions, bowel resection and ostomy may be necessary.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Prognosis depends on extent of involvement and degree of bowel ischemia.
- A majority of these children develop a profound ileus and require TPN for days or potentially weeks postoperatively.
- Third-space volume loss is common postoperatively. Monitoring of intake/output is critical to maintain euvolemia.
- Postoperative small bowel obstruction and even recurrent volvulus can occur.

COMPLICATIONS

- Recurrent volvulus (occurs in 2% of patients)
- Short gut syndrome
- Adhesive bowel obstruction
- Wound infection and abdominal abscess

CODES

ICD10

- K56.2 Volvulus
- K31.89 Other diseases of stomach and duodenum
- Q43.8 Other specified congenital malformations of intestine

FAQ

- Q: When should workup for volvulus be initiated?
- A: In any child with bilious vomiting.
- Q: What is the best diagnostic study to confirm the diagnosis?
- A: Limited upper GI to evaluate the duodenal sweep and position of the ligament of Treitz.
- Q: What is the most common age of presentation of volvulus?
- A: In the 1st month of life; however, it can occur in any age.
- Q: What are the other types of volvulus that have been reported in children?
- A: Gastric, small bowel, and colonic volvulus can occur in children. Gastric volvulus presents with abdominal pain and retching. Two types occur: meso-axial (rotation about the lesser and greater curvature) and organo-axial (rotation around the longitudinal axis of the stomach). A

majority of these children have structural abnormality of the stomach such as asplenia or abnormal fixation to the esophagus. Both small bowel and colonic volvulus present similarly to midgut volvulus, with high-grade bowel obstruction, abdominal pain, and bilious vomiting.

- Q: Can volvulus occur in teenagers and young adults?
- A: Yes. Age is not a determinant of presentation of volvulus, which may occur in older children and adults. As in infants, catastrophic consequences can occur, including entire midgut loss.
- Q: Who developed the Ladd procedure?
- A: William Edwards Ladd, MD (1880–1967) first described the procedure in 1936. He was a pioneer in the field of pediatric surgery. He was the first surgeon-in-chief at Boston Children's Hospital and coauthored the first pediatric surgical textbook.

VOMITING

Peter D. Ngo

BASICS

DESCRIPTION

- Vomiting is the forceful expulsion of gastric contents through the mouth.
 - Vomiting is a prominent feature of many disorders of infancy and childhood.
 - It is often the only presenting symptom of many diseases.
- Regurgitation is defined as small, effortless mouthfuls of food or stomach contents.
- Retching is contraction of the abdominal musculature against a closed glottis, restricting expulsion of stomach contents (also referred to as “dry heaves”).

PATHOPHYSIOLOGY

- Vomiting can be:
 - A defense mechanism to expel ingested toxins
 - An abnormality of, or damage to, the postrema area of the brain (a.k.a. the chemoreceptor trigger zone or vomiting center), which is located at the base of the fourth ventricle
 - A result of intestinal obstruction or anatomic abnormalities
 - Due to chronic gastrointestinal mucosal disease
 - The result of a generalized metabolic disease
 - A result of increased intracranial pressure

DIAGNOSIS

HISTORY

- A full history should include medication and drug use, trauma, family history of migraines and chronic gastrointestinal diseases, and travel history.

- Special attention should be directed to the timing of the emesis, relationship to meals, position and time of day, as well as to the chronicity of symptoms.
- Fever: may suggest an infectious etiology
- Abdominal pain and frequent, forceful, or bilious emesis
 - Often associated with anatomic or obstructive intestinal disorder
 - For example, obstruction of a lumen (i.e., common bile duct stone or ureteropelvic junction [UPJ] obstruction) can present as vomiting.
- Age of patient
 - Some etiologies of vomiting may be aged-based.
 - For example, pyloric stenosis or inborn errors of metabolism should be considered in infants with vomiting, dehydration, and biochemical abnormalities.
 - In adolescents, disordered eating patterns (bulimia) and the possibility of pregnancy should be considered.
- Mental retardation, pica, and patchy baldness: indicate foreign body or hair ingestion and the development of a gastric bezoar
- Nausea and epigastric pain related to meals: often indicate gastritis, gastric emptying delay, or gallbladder disease
- Symptoms alleviated by meals: may signify gastroesophageal reflux or gastric ulcer
- Alternating vomiting and lethargy: may indicate intussusception
- Chronic headaches, fatigue, weakness, weight loss, and early morning vomiting: neurologic causes of vomiting secondary to increased intracranial pressure
- Right- or left-sided abdominal pain: may indicate renal disease
- Recurrent, intermittent episodes of vomiting interspersed with periods of wellness may suggest cyclic vomiting syndrome (CVS).
- Recurrent vomiting and other gastrointestinal symptoms are commonly seen with mucosal diseases such as celiac disease, eosinophilic esophagitis, and inflammatory bowel disease.

PHYSICAL EXAM

A careful and complete physical examination can often contribute to determining the cause of vomiting in children:

- Visible bowel loops: obstruction
- Palpation for bowel loops and tenderness and auscultation for evidence of absent bowel sounds or borborygmi (rumbling bowel sounds): intestinal obstruction
- Rectal examination: testing the stool for occult blood
- Discoloration of skin and sclera: jaundice (liver/gallbladder or metabolic disease)
- Orange tint of sclera or skin: hypervitaminosis A
- Unusual odor: metabolic disease, diabetic ketoacidosis
- Chronic vomiting: evidence of neurologic dysfunction, including nystagmus, head tilt, papilledema, abnormal reflexes, and weakness
- Tense anterior fontanelle: may indicate meningitis, hydrocephalus, or vitamin A toxicity
- Enlarged parotid glands and hypersalivation: bulimia and other feeding disorders
- Pelvic examination: pregnancy, pelvic inflammatory disease, or ovarian disease

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Anemia and iron deficiency can occur with gastritis/esophagitis, inflammatory bowel disease, celiac disease, and ulcer disease.
- Blood chemistry
 - Electrolyte abnormalities are found in pyloric stenosis and metabolic disease.
 - An elevated alanine aminotransferase, conjugated bilirubin, and gamma-glutamyl transferase (GGT) can indicate liver, gallbladder, or metabolic disease.
- Urinalysis: pyelonephritis, nephrolithiasis
- Lipase/amylase: pancreatitis
- BUN/creatinine: Elevated levels can occur with renal disease.
- Urine culture: UTI
- Stool studies: occult blood, infection, *Helicobacter pylori* antigen
- If chronic vomiting history
 - Tissue transglutaminase IgA, endomysial antibody, or deamidated

- gliadin IgA and serum IgA (celiac disease)
- Erythrocyte sedimentation rate and/or C-reactive protein (inflammatory bowel disease but can also be elevated in acute infection/illness)

Imaging

- Plain abdominal radiographic study
 - Can detect ileus and/or obstruction
 - May also need upright or left lateral decubitus films
- Abdominal ultrasound
 - Liver, gallbladder, renal, pancreatic, ovarian, or uterine disease
 - In infants, abdominal ultrasound is the test of choice for pyloric stenosis.
 - Useful when considering abdominal abscess and appendicitis
 - Can detect intussusception
- Contrast radiography
 - Intestinal anatomic abnormalities (e.g., malrotation, intussusception, volvulus, hiatal hernia), gastric bezoar, achalasia
- Gastric scintigraphy (gastric emptying study)
 - Evaluate rate of gastric emptying; assess for gastroparesis.
- Abdominal CT
 - Not generally indicated for evaluation of vomiting, although it is an effective tool when more anatomic abdominal detail is required (abscess, tumor).
- Head CT
 - Can be helpful in evaluation of acute neurologic causes of vomiting (i.e., cerebrovascular insult; hydrocephalus)
- Brain MRI
 - Provides superior imaging of the brain stem, where the vomiting center is located, without radiation exposure
 - Test of choice if considering intracranial mass

Diagnostic Procedures/Surgery

- Upper endoscopy
 - Can identify esophageal, gastric, and duodenal inflammation (reflux esophagitis, eosinophilic esophagitis, gastritis, ulcer disease, celiac disease)

- Provides means to obtain biopsies or cultures for infections (H. pylori, duodenal Giardia, cytomegalovirus gastritis)
- Gastroesophageal and antroduodenal manometry: can be used to evaluate for primary or secondary motility disorders, evaluation of suspected rumination syndrome

DIFFERENTIAL DIAGNOSIS

- Disorders of gastrointestinal tract:
 - Anatomic
 - Esophageal: stricture, web, ring, atresia
 - Stomach: pyloric stenosis, web, hiatal hernia
 - Intestine: duodenal atresia, malrotation, duplication
 - Colon: Hirschsprung disease, imperforate anus
 - Motility
 - Achalasia
 - Gastroesophageal reflux
 - Intestinal pseudoobstruction
 - Gastroparesis
 - Ileus
 - Obstruction
 - Foreign body/bezoar
 - Intussusception
 - Stricturing Crohn disease
 - Volvulus
 - Incarcerated hernia
 - Eosinophilic esophagitis
 - Hepatobiliary disease
 - Appendicitis
 - Necrotizing enterocolitis
 - Peritonitis
 - Celiac disease
 - Peptic ulcer
 - Trauma
 - Duodenal hematoma
 - Pancreatitis (pseudocyst)
- Neurologic

- Intracranial mass lesions:
 - Tumor
 - Cyst
 - Subdural hematoma
- Cerebral edema
- Hydrocephalus
- Pseudotumor cerebri
- Arnold-Chiari malformation
- Migraine (head, abdominal)
- Seizures
- Postconcussion syndrome
- Renal
 - Obstructive uropathy
 - UPJ obstruction
 - Hydronephrosis
 - Nephrolithiasis
 - Renal insufficiency
 - Glomerulonephritis
 - Renal tubular acidosis
- Metabolic
 - Inborn errors of metabolism:
 - Galactosemia
 - Fructose intolerance
 - Hereditary fructose intolerance
 - Amino acid or organic acid metabolism
 - Urea cycle defects
 - Fatty acid oxidation disorders
 - Lactic acidosis
- Infection
 - Sepsis
 - Meningitis
 - UTI
 - H. pylori
 - Parasites
 - Giardia

- Viral/bacterial gastroenteritis
- Viral hepatitis (A, B, C)
- Pneumonia
- Bordetella pertussis
- Streptococcal pharyngitis
- Endocrine
 - Diabetes
 - Diabetic ketoacidosis
 - Diabetic gastroparesis
 - Adrenal insufficiency
- Respiratory
 - Sinusitis
 - Laryngitis
- Immunologic
 - Food allergy
 - Anaphylaxis
 - Graft-versus-host disease
 - Chronic granulomatous disease
- Other:
 - Pregnancy
 - Rumination
 - Bulimia
 - Motion sickness
 - CVS
 - Overfeeding
 - Pain
 - Cannabinoid hyperemesis
 - Medications:
 - Drugs (chemotherapy)
 - Vitamin toxicity
 - Vascular (superior mesenteric artery syndrome)
 - Porphyria
 - Familial dysautonomia

ALERT

Vomiting accompanied by hematemesis, intestinal obstruction (bilious

vomiting), dehydration, neurologic dysfunction, or an acute abdomen should be treated as a medical emergency, and hospitalization should be considered.

TREATMENT

- Potential therapeutic interventions are broad, and therapy should be directed toward the underlying etiology.
- Historically, empiric antiemetic medications were contraindicated in cases of acute vomiting, although more recent studies suggest ondansetron may reduce frequency of admission.
- Oral rehydration therapy is typically the first line of treatment. IV fluids are appropriate if oral rehydration therapy fails or are contraindicated.
- Neurotransmitters involved in vomiting include dopamine, acetylcholine, histamine, endorphins, serotonin, and neurokinins. The mechanism of many antiemetic medications is blockade of these neurotransmitters.

ISSUES FOR REFERRAL

- Chronic vomiting (2–3 weeks)
- Weight loss
- Severe abdominal pain or irritability
- Gastrointestinal bleeding
- Bilious emesis
- Evidence of intestinal obstruction
- Serum electrolyte abnormalities
- Abnormal neurologic examination
- Dehydration
- Signs of acute abdomen
- Lethargy

CODES

ICD10

- R11.10 Vomiting, unspecified
- P92.1 Regurgitation and rumination of newborn

FAQ

- Q: What are the most common causes of nonbilious vomiting in an infant?
- A: Gastroesophageal reflux and milk protein allergy, although hypertrophic pyloric stenosis, sepsis, and malrotation must be considered.
- Q: What is appropriate management of a 6-month-old presenting with an episode of bilious emesis and lethargy?
- A: Referral for emergent abdominal ultrasound and surgical consult for possible intussusception
- Q: Is bilious emesis always associated with small bowel obstruction?
- A: Repeated episodes of vomiting can cause duodenal contents to reflux into the stomach resulting in bile-stained emesis without small bowel obstruction. Nevertheless, evaluation should include high suspicion and workup for possible obstruction.

VON WILLEBRAND DISEASE

Char Witmer

BASICS

DESCRIPTION

- An inherited bleeding disorder caused by either a quantitative or qualitative defect of the von Willebrand protein
- Characterized by mucocutaneous bleeding or bleeding after surgical procedures

EPIDEMIOLOGY

Prevalence

The prevalence of von Willebrand disease in the general pediatric population is estimated to be ~1%.

RISK FACTORS

Genetics

- The gene for von Willebrand factor is found on chromosome 12.
- Type 1 (see “[Pathophysiology](#)”) follows an autosomal dominant inheritance pattern with variable penetrance.
- Type 2 can be autosomal dominant or recessive.
- Type 3 follows an autosomal recessive inheritance pattern.

GENERAL PREVENTION

- Avoid contact sports.
- For patients with recurrent epistaxis, measures should be taken to avoid drying of the mucosa by applying petroleum jelly, humidifying the air, and reducing trauma to the nasal mucosa by keeping the fingernails short and discouraging nose picking.
- It may be advisable for patients to wear an emergency ID bracelet indicating that they have von Willebrand disease in the event they are involved in an accident that renders them unconscious.
- Avoid medications that negatively affect platelet function (i.e., ibuprofen, aspirin).

- Combination oral contraceptive pills are very effective for some patients with menorrhagia.
- Appropriate hemostatic therapy is needed prior to dental or surgical procedures to prevent bleeding.

PATHOPHYSIOLOGY

- Von Willebrand factor is a large multimeric protein that allows platelets to adhere to sites of endothelial injury, initiating the primary step in hemostasis—formation of the platelet plug.
- Von Willebrand factor also serves as a carrier for factor VIII in the peripheral circulation, protecting it from degradation. Deficiency of von Willebrand factor results in a shorter factor VIII half-life, causing a lower level of circulating factor VIII.
- When von Willebrand factor is either deficient or defective, primary hemostasis is compromised, resulting in a bleeding diathesis characterized by easy bruising, frequent epistaxis, menorrhagia, and prolonged bleeding following surgical or dental procedures.
- Acquired forms of von Willebrand disease have been described in association with hypothyroidism, Wilms tumor, other neoplasms, cardiovascular disorders with increased shear stress (aortic stenosis), myeloproliferative disorders, uremia, and medications, including ciprofloxacin, griseofulvin, and valproate therapy.
- Classification: There are three major categories of von Willebrand disease:
 - Type 1
 - Mild to moderate quantitative deficiency
 - The most common type, accounting for 70–80% of patients
 - Generally a mild bleeding disorder
 - Type 2
 - Qualitative deficiency of von Willebrand factor
 - Diagnosed in 15–20% of patients
 - Tend to have more significant bleeding symptoms than in type 1
 - Type 2 von Willebrand disease is further classified into four subtypes.
 - Type 2A: loss of the intermediate- and high-molecular-weight multimers. The loss is secondary to either abnormal assembly or

secretion of multimers or increased proteolytic degradation. The multimer deficiency results in decreased platelet binding.

- Type 2B: an abnormal von Willebrand factor that spontaneously binds to normal platelets, resulting in accelerated clearance of these platelets and loss of high-molecular-weight multimers. This can result in mild thrombocytopenia.
- Type 2N: The abnormal von Willebrand factor does not bind factor VIII optimally. This decrease in binding results in a shorter plasma half-life of factor VIII, resulting in reduced plasma factor VIII levels. Type 2N can be confused with mild hemophilia.
- Type 2M: The abnormal von Willebrand factor fails to bind normally to platelets. Normal multimers
- Type 3
 - Near-complete quantitative deficiency of von Willebrand factor, which also results in a secondary deficiency of factor VIII
 - Accounts for <5% of patients and results in a severe bleeding disorder

DIAGNOSIS

HISTORY

- A family history of von Willebrand disease or bleeding tendency is an important question in the evaluation for von Willebrand disease. However, be aware that variation in frequency and severity of bleeding symptoms can occur from person to person, even within an affected family.
- Bruising is common, with increased quantity, increased size (>5 cm), and often in unusual locations with minimal trauma.
- Recurrent and/or prolonged epistaxis
- Menorrhagia occurs in 70–90% of women with von Willebrand disease.
- Excessive posttraumatic or postsurgical bleeding

PHYSICAL EXAM

- Bruises: increased number, size, and/or unusual location

- May be entirely normal

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Screening tests for a bleeding disorder:
 - Prothrombin time (PT) is normal in von Willebrand disease.
 - Activated partial thromboplastin time (aPTT) may be prolonged if there is a decrease in factor VIII levels but can be normal.
 - Platelet count is normal except in type 2B patients, who may have mild thrombocytopenia.
 - Bleeding time is usually prolonged but may be normal in patients with mild type 1 von Willebrand disease (not recommended as a screening test).
 - Platelet function assay (PFA)-100 is usually prolonged but may be normal in mild type 1 von Willebrand disease (not recommended as a screening test).
- Specific tests for von Willebrand disease include the following:
 - Von Willebrand factor antigen: quantitation of von Willebrand factor by immunoassay
 - Von Willebrand factor activity (ristocetin cofactor): assesses the function of von Willebrand factor using the antibiotic ristocetin, which induces platelet aggregation in the presence of von Willebrand factor
 - Factor VIII: factor VIII clotting activity
 - Von Willebrand factor multimers: multiple molecular forms of von Willebrand factor evaluated on agarose gel
 - Multimer analysis is important in delineating the type of von Willebrand disease. Do not send as part of the initial screening for von Willebrand disease.

DIFFERENTIAL DIAGNOSIS

- Primary hemostatic disorders
 - Platelet function abnormalities, congenital thrombocytopenia
 - Mild inherited coagulation factor deficiencies
 - Hemophilia A
- Acquired and secondary hemostatic disorders

- Liver disease
- Uremia
- Acquired thrombocytopenia
- Drugs that affect platelet function
- Acquired factor inhibitors (extremely rare in children)
- Connective tissue disorders
 - Ehlers-Danlos syndrome
 - Scurvy
- Prolonged aPTT but no bleeding symptoms
 - Inhibitor
 - Factor XII deficiency

ALERT

- The diagnosis of von Willebrand disease is not always straightforward.
- Because of normal physiologic variation in plasma levels of von Willebrand factor, repeated measurements over time may be necessary to establish the diagnosis.
- Conditions that may increase von Willebrand factor levels:
 - The newborn period
 - Surgery
 - Liver disease
 - Hyperthyroidism
 - High-stress states
 - Pregnancy
 - Inflammatory or infectious disease
 - Steroids
 - Oral contraceptives (high dose)
 - Other estrogens

TREATMENT

GENERAL MEASURES

- There are several options for the management of bleeding in patients with von Willebrand disease. Superficial bleeding can usually be stopped by applying local pressure, ice, or topical thrombin,

particularly in type 1.

- There are two main approaches to systemic therapy in von Willebrand disease: increasing the release of endogenous von Willebrand factor or exogenous replacement of von Willebrand factor. The appropriate therapy depends on the type of von Willebrand disease and the clinical scenario.

MEDICATION

- Desmopressin (DDAVP) is a synthetic analog of vasopressin that stimulates endothelial cell release of von Willebrand factor. It is effective in patients who have a functional von Willebrand factor, as in type 1 von Willebrand disease. It may be used for some patients with type 2 von Willebrand disease but is ineffective in type 3:
 - Available in intravenous and intranasal formulations
 - An infusion of 0.3 µg/kg results in a 3–5-fold increase in von Willebrand factor and factor VIII; nasal administration is slightly less effective.
 - Side effects include facial flushing, light-headedness, or nausea.
 - Prior to use in a surgical setting, patients should have a trial to demonstrate an appropriate response (10% of patients do not respond).
 - May worsen thrombocytopenia in type 2B; it is not recommended
 - DDAVP may not be useful when prolonged hemostasis is required. After 24–48 hours, there is depletion of stored von Willebrand factor, causing it to be ineffective (tachyphylaxis).
 - It is important to remember that DDAVP will also cause fluid retention and, in some cases, hyponatremia. This can be avoided with fluid restriction for 24 hours following treatment.
- Factor concentrates
 - Humate-P or Alphanate
 - Plasma-derived, intermediate-purity factor VIII concentrate products with adequate levels (especially large multimers) of von Willebrand factor
 - Therapy of choice for some patients with type 2 von Willebrand disease and all patients with type 3 von Willebrand disease
 - Useful in type 1 von Willebrand disease when prolonged hemostasis

is necessary

- Antifibrinolytics: aminocaproic acid or tranexamic acid
 - Stabilize the fibrin clot by inhibiting the physiologic process of clot lysis
 - Best for oral mucosal bleeding

ONGOING CARE

PROGNOSIS

- Von Willebrand disease type 1 is often a very mild bleeding disorder and may go undetected.
- Most patients with von Willebrand disease have a normal life expectancy and, with proper education and treatment, minimal risk for permanent disability.
- Type 3 von Willebrand disease is a severe bleeding disorder, and life-threatening hemorrhage can occur.

COMPLICATIONS

- Significant perioperative bleeding can occur, especially with tonsillectomy, but the most common complications are recurrent epistaxis, prolonged bleeding with cuts and abrasions, and menorrhagia.
- Patients with type 3 von Willebrand disease have a more severe bleeding disorder and can have bleeding complications similar to those seen in hemophilia such as hemarthroses and intracranial hemorrhage.

CODES

ICD10

D68.0 Von Willebrand's disease

FAQ

- Q: What sports activities can a person with von Willebrand disease participate in safely?
- A: People with type 1 von Willebrand disease can participate in most activities, although it is usually advised to avoid situations in which significant trauma takes place, like contact sports such as football or boxing. Patients with type 3 von Willebrand disease should avoid activities with moderate trauma. For type 2 patients, the risk of bleeding varies.
- Q: Is life expectancy lower in people with von Willebrand disease?
- A: For most patients with von Willebrand disease, their life expectancy and quality of life will be normal.
- Q: Are there any medications contraindicated in a patient with von Willebrand disease?
- A: Aspirin should not be given, as it interferes with platelet function. Nonsteroidal anti-inflammatory agents cause a milder effect on platelets and should also be avoided when possible. Patients should use acetaminophen for fever or pain.

WARTS

Prina P. Amin • Erika Abramson

BASICS

DESCRIPTION

- Warts (verrucae) are common, benign, and frequently self-limited epithelial growths caused by human papillomavirus (HPV) infection of keratinocytes.
- Types of warts
 - Cutaneous
 - Common warts (verruca vulgaris)
 - Flat warts (verruca plana)
 - Plantar warts (weight-bearing)
 - Anogenital
 - Laryngeal (laryngeal papillomatosis)

EPIDEMIOLOGY

Prevalence

- Cutaneous warts
 - Mostly affect children and young adults
 - Affect girls more than boys
 - 5.3% prevalence from age 6 to 15 years of age
 - Up to 1/3 of school-aged children have had warts.
- Anogenital warts
 - Exact prevalence in children and adolescents is unknown.
 - Approximately 1% of sexually active adults have external genital warts.
- Laryngeal warts
 - Rare with no known cure; transmission occurs in utero or through birth canal

RISK FACTORS

- Direct or indirect contact
- Autoinoculation can cause persistent infection and spread.

- Use of communal pool surfaces, bathrooms, and shower rooms increases risk.
- Areas of skin trauma and breakdown have increased susceptibility to HPV infection.
- Regularly walking barefoot outside also increases risk.
- Excessive foot perspiration
- Immunosuppressed patients, particularly transplant patients, are highly vulnerable.
- Individual susceptibility factors related to developing warts after exposure to HPV are less clear.

GENERAL PREVENTION

- Cutaneous warts
 - Use protective footwear in warm, moist environments and communal areas.
 - Wear cotton socks and change twice a day, especially if significant perspiration.
 - Avoid sharing nail files.
 - Avoid scratching and nail-biting to prevent autoinoculation.
- Anogenital warts
 - Avoid sexual contact with multiple partners.
 - Condoms may be protective.
 - Quadrivalent HPV vaccine protects against HPV subtypes 6, 11, 16, and 18.
 - Recommended universally for males and females, ages 9–26 years

PATHOPHYSIOLOGY

- Warts are caused by HPV infection of the epithelium.
- HPV replication leads to cell proliferation and formation of characteristic lesions.

ETIOLOGY

- Over 150 subtypes of HPV exist.
- Certain subtypes have a predilection for particular body sites and produce characteristic lesions:
 - Plantar and common palmar warts often caused by HPV 1 and 2
 - Anogenital warts commonly caused by HPV 6, 11, 16, 18, 31, and

- Laryngeal papillomatosis is associated with HPV 6 and 11.

DIAGNOSIS

HISTORY

- Ask about risk factors for warts.
- Assess history of warts in close contacts (caregiver).
- Assess for immunosuppression.
- For anogenital warts: Take detailed sexual history and assess risk for sexual abuse.
- Assess symptoms: Warts are usually asymptomatic with the exception of plantar warts or warts near nails, which may be painful.
- Assess duration: Warts may be present for months to years without intervention.

PHYSICAL EXAM

- Common warts (*verruca vulgaris*)
 - Rough keratotic papules and nodules that can be single or grouped
 - Often dome-shaped
 - Appear anywhere but most often affect fingers, hands, knees, and elbows
- Flat warts (*verruca plana*)
 - Generally 2–4 mm, slightly elevated, flat-topped lesions with minimal scale
- Plantar warts (weight-bearing warts)
 - Thick, hyperkeratotic lesions that may be tender to palpation
 - Tend to occur at pressure points on soles of feet
 - May have punctate black dots representing thrombosed capillaries
 - Disrupt normal skin markings
- Anogenital warts
 - Usually multiple, clustered soft lesions that are pink or gray
 - 4 morphologic types: condyloma acuminata (cauliflower-shaped), smooth papules (dome-shaped, flesh-colored), keratotic papules (resemble common warts), flat warts

- Laryngeal warts (laryngeal papillomatosis)
 - Visible only under direct airway examination
 - Children may present with stridor, hoarseness, and signs of airway obstruction.
 - In children, laryngeal warts are diagnosed most often between 2 and 3 years, with most children presenting before age 5 years.

DIAGNOSTIC TESTS & INTERPRETATION

- Diagnosis is based on visual identification.
- Biopsy may be indicated when the diagnosis is uncertain or warts are resistant to treatment.
- In anogenital warts, testing for other sexually transmitted infections is recommended.

DIFFERENTIAL DIAGNOSIS

- Common warts
 - Molluscum contagiosum
 - Moles
 - Skin tag
 - Squamous cell carcinoma or melanoma
- Flat warts
 - Lichen planus
 - Lichenoid keratosis
- Plantar warts
 - Callus
 - Corns
 - Squamous cell carcinoma or melanoma
 - Foreign body
- Anogenital warts
 - Pearly penile papules
 - Molluscum contagiosum
 - Condylomata lata (secondary syphilis lesions)
 - Vulvar carcinoma
 - Lichen planus
 - Squamous cell carcinoma

ALERT

- Any child or adolescent with anogenital warts should prompt consideration for sexual abuse and consultation with a child abuse specialist as necessary.
- Testing for other sexually transmitted infections should occur in any pediatric patient with anogenital warts.
- In any patient with extensive HPV infection, consideration must be given to underlying immunodeficiencies including HIV.

TREATMENT

- General
 - Warts are often self-limited and resolve without treatment.
 - 2/3 of warts will resolve within 2 years with no treatment.
 - Earlier treatment may be warranted for warts that are painful or cause significant social stigma.
- Cutaneous warts
 - Salicylic acid
 - 1st-line therapy for cutaneous warts
 - Over-the-counter (OTC) formulations contain 5–27% salicylic acid and are applied topically 1–2× daily for up to 12 weeks.
 - Prescription strength 40% adhesive plaster is available to be applied for 24–48 hours and are particularly useful for plantar warts.
 - Repetitive filing of the wart with either an emery board, pumice stone, or metal file and soaking the wart for 10–20 minutes prior to treatment may improve response to topical salicylic acid.
 - Applying a thin layer of petrolatum around the wart to protect the surrounding healthy tissue may prevent pain during treatment.
 - Duct tape or moleskin
 - Used as 1st-line therapy
 - May be helpful, although studies on effectiveness are mixed
 - To use, cut tape or moleskin approximately ¼ inch larger than wart and cover for 6 days.
 - After 6 days, remove, soak wart, and file with an emery board, pumice stone, or metal file; leave uncovered overnight.

- Reapply duct tape in 6 day cycles until resolution.
- Cryotherapy
 - 2nd-line therapy
 - Involves freezing the wart using one of several methods, the most commonly used being liquid nitrogen
 - Can be painful and is more expensive than 1st-line agents
 - Fewer data support its efficacy as compared to salicylic acid.
 - Most commonly used in the office although newer OTC cryotherapy products are available.
- 3rd-line therapies are generally performed in conjunction with a pediatric dermatologist.
 - Phototherapy
 - Immunotherapies
 - Intralesional therapies
 - Antimitotic therapies
 - Curettage
 - Laser ablation
- Anogenital warts
 - Treatment issues
 - Main goal of treatment is to remove symptomatic warts.
 - Most warts will clear within 3 months after initiation of therapy.
 - Treatment does not eradicate HPV, prevent recurrence, or reduce cancer risk.
 - Podofilox (0.5% gel) or imiquimod (5% cream) are 1st-line therapy (avoid in pregnancy).
 - Podofilox gel is applied topically q12h for 3 days; no treatment for 4 days; then repeat cycles until warts disappear; avoid unprotected sexual activity during treatment due to possible irritant effect.
 - Imiquimod: for patients aged 12 years and older; apply 3×/week at bedtime; wash off 6–10 hours later; treat until resolution
 - Cryotherapy for anogenital warts is an option for experienced providers.
 - 2nd-line options include podophyllin resin, intralesion treatments, trichloroacetic acid, surgical removal, laser therapy, and

photodynamic therapy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Patients should be seen at regular intervals to assess clearance of the lesions and monitor for side effects.

Issues for Referral

Consider referral to pediatric dermatology if

- Lesions are atypical or extensive.
- Lesions progress during therapy.
- Multiple failed treatment occurs.
- Lesions are located on the face.
- Frequent or prompt recurrence occurs.
- Warts are pigmented, indurated, ulcerated, or fixed to underlying structures.
- Individual warts are greater than 1 cm.
- Patients are immunocompromised.

Consider referral to a child abuse specialist if anogenital warts are present
AND

- Caregivers suspect sexual abuse.
- A sexual predator has access to the child.
- Child discloses abuse.
- Child is older than 48 months of age.
- Any other sexually transmitted infection is detected.
- Physical exam suggests any type of abuse.
- Provider is uncomfortable with evaluating for sexual abuse.

PROGNOSIS

- 2/3 of warts clear without treatment within 2 years.
- However, early treatment is recommended while warts are small and few in number to prevent enlargement and spread.

COMPLICATIONS

- Bacterial infection such as cellulitis or abscess can occur if patients pick at warts.
- Other complications are generally related to treatment and can include pain and scarring.
- Malignant transformation to squamous cell carcinoma can rarely occur for both cutaneous and anogenital warts; this is most problematic in immunosuppressed patients.

CODES

ICD10

- B07.9 Viral wart, unspecified
- B07.0 Plantar wart
- A63.0 Anogenital (venereal) warts

FAQ

- Q: Do condoms protect against HPV?
- A: Condoms lower the risk of HPV; however, HPV can infect areas not covered by the condom and so condoms are not fully protective.
- Q: Does a patient with cutaneous warts need to be excluded from school or sports?

- A: No. Exclusion is not fully effective because asymptomatic transmission can occur. In addition, risk of transmission is low.
- Q: How can a callous and wart be differentiated?
- A: Careful paring with a #15 scalpel of a callous shows preserved skin markings and no bleeding. Paring of a wart often reveals black dots, which are thrombosed blood vessels.

WEIGHT LOSS

Mark F. Ditmar

BASICS

DESCRIPTION

Documented decrease in weight from a previous measurement. Outside of newborn period (weight loss in the first 2 weeks is common), acute illnesses resulting in fluid losses, and obese children voluntarily on a designed weight reduction program, weight loss is an unusual and worrisome symptom, regardless of the percentage decline.

DIAGNOSIS

HISTORY

Determine that weight loss is real and not due to scale error, different scales, different technique (e.g., clothed vs. unclothed).

- **Question:** Child's diet?
- **Significance:** A prospective 3-day dietary record can be useful for demonstrating insufficient caloric intake.
- **Question:** Age?
- **Significance:** The patient's age can very much indicate the most likely causes of weight loss to which questions about the history can be directed.
 - Patient <2 weeks old: physiologic weight loss, underfeeding, inappropriate feeding, inborn error of metabolism, congenital heart disease, gastroesophageal reflux
 - Patient <4 months old: malnutrition, improper formula preparation, cystic fibrosis, gastroesophageal reflux, pyloric stenosis, congenital heart disease, congenital adrenal hyperplasia, inborn error of metabolism
 - Patient 4 months–8 years old: chronic infection, cystic fibrosis, malabsorption, neglect/abuse, renal disease, liver disease, diabetes mellitus

- Patient >8 years old: eating disorder, chronic infection, neoplasm, renal disease, liver disease, substance abuse, diabetes mellitus, inflammatory bowel disease, collagen vascular disease
- **Question:** Vomiting, especially projectile?
- Significance: suggestive of intestinal obstruction, gastroesophageal reflux, inborn error of metabolism
- **Question:** Cramping, bloating, or abnormally greasy, voluminous stools?
- Significance: possible malabsorption
- **Question:** Tiring during feeding or difficulty feeding due to cough and dyspnea?
- Significance: suggests congestive heart failure in newborn/infant, hypothyroidism
- **Question:** Altered mental status, seizures, unusual body/fluid odors?
- Significance: possible inborn error of metabolism
- **Question:** Maternal history of multiple miscarriages, neonatal deaths, or consanguinity?
- Significance: possible inborn error of metabolism
- **Question:** Foreign travel?
- Significance: possible chronic infection (e.g., tuberculosis, parasitic disease)
- **Question:** History of severe infections, persistent candidal infections?
- Significance: possible immunodeficiency, congenital or acquired
- **Question:** Headaches, especially early morning?
- Significance: possible increased intracranial pressure, CNS malignancy
- **Question:** Increased appetite with weight loss?
- Significance: suggests hyperthyroidism, cystic fibrosis, pheochromocytoma
- **Question:** Polyuria, polydipsia, and polyphagia?
- Significance: possible new-onset diabetes
- **Question:** Concomitant delayed puberty?
- Significance: suggests chronic severe weight loss, pituitary abnormalities, anorexia nervosa
- **Question:** Fear of fatness, preoccupation with food, distorted body image, and/or amenorrhea?

- Significance: possible eating disorder
- **Question:** Chronic sadness or irritability, insomnia or hypersomnia?
- Significance: possible depression/affective disorder

PHYSICAL EXAM

- **Finding:** Hypothermia, bradycardia?
- Significance: suggests anorexia nervosa, hypothyroidism
- **Finding:** Tachycardia, resting?
- Significance: hyperthyroidism, pheochromocytoma, anemia, acute weight loss
- **Finding:** Orthostatic changes?
- Significance: significant weight loss, possibly acute
- **Finding:** Hypotension, resting?
- Significance: Addison disease, anorexia nervosa, significant acute dehydration
- **Finding:** Visual field abnormalities?
- Significance: suggests possible CNS malignancy
- **Finding:** Clubbing?
- Significance: suggests chronic cardiac, pulmonary, or intestinal disease
- **Finding:** Swollen joint?
- Significance: juvenile idiopathic arthritis, inflammatory bowel disease
- **Finding:** Significant abdominal distension?
- Significance: suggests celiac disease
- **Finding:** Enlarged liver and/or spleen?
- Significance: suggests malignancy, chronic infection, storage disease, inborn error of metabolism
- **Finding:** Muscle weakness?
- Significance: connective tissue disorder, electrolyte abnormality, muscular dystrophy

ALERT

- Be certain that the weight loss is real. In some studies, up to 25% of weight loss is artifactual, resulting from measurement errors (e.g., excessive movement of scale, dressed vs. undressed patient).
- Newborns with weight loss, especially at the 2-week visit, may manifest passivity and paradoxical lack of interest in feeding, although

the reason for their problem is malnourishment due to inadequate intake (often from improper positioning or too infrequent feedings). They may not act “hungry.” Observation of the feeding technique (by a practitioner with expertise or a lactation consultant for breastfed babies) is vital.

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** CBC for evidence of the following:
- Significance:
 - Anemia—macrocytic associated with folate/B₁₂ deficiency, microcytic with iron deficiency or chronic infection
 - Polycythemia—suggestive of chronic pulmonary or cardiac disease
 - Neutropenia—suggestive of hematologic malignancy, Shwachman syndrome, immunodeficiency
 - Lymphopenia—suggestive of immunodeficiency
 - Eosinophilia—suggestive of parasitic disease
 - Leukocytosis—suggestive of infection
 - Lymphoblasts—suggestive of leukemia
 - Thrombocytosis—suggestive of chronic infection, malignancy
- **Test:** serum electrolytes
- Significance: abnormalities in dehydration, adrenal insufficiency (low sodium, high potassium), renal disease, anorexia nervosa
- **Test:** BUN, creatinine
- Significance: abnormal in renal disease, dehydration
- **Test:** erythrocyte sedimentation rate
- Significance: may be elevated in inflammatory bowel disease, chronic infections, rheumatoid diseases
- **Test:** stool for occult blood and pH, reducing substances (Clinitest)
- Significance:
 - Occult blood suggests inflammatory bowel disease.
 - Low pH and positive reducing substances suggest malabsorption.
- **Test:** Urinalysis
- Significance:
 - Hematuria and/or proteinuria suggest renal disease.
 - Glycosuria suggests diabetes mellitus.
 - Very low specific gravity suggests diabetes insipidus, chronic renal

- failure, hypercalcemia.
- Pyuria suggests UTI.
- pH >6 suggests renal tubular acidosis (type I).
- **Test:** urine culture
- Significance: Evaluation for UTI
- **Test:** serum protein levels
- Significance: Very low levels imply impaired liver function, severe chronic weight loss, or protein malabsorption.
- **Test:** tuberculosis skin test
- Significance: possible chronic infection
- **Test:** liver function tests
- Significance: evaluation for hepatitis, chronic liver disease
- **Other tests:** Depending on age and clinical findings, other tests to consider include the following: thyroid function tests (TSH), sweat test, tests for malabsorption (e.g., lactose breath test, stool fat, stool for trypsin), tests for metabolic disease (e.g., plasma ammonia, lactate, serum/urine amino acids, urine organic acids), imaging studies (e.g., CT, MRI, bone scan), immunologic studies.

DIFFERENTIAL DIAGNOSIS

- Nutritional
 - Malnutrition
 - Dieting
 - Iron deficiency/zinc deficiency
 - Postoperative recovery
 - Inability to eat (new orthodontic appliances, loss of teeth, chronic mouth ulcerations)
- Congenital/anatomic
 - Congenital heart disease
 - Pyloric stenosis
 - GI malformation (duodenal atresia, annular pancreas, and volvulus)
 - Short bowel syndrome
 - Lymphangiectasia
 - Superior mesenteric artery syndrome
 - Gastroesophageal reflux
 - Immunodeficiency disorders

- Hirschsprung disease
- Infectious
 - UTI
 - Tuberculosis
 - Stomatitis
 - Osteomyelitis
 - HIV
 - Hepatitis
 - Parasitic disease
 - Abscess, intraabdominal
 - Gastroenteritis
 - Postinfectious malabsorption
 - Pericarditis
 - Histoplasmosis
 - Acute severe febrile illness (pyelonephritis, pneumonia, septic arthritis)
- Tumor
 - Diencephalic syndrome
 - Leukemia
 - Lymphoma
 - Pheochromocytoma
 - Other neoplasms
- Endocrine
 - Diabetes mellitus
 - Diabetes insipidus
 - Hyperthyroidism
 - Adrenal insufficiency
 - Congenital adrenal hyperplasia
 - Hypopituitarism
 - Hypercalcemia
- Genetic/metabolic
 - Cystic fibrosis
 - Shwachman-Diamond syndrome
 - Lactose intolerance
 - Renal tubular acidosis

- Chronic renal failure
- Inborn errors of metabolism
- Storage diseases
- Muscular dystrophy
- Lipodystrophy
- Allergic/inflammatory
 - Inflammatory bowel disease
 - Juvenile idiopathic arthritis
 - Systemic lupus erythematosus
 - Sarcoidosis
 - Pancreatitis
 - Hepatitis
 - Celiac disease (gluten enteropathy)
- Psychiatric
 - Rumination syndrome
 - Depression/affective disorders
 - Anorexia nervosa/bulimia nervosa
- Toxic, environmental, drugs
 - Lead poisoning
 - Mercury poisoning
 - Vitamin A poisoning
 - Chronic methylphenidate, dextroamphetamine, or valproic acid use
 - Substance abuse, especially amphetamines and crack cocaine
- Trauma
 - Chronic subdural hematomas
- Miscellaneous
 - Child abuse
 - Chronic illness (e.g., pulmonary disease, renal disease)
 - Cerebral palsy
 - Factitious (e.g., scale error)

ALERT

Emergency care is indicated for the following:

- Significant dehydration
 - Abnormal vital signs with orthostasis, decreased urine output, decreased skin turgor, delayed capillary refill (>3 seconds)

- Mandates cardiovascular support (IV hydration) and a more urgent diagnosis (e.g., inborn error of metabolism, obstructive GI disease, congenital adrenal hyperplasia, diabetic ketoacidosis)
- Abnormal mental status or significant lethargy which may be seen in the following:
 - Severe dehydration
 - Adrenal insufficiency
 - Hypoxic states
 - Toxic ingestions
 - Renal or respiratory failure
 - Increased intracranial pressure
 - Severe electrolyte abnormalities
- Increasing vomiting in the setting of known weight loss in infants
 - High risk for dehydration, hypoglycemia, and electrolyte abnormalities
 - Need to evaluate for treatable conditions (e.g., obstructive GI disease, inborn errors of metabolism, congenital adrenal hyperplasia, congenital heart disease) in which a delay is life-threatening
- Severe malnutrition (weight loss >20% of ideal body weight)
 - High risk for metabolic derangements, including dysrhythmias secondary to electrolyte abnormalities
- Aggressive evaluation is warranted.

TREATMENT

APPROACH TO THE PATIENT

- Establish if the weight loss is voluntary or involuntary.
- Determine the acuity or chronicity and severity of weight loss, and the need for hospitalization.
- Attempt to narrow the diagnostic possibilities by history and physical exam, particularly by assessing if the loss might be attributable to diminished intake, diminished absorption, or increased requirements.
- Treatment is then based on the most likely diagnosis following evaluation.

CODES

ICD10

- R63.4 Abnormal weight loss
- K21.9 Gastro-esophageal reflux disease without esophagitis
- E46 Unspecified protein-calorie malnutrition

FAQ

- Q: How common is weight loss in the first 2 weeks of life?
- A: Formula-fed babies may lose up to 7% of birth weight and breastfed newborns up to 10% before regaining their birth weight by 2 weeks of age. An infant who has not regained his or her birth weight by 2 weeks requires evaluation and intervention.
- Q: How important a finding is weight loss?
- A: Involuntary weight loss is a diagnostic exigency—a cause must be found or the loss self-resolved. If a diagnosis is not uncovered in the setting of continued weight loss, referral to a pediatric diagnostic center is indicated.

WEST NILE VIRUS (AND OTHER ARBOVIRUS ENCEPHALITIS)

Jessica Newman • Jason Newland

BASICS

DESCRIPTION

- Viruses transmitted by an arthropod vector that can cause CNS infections, undifferentiated febrile illness, acute polyarthropathy, and hemorrhagic fevers
- Most arboviral infections are asymptomatic.
- West Nile virus (WNV) is an arbovirus in the flavivirus family.
- WNV was first recognized in the United States in 1999 during an outbreak of encephalitis in New York City.
- More than 150 arboviruses are known to cause human disease.
- Other arboviruses can produce similar syndromes or acute hemorrhagic fevers.

EPIDEMIOLOGY

- Arboviruses are spread by mosquitoes, ticks, and sand flies. The major vector for WNV in the United States is the Culex mosquito. WNV has been spread through blood transfusions, transplanted organs, and, rarely, intrauterine.
- Arboviruses are maintained in nature through cycles of transmission among birds, horses, and small animals. Humans and domestic animals are infected incidentally as “dead-end” hosts.
- Disease among birds has been a hallmark of WNV in the United States and has served as a sensitive surveillance indicator of WNV activity.
- Each North American arbovirus has specific geographic distributions and is associated with a different ratio of asymptomatic to clinical infections. These agents cause disease of variable severity and have distinct age-dependent effects. WNV has now been identified throughout the United States and is also found in Europe, Africa, and Asia.

Incidence

- The peak incidence of arboviral encephalitis occurs during the late summer and early fall. Seasonality depends on the breeding and feeding seasons of the arthropod host.
- WNV is the leading cause of arboviral CNS disease. Encephalitis is most commonly seen in older adults, generally aged >60 years. Cases of WNV in children are unusual.
- Fewer than 10 cases each of Eastern equine encephalitis and Western equine encephalitis are reported nationally each year. Eastern equine encephalitis tends to produce a more fulminant illness than LaCrosse or Western equine encephalitis.

GENERAL PREVENTION

- Public health department efforts focus on surveillance of viral activity to predict and prevent outbreaks:
 - Active bird surveillance to detect the presence of WNV activity
 - Active mosquito surveillance to detect viral activity in mosquito populations
 - Passive surveillance by veterinarians and human health care professionals to detect neurologic illnesses consistent with encephalitis
 - Screening of blood and organ donors
- Personal precautions to avoid mosquito bites including use of repellents, protective clothing, and screens; avoiding peak feeding times (dawn and dusk); and installation of air conditioners
- Coordination of mosquito control programs in endemic infection areas
- Vaccines for prevention of most arbovirus infections are not available. A vaccine is available for Japanese encephalitis and yellow fever (YF) for travelers to endemic areas who are planning prolonged stays.
- Infection control measures
 - Standard precautions are recommended for the hospitalized patient.
 - Respiratory precautions are recommended when vector mosquitoes are present.
 - Patients with dengue and YF can be viremic and should be protected against vector mosquitoes to avoid potential transmission.

PATHOPHYSIOLOGY

- The incubation period for WNV and other arboviral encephalitis agents is 2–14 days (up to 21 days in immunocompromised hosts).
- The incubation period reflects the time necessary for viral replication, viremia, and subsequent invasion of the CNS.
- Virus replication begins locally at the site of the insect bite; transient viremia leads to spread of virus to liver, spleen, and lymph nodes. With continued viral replication and viremia, seeding of other organs including the CNS occurs.
- Virus can rarely be recovered from blood within the 1st week of onset of illness but not after neurologic symptoms have developed.

ETIOLOGY

- Arboviruses can be divided into 2 groups based on the predominant clinical syndrome.
- In the United States, 7 arboviruses are important causes of encephalitis: WNV, California encephalitis virus (LaCrosse strain), Eastern equine encephalitis, Western equine encephalitis, St. Louis encephalitis, Powassan encephalitis virus, and Venezuelan equine encephalitis virus.
- Arboviruses such as YF, dengue fever, and Colorado tick fever typically cause acute febrile diseases and hemorrhagic fevers and are not characterized by encephalitis.
- Clinical manifestations of WNV
 - Asymptomatic: most common
 - Self-limited febrile illness: 67% of symptomatic cases
 - Neuroinvasive disease: aseptic meningitis, encephalitis, or flaccid paralysis—<1% cases

DIAGNOSIS

HISTORY

- The diagnosis of arboviral infections of the CNS is difficult.
- Characteristic epidemiology that suggests a specific etiology is an important part of the history.
- The season of disease, prevalent diseases within the community, and

animal exposures may provide clues to the diagnosis:

- Enteroviral infections are seen in the warmer months (summer and early fall) in temperate climates.
- Mosquito propagation in damp climates or standing water during the summer months may increase the likelihood of arthropod-borne viruses.
- History of an animal bite or bat exposure may suggest the possibility of rabies.
- WNV (symptomatic infection) is characterized by sudden onset of fever, headache, myalgias, muscle weakness, and GI symptoms (nausea, vomiting, or diarrhea).
- Neuroinvasive WNV can be characterized by neck stiffness and headache, mental status changes, movement disorders, or flaccid paralysis.
- Encephalitis caused by arboviruses is characterized by acute onset of fever and headache in almost all patients. Associated symptoms may include seizures, altered consciousness, disorientation, and behavioral disturbances.

PHYSICAL EXAM

- Neurologic signs are more commonly diffuse but may be focal. These clinical findings can help to distinguish patients with meningitis, which is characterized by nuchal rigidity and fever usually without an altered sensorium.
- Other signs possibly observed in WNV infection:
 - A rash is seen in ~50% of patients and is described as nonpruritic, roseolar, or maculopapular on the chest, back, and arms, which lasts 1 week.
 - Diffuse lymphadenopathy is also common.
- Neurologic examination in WNV infection may reveal motor weakness or flaccid paralysis, increased deep tendon reflexes and extensor plantar responses, and tremor or abnormal movement of extremities.

DIAGNOSTIC TESTS & INTERPRETATION

The diagnosis of arboviral encephalitis depends on the recognition of epidemiologic risk factors and typical signs and symptoms with the aid of

laboratory and radiographic studies.

Lab

- Routine laboratory tests
 - CBC typically reveals a mild leukocytosis.
 - Mild increase in erythrocyte sedimentation rate (ESR)
 - Mild to moderate CSF pleocytosis, predominately mononuclear cells
 - Elevated CSF protein
 - Normal CSF glucose
- Serology
 - IgM and IgG enzyme-linked immunosorbent assay (ELISA) or indirect fluorescent antibody (IFA) for WNV and other arboviruses
 - The diagnosis of arbovirus encephalitis is made by 1 of the following:
 - Detection of virus-specific IgM antibodies in the CSF is confirmatory.
 - A 4-fold rise in serum antibody titers is confirmatory. Acute-phase titers should be collected 0–8 days after onset of symptoms. Convalescent phase titers should be collected 14–21 days after acute specimen. A single negative acute-phase specimen is inadequate for diagnosis, but a positive test can provide evidence of recent infection.
 - Isolation of the virus from tissue, blood, or CSF
 - Polymerase chain reaction (PCR) to detect viral RNA

Imaging

- Imaging studies such as MRI or CT can assist in ruling out other potential causes of encephalopathy or encephalitis.
- MRI has proved useful in differentiating postinfectious encephalomyelitis from acute viral encephalitis. The former is characterized by enhancement of multifocal white matter lesions.

Diagnostic Procedures/Other

- EEG
 - Diffuse generalized slowing of brain waves
 - Periodic high-voltage spike waves originating in the temporal lobe

region and slow-wave complexes at 2–3-second intervals are suggestive of herpes simplex virus infection.

DIFFERENTIAL DIAGNOSIS

Infectious

- Viral
 - Herpes simplex virus
 - Enterovirus
 - HIV
 - HHV-6
 - Epstein-Barr virus
 - Cytomegalovirus
 - Lymphocytic choriomeningitis virus
 - Rabies
 - Mumps
 - Influenza
 - Adenovirus
- Nonviral
 - Cat-scratch disease (*Bartonella henselae*)
 - *Mycoplasma pneumoniae*
 - Postinfectious encephalomyelitis: generally follows a vague viral syndrome, usually upper respiratory tract, by days to weeks
 - Abscess/subdural empyema
 - Meningitis
 - Tuberculous
 - Cryptococcal or other fungal (histoplasmosis, coccidioidomycoses, blastomycoses)
 - Bacterial
 - *Listeria*
 - Toxoplasmosis
 - *Plasmodium falciparum* infection (malaria)
 - Parasites (cysticercosis, echinococcus, amebiasis, trypanosomiasis)

Noninfectious: tumor, carcinomatous meningitis, systemic lupus erythematosus, sarcoidosis, vasculitis, hemorrhage, toxic encephalopathy, metabolic disorders

TREATMENT

GENERAL MEASURES

- No specific antiviral therapy is available.
- Supportive therapy including cardiorespiratory function, fluid and electrolyte balance, seizure control, and reduction of intracranial pressure is important.
- Consider intravenous immunoglobulin (IVIG)/plasmapheresis for associated Guillain-Barré syndrome; IVIG has been used in cases of flaccid paralysis with some response.
- Recovery can be seen after prolonged periods of coma.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Neurobehavioral follow-up should be considered in children with severe or complicated disease.
- If WNV is diagnosed during pregnancy, detailed fetal ultrasound (US) should be considered 2–4 weeks after illness onset with evaluation for congenital anomalies and neurologic deficits.
- Infant serum should be tested for WNV IgM at birth and 6 months with IgG at 6 months.

PROGNOSIS

- Prognosis for recovery depends on the specific infecting agent and host factors such as age and underlying illness.
- Eastern equine and Japanese encephalitis have the worst prognoses, with mortality occurring in 30% of cases.

COMPLICATIONS

- Optic neuritis
- Seizures
- Coma
- Death

- Guillain-Barré syndrome
- Severe neurologic sequelae
- Myocarditis
- Pancreatitis
- Hepatitis

ADDITIONAL READING

CODES

ICD10

- A92.30 West Nile virus infection, unspecified
- A92.31 West Nile virus infection with encephalitis
- A85.2 Arthropod-borne viral encephalitis, unspecified

FAQ

- Q: Should testing for arboviruses, including WNV, be performed on all patients with encephalitis?
- A: Diagnostic testing for arboviruses is not recommended for all patients with encephalitis. The prevalence of these diseases is low, and

the diagnosis of more common causes of childhood encephalitis (e.g., herpes simplex virus) should be pursued initially. Patients with no other identifiable cause of encephalitis who have epidemiologic risk factors such as geographic location, season, and exposure history suggestive of arbovirus encephalitis should be evaluated. Testing of patients with aseptic meningitis or Guillain-Barré syndrome is low yield.

WHEEZING

Samuel B. Goldfarb • Lee J. Brooks

BASICS

DESCRIPTION

Wheezing is a continuous sound that is caused by turbulent airflow through an obstructed airway.

- Often described as musical in nature and with a variable pitch
- Wheezing is an expiratory sound; stridor is an inspiratory sound.
- Wheezing occurs from obstruction in the intrathoracic airway, whereas stridor is caused by an obstruction in the extrathoracic airway.
- If heard in both inspiration and expiration, there may be a fixed obstruction or separate lesions in both the intrathoracic and extrathoracic airways.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Extrathoracic (usually results in stridor or stertor rather than wheezing)

- Nasal/nasopharynx
 - Acute: nasal turbinate edema or secretions, foreign body
 - Chronic: adenoidal enlargement, nasal polyps, choanal stenosis, midface hypoplasia
- Oropharynx
 - Acute: peritonsillar abscess, retropharyngeal abscess, palatine tonsillitis
 - Chronic: adenotonsillar hypertrophy, macroglossia, micrognathia
- Hypopharynx
 - Acute: acute nasal, nasopharyngeal, or oropharyngeal obstruction
 - Chronic: hypopharyngeal hypotonia, glossoptosis, obesity, neoplasia
- Larynx
 - Acute: laryngospasm, laryngotracheobronchitis (croup), epiglottitis,

- foreign body (large and irregular)
- Chronic: laryngomalacia, papillomatosis, hemangioma, granuloma, congenital cyst or web, laryngocele
- Glottis
 - Acute: vocal cord paralysis or paresis, vocal cord inflammation or polyp, psychogenic wheezing
 - Chronic: paradoxical vocal cord motion (vocal cord dysfunction); psychogenic wheezing; brainstem compression; injury to the vagus, glossopharyngeal, or recurrent laryngeal nerves; papillomatosis
- Subglottis/extrathoracic trachea
 - Acute: laryngotracheobronchitis (croup), bacterial, rachitic, recent endotracheal extubation
 - Chronic: subglottic stenosis (congenital or after prolonged intubation), papillomatosis

Intrathoracic

- Trachea (extrinsic compression)
 - Acute: uncommon
 - Chronic
 - Vascular: vascular ring/sling, compression by an aberrant pulmonary artery
 - Cardiac: left main bronchus compression, recurrent laryngeal nerve compression “cardiovocal syndrome”
 - Anterior mediastinum: lymphoma, thymoma, teratoma
 - Middle mediastinum: lymphoma, lymphadenopathy (tuberculosis, mycotic infection, sarcoidosis)
 - Posterior mediastinum: neurogenic tumors, esophageal duplication or cyst, bronchogenic cyst
- Trachea (intramural lesions)
 - Acute: uncommon
 - Chronic: tracheomalacia
 - Congenital: cartilaginous defect (Campbell-Williams syndrome), muscular defect (Mounier-Kuhn syndrome), s/p tracheoesophageal fistula (TEF) repair, external compression/distortion, complete tracheal rings
 - Acquired: chronic inflammation (recurrent infection,

gastroesophageal reflux, recurrent aspiration), prolonged positive pressure ventilation, external compression

- Trachea (intraluminal lesions)
 - Acute: foreign body (irregularly shaped and elongated), bacterial tracheitis (with chronic tracheostomy tube usage)
 - Chronic: tracheal granulomas, hemangioma, papillomatosis, tracheal web
- Bronchi/bronchioles
 - Acute: viral bronchiolitis, bronchopneumonia, foreign body (small, smooth shape), immune defect (transient hypogammaglobulinemia of the newborn is most common), granuloma, neoplasia
 - Chronic: asthma, bronchopulmonary dysplasia, bronchomalacia, carcinoid, adenoma

APPROACH TO THE PATIENT

- Phase 1: Determine the severity of the patient's general status and degree of respiratory distress and triage accordingly.
- Phase 2: Construct a differential diagnosis.
- Phase 3: Initiate appropriate therapies.

HISTORY

- **Question:** Pattern of the wheezing?
- Significance:
 - A rapid onset suggests a foreign body or a postexposure exacerbation of asthma.
 - A slow onset suggests an infection.
 - Periods of recurrent wheezing suggest asthma.
 - Nocturnal and early morning wheezing or coughing are consistent with gastroesophageal reflux, sinusitis, and/or sensitivity to common bedroom allergens.
 - Wheezing in association with or soon after a meal can be seen in swallowing dysfunction, gastroesophageal reflux, or, less commonly, tracheoesophageal fistula.
 - Wheezing that worsens with crying is suggestive of tracheomalacia and/or bronchomalacia or a fixed intraluminal or extraluminal obstruction.

- **Question:** Wheezing correlated with exertion?
- Significance: Suggests asthma triggered by exercise
- **Question:** Multiple exacerbations with recurrent or chronic symptoms?
- Significance:
 - Recurrent cycles of exacerbations, with clearing in between, suggest a process such as asthma, cystic fibrosis, ciliary dyskinesia, and bronchopulmonary dysplasia.
 - Chronic or persistent wheezing is more common with fixed anatomic abnormalities.
- **Question:** Common triggers?
- Significance: Could be
 - Smoke
 - Dust
 - Animal dander
 - Change in humidity or temperature
 - Change in seasons (pollens, grasses, molds)
 - Exercise
 - Infections (usually viral)
 - Inflammation of any sort
 - meals (aspiration, GERD, TEF)
- **Question:** Family history?
- Significance: A family history of wheezing, asthma, allergic rhinitis, or atopy suggests a diagnosis of asthma.
- **Question:** An episode of choking preceding the first onset of wheezing?
- Significance: Suggests foreign body aspiration

PHYSICAL EXAM

- **Finding:** Patient's degree of respiratory difficulty?
- Significance:
 - Tachypnea
 - Accessory muscle usage: Use of intercostal and sternocleidomastoid muscles and abdominal musculature indicates increased expiratory effort to overcome airway obstruction.
 - Nasal flaring: With increasing respiratory difficulty, the nares will be dilated to decrease the resistance to air flow.

- **Finding:** Auscultate: Assess airflow, adventitious sounds, and the inspiratory-to-expiratory ratio. Is the wheezing diffuse or localized?
- **Significance:**
 - Aeration: Decreased aeration is much worse prognostically than wheezing because it is directly related to the amount of aeration and ventilation. With decreased aeration, wheezing may not be audible.
 - Ratio of inspiration to exhalation: With increased intrathoracic airway obstruction, the time needed to exhale will become greater because of a greater decrease in airway caliber during exhalation. Normal ratio is 1:3.
 - Localized wheezing may suggest a foreign body.
- **Finding:** Presence of nasal crease, the “allergic salute” (i.e., rubbing the nose with the palm of the hand), atopic dermatitis, boggy nasal turbinates, clear postnasal drainage, allergic shiners, or Dennie lines?
- **Significance:** Suggestive of allergic rhinitis or atopic disease including asthma
- **Finding:** Patients with first-time, persistent, or atypical episodes of wheezing?
- **Significance:** “All that wheezes is not asthma”: Although most episodes of wheezing will represent viral infections or asthma, clinicians need to be mindful of alternative diagnoses.
- **Finding:** The 3 R’s of asthma?
- **Significance:**
 - Recurrence: symptoms that recur multiple times with full resolution in between episodes
 - Reactivity: symptoms that can be triggered during exposures (temperature extremes, smoke, dust, humid or dry air, aromas, etc.)
 - Reversibility: symptoms that resolve with bronchodilator therapy

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** Bronchodilator responsiveness
- **Significance:**
 - A postbronchodilator improvement in wheezing indicates a reversible process such as asthma.
 - A bronchodilator may worsen wheezing in disorders of airway wall rigidity such as bronchomalacia or tracheomalacia.

- There may be no change following a bronchodilator in situations with foreign bodies, fixed airway obstruction due to significant inflammation (i.e., status asthmaticus), or airway remodeling.
- **Test:** Pulmonary function testing (spirometry)
- Significance:
 - Spirometry remains the standard and most helpful measure of pulmonary function.
 - Normative data have been described in children >6 years of age.
 - Normal spirometry does not rule out asthma.
 - Methacholine challenge test is a provocative test to evaluate for asthma.
 - Exercise test with spirometry to evaluate for exercise-induced asthma
- **Test:** Pulse oximetry measurement of oxygen saturation (SpO_2)
- Significance: Pulse oximetry is an insensitive measure of mild to moderate respiratory difficulty during wheezing, but oxyhemoglobin saturation <92% may be seen in severe compromise.
- **Test:** Arterial blood gas
- Significance:
 - Arterial blood gases provide a direct measure of oxygenation (PaO_2) and ventilation (PaCO_2) and can also help to determine severity.
 - A normal or high normal PaCO_2 in a tachypneic patient (when it should be low) may be a sign of impending respiratory failure.

Lab

- **Test:** Microbiologic studies
- Significance:
 - Positive bacterial culture of sputum is helpful in directing or focusing antibiotic therapy. A Gram stain showing sheets of polymorphonuclear leukocytes and a predominant organism is helpful to differentiate a potentially causative organism from the multitude of normal flora.
 - Positive respiratory virus screen or culture (often within 12 hours) can prevent needless antibiotic therapy and may be helpful in predicting future disease.

- **Test:** Tuberculosis skin test
- **Significance:** Mantoux purified protein derivative—tuberculosis. May be falsely positive in a patient who received BCG vaccine. May be falsely negative in a patient who is anergic
- **Test:** CBC including eosinophil count, quantitative immunoglobulins, IgE, complement, HIV testing, allergy skin testing
- **Significance:** Screening for immune defects, atopy

Imaging

- Chest radiography (posteroanterior and lateral views)
 - Should be strongly considered in all patients with new-onset wheezing or an asymmetric lung exam
 - Can show findings suggestive of airway obstruction (hyperinflation, hyperlucency, flattening of the diaphragms)
 - Asymmetry in aeration on right and left lateral decubitus films suggests foreign body or other obstructing lesions on the side having the greatest air trapping.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- A trial of bronchodilator therapy (e.g., albuterol) may be both therapeutic and diagnostic of the reversible airway obstruction characteristic of asthma.
- For acute asthma exacerbation: corticosteroids PO or IV
- Ipratropium bromide may be helpful in reducing airway secretions and reducing airway obstruction, but it is not FDA approved for treatment of asthma. May be helpful in tracheomalacia as might bethanechol.
- Inhaled corticosteroids, antileukotriene agents, and, less, frequently methylxanthines (aminophylline and theophylline) are used as maintenance medications.
- Antibiotics should be used in patients with suspected pneumonia.
- In emergency setting epinephrine, terbutaline, and magnesium sulfate can be used along with supportive care such as supplemental oxygen.

ALERT

Factors that may indicate a respiratory emergency:

- Signs of mild to moderate respiratory difficulty: tachypnea, intercostal and suprasternal retractions, nasal flaring, head bobbing and exaggerated shoulder movement during breathing, abdominal breathing and subcostal retractions (may be normal in infants, especially during active [REM] sleep), relative difficulty speaking in complete sentences, significant wheezing, prolonged exhalation, and low PaCO_2 in the face of tachypnea
- Signs of impending respiratory failure: cyanosis, fatigue, inability to speak in >1- or 2-word phrases, altered mental status (e.g., confusion, agitation), decreased respiratory drive, inadequate ventilation (poor air flow), no audible wheezing, high normal or rising PaCO_2 in the face of tachypnea or respiratory distress
- Determine which patients require assisted ventilation (e.g., bag-mask ventilation, noninvasive [nasal] ventilation, or endotracheal intubation)
- Lack of response to aggressive bronchodilator therapy, without a history of asthma or recurrent wheeze, or biphasic adventitious sounds should immediately raise the suspicion of a fixed lesion.

CODES

ICD10

R06.2 Wheezing

FAQ

- Q: What percentage of recurrent wheezing resolves by school age?
- A: Roughly 40% of children with ≥ 1 episode of wheezing before 3 years clear by 6 years of age.
- Q: Should chest radiographs be routinely obtained in children experiencing their first episodes of wheezing?
- A: For a child with new-onset asymmetric wheezing, a chest radiograph should be obtained. For a child with symmetric wheezing, chest radiography may not be helpful and should be ordered judiciously.

WILMS TUMOR

David T. Teachey

BASICS

DESCRIPTION

Wilms tumor is a malignant tumor of the kidney occurring in the pediatric age group. It is also called nephroblastoma.

EPIDEMIOLOGY

More common in girls than boys

Incidence

- 1 in 10,000 live births
- Increased incidence in children with neurofibromatosis

Prevalence

- Most common primary malignant renal tumor of childhood
- 5–6% of all childhood cancers

RISK FACTORS

Genetics

- 15–20% are presumed hereditary.
- Familial cases are more often bilateral and occur at an earlier age.
- A tumor suppressor gene related to Wilms tumor (WT1) has been localized to chromosome 11p13. Mutations in this gene occur in ~20% of Wilms tumors.
- Another tumor suppressor gene, WT2, has been localized on 11p15.

ETIOLOGY

- 20% of Wilms tumors have a mutation in the WT1 tumor suppressor gene.
- Causes in the remaining 80% of patients are unknown.

COMMONLY ASSOCIATED CONDITIONS

- 12–15% of patients have other congenital anomalies.
- May be associated with aniridia, hemihypertrophy, and cryptorchidism

- Associated syndromes
 - WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation)
 - Beckwith-Wiedemann syndrome (macroglossia, omphalocele, visceromegaly, hemihypertrophy)
 - Denys-Drash syndrome (ambiguous genitalia, progressive renal failure, and increased risk of Wilms tumor)

DIAGNOSIS

HISTORY

- Abdominal distention
- Abdominal pain (20–30% of cases)
- Hematuria (20–30% of cases)
- Fever, anorexia, vomiting
- Family history of Wilms tumor
- Rapid increase in abdominal size (suggestive of hemorrhage in the tumor)

PHYSICAL EXAM

- Asymptomatic abdominal mass extending from flank toward midline (most common presentation)
- Anemia (secondary to hemorrhage in the tumor)
- Fever
- Hypertension (owing to increased renin production in 25% of cases)
- Varicocele (indicates obstruction to spermatic vein owing to tumor thrombus in renal vein or inferior vena cava)
- Aniridia, hemihypertrophy, cryptorchidism, hypospadias
- Signs of Beckwith-Wiedemann and neurofibromatosis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
- Electrolytes
- Urine analysis: for microscopic hematuria
- Liver and kidney function tests

- Coagulation factors

Imaging

- Ultrasound of abdomen
 - Diagnostic of mass of renal origin
 - Evaluate for extension of tumor into inferior vena cava.
- CT scan of abdomen, chest radiograph, and chest CT: to evaluate for metastatic disease
- Bone scan: only if clear cell sarcoma, renal cell carcinoma, or rhabdoid tumor on pathology
- MRI of head: only for clear cell sarcoma and rhabdoid tumors
- EKG and echocardiogram in patients who will receive anthracycline chemotherapy

Pathologic Findings

- Gross pathology
 - Often cystic with hemorrhages and necrosis
 - Usually no calcification (useful in differentiating from neuroblastoma, which is calcified on plain radiograph)
 - May extend into the inferior vena cava
- Histology
 - Triphasic pattern blastemal, epithelial, and stromal cell
 - Blastemal cells aggregate into nodules like primitive glomeruli; the presence of diffuse anaplasia indicates a poor prognosis.
- Clinicopathologic staging
 - Stage I: Tumor is restricted to one kidney and completely resected. The renal capsule is intact.
 - Stage II: Tumor extends beyond the kidney but is completely excised.
 - Stage III: Residual nonhematogenous tumor is confined to the abdomen.
 - Stage IV: There is hematogenous spread to lungs, liver, bone, or brain.
 - Stage V: Bilateral disease

DIFFERENTIAL DIAGNOSIS

- Polycystic kidney

- Renal hematoma
- Renal abscess
- Neuroblastoma
- Other neoplasms of kidney: clear cell carcinoma, rhabdoid tumor

ALERT

Rarely, Wilms tumor may present with polycythemia. It can present as fever of unknown origin without any other signs or symptoms.

TREATMENT

SPECIAL THERAPY

Radiotherapy

- Not required for stage I and II patients unless anaplastic, clear cell, or rhabdoid
- Radiotherapy to tumor bed with 1,080 cGy for stages III and IV. If gross tumor spillage or peritoneal seeding, treat whole abdomen
- Whole-lung radiation (1,200 cGy) for pulmonary metastasis

MEDICATION

- Chemotherapy
 - For stages I and II favorable histology: vincristine and actinomycin D every 3 weeks for 6 months
 - For stages III and IV favorable histology, stage I–III focal anaplasia, and stage I diffuse anaplasia: vincristine, actinomycin D, and doxorubicin for 6–15 months
 - Add cyclophosphamide and/or etoposide for higher stage anaplastic tumors (stage IV focal or II–IV diffuse).
- Side effects of therapy
 - Temporary loss of hair
 - Peripheral neuropathy
 - Impaired function of the remaining kidney over years following radiation
 - Cardiac toxicity with doxorubicin
 - Second malignant neoplasms in few cases

SURGERY/OTHER PROCEDURES

- Nephrectomy
 - Preoperative chemotherapy in case of very large tumors with inferior vena cava extension
 - For bilateral disease, nephrectomy of more affected side and partial nephrectomy of the other side, followed by chemotherapy and radiation

ONGOING CARE

PROGNOSIS

- Stages I and II: >90% cured
- Stage III: 85% cured
- Stage IV: 70% cured
- Favorable prognostic factors
 - Tumor weight <250 g
 - Age at presentation <24 months
 - Stage I disease
 - Favorable histology
- Poor prognostic factors
 - Diffuse anaplastic pathology
 - Clear cell sarcoma variant
 - Rhabdoid tumor variant
 - Lymph node involvement
 - Distant metastasis
 - Tumors with loss of heterozygosity (LOH) of chromosomes 1p and/or 16q

COMPLICATIONS

- Extension into inferior vena cava
- Metastasis to lungs and liver
- Cardiac toxicity secondary to doxorubicin
- Liver dysfunction secondary to actinomycin D and radiation therapy

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Every 3 months for 18 months, every 6 months for 1 year, and then yearly
- Chest radiograph, urinalysis, and abdominal ultrasound at regular intervals

CODES

ICD10

- C64.9 Malignant neoplasm of unsp kidney, except renal pelvis
- C64.1 Malignant neoplasm of right kidney, except renal pelvis
- C64.2 Malignant neoplasm of left kidney, except renal pelvis

FAQ

- Q: What should be done to protect the remaining kidney during sports?
- A: Children should wear a kidney guard to protect the unaffected kidney during contact sports.
- Q: Can a child grow and live normally with 1 kidney?
- A: Yes.

WILSON DISEASE

Waqar Waheed

BASICS

DESCRIPTION

Wilson disease (WD), also known as hepatolenticular degeneration, is an autosomal recessive disorder of copper metabolism affecting several organs, most notably the liver, brain, and cornea.

EPIDEMIOLOGY

Children usually present with hepatic manifestations; adolescents and young adults may present with neurologic symptoms.

- Worldwide carrier rate is 1:100.
- Prevalence is 1:30,000.
- Most cases present between ages 5 and 35 years.
- Worldwide distribution

RISK FACTORS

Genetics

- Autosomal recessive inheritance with 1 of >500 known defects of the WD gene (ATP7B) on chromosome 13q14.3 membrane (ATPase)
- The affected protein facilitates biliary excretion of excess copper; incorporates copper into apoceruloplasmin for transport
- Heterozygotes are generally asymptomatic.
- Siblings have 25% risk of disease, 50% chance of being an asymptomatic carrier, and a 25% chance of being unaffected and not a carrier.
- Clinical phenotype of WD is modified by mutations in other genes, including MTHFR, COMMD1, ATOX1, and XIAP.
- Use of direct mutational analysis to phenotype WD is limited by the high number of mutations.

PATHOPHYSIOLOGY

- Loss of ATP7b function causes; a) impaired biliary copper excretion

(the only route for elimination of copper) and b) failure to incorporate copper to apoceruloplasmin during ceruloplasmin biosynthesis, leading to ceruloplasmin deficiency

- Copper accumulates preferentially in the liver, leading to cirrhosis.
- After liver is saturated, copper overflows and settles in the brain (primarily in the basal ganglia leading to impaired motor control), as well as other tissues including kidneys, heart, blood, and cornea.
- Excess copper damages mitochondria, causing oxidative damage to cells. In addition, toxic intracellular copper deposition promotes apoptotic cell death by the inhibition of IAPs (inhibitor of apoptosis proteins).

DIAGNOSIS

HISTORY

- Hepatic
 - In children, symptoms of hepatic disease predominate, ranging from asymptomatic hepatomegaly and elevated transaminases to chronic hepatitis and even fulminant hepatic failure.
 - Mean age for onset of hepatic symptoms ~10 years
 - Fulminant liver failure is associated with hemolysis and coagulopathy unresponsive to vitamin K.
- Neurologic
 - Neurologic symptoms are rare before age 10 years.
 - Neurologic signs in children: behavior change, decline in school performance, poor hand–eye coordination, motor abnormalities—dystonia, tremors, dysphagia, dysarthria, chorea, ataxia, and parkinsonism
 - Other manifestations include seizures, myoclonus, and dysautonomia.
- Psychiatric: develop depression, anxiety, psychosis, and/or obsessive-compulsive disorder
- Other: Nonspecific complaints are common—abdominal pain, nausea, anorexia, and fatigue.
- Signs and symptoms:

- 45% of all patients present with liver disease, 35% with neurologic symptoms and 10% psychiatric.
- Remaining 10%: hemolytic anemia, jaundice, cardiomyopathy, other
- Consider WD in all cases of liver abnormality in which viral and autoimmune causes have been excluded.
- Also consider WD in every young patient with unexplained neuropsychiatric symptoms including with a movement disorder.

PHYSICAL EXAM

- Ophthalmologic
 - Kayser-Fleischer (KF) rings: copper deposits on Descemet membrane of cornea (at limbus)
 - Not pathognomonic for WD; may be seen in cholestatic liver disease
 - May require slit-lamp examination to detect
 - 95% with neurologic signs have KF rings.
 - 50–65% with hepatic presentation has KF rings.
- Cardiovascular: signs of cardiomyopathy, dysrhythmia, congestive heart failure
- Abdominal
 - Hepatomegaly, ascites
 - Splenomegaly from portal hypertension
- Skin
 - Jaundice due to hemolysis
 - Bleeding diathesis from liver disease
 - Edema
- Neurologic
 - Movement disorders
 - Neurologic deficits

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum ceruloplasmin
 - An acute-phase reactant; increased with inflammation, infection, or trauma; level may increase to reference range.

- Made mostly in the liver; it is the major carrier of copper in blood.
- Low serum ceruloplasmin can be helpful in diagnosing WD.
 - Very low (<50 mg/L): strong evidence for WD
 - Low (<200 mg/L) plus symptoms and KF rings: diagnostic of WD
- Ceruloplasmin levels also low in renal or GI protein loss, Menkes disease, and end-stage liver disease
- Serum copper
 - Low total serum copper (<80 mcg/dL) in WD
 - Level is decreased in proportion to decreased ceruloplasmin in circulation.
 - In acute fulminant liver failure, serum copper is increased owing to sudden release of stores (most is not bound to ceruloplasmin).
- Free copper estimation
 - Measure of nonceruloplasmin toxic copper in the blood; normal values 1.3–1.9 $\mu\text{mol/L}$ (8–12 mcg/dL), in WD >3.9 $\mu\text{mol/L}$ (25 mcg/dL).
 - Useful in cases where false elevation of ceruloplasmin is suspected; when a measurement of urinary copper is difficult to obtain, as well to monitor chelators efficacy during maintenance phase of therapy (goal <25 mcg/dL)
 - Calculated by the formula: total serum copper in mcg/mL \times 100 – (ceruloplasmin in mg/dL \times 3) = free copper
- Urinary copper excretion
 - Reflects unbound copper in blood
 - Level is high in WD: >100 mcg/24 h in symptomatic patient is diagnostic.
 - In equivocal cases, marked increase in urinary copper output after initiation of chelation therapy may help in diagnosis.
- Other:
 - Mutational analysis if familial mutation is known

Imaging

- Abdominal ultrasound for liver size and pathology
- MRI of the brain/basal ganglia should be obtained prior to initiation of therapy.

- “Face of the giant panda” sign that is characteristic of Wilson disease (red nuclei, substantia nigra, tegmentum)

Diagnostic Procedures/Other

- Liver biopsy is the definitive procedure for tissue diagnosis and hepatic disease staging.
- Biopsy should be obtained when diagnosis is not straightforward and in younger patients.
- Hepatic parenchymal copper concentration >250 mcg/g dry weight
- Hepatic copper level <50 mcg/g dry weight excludes WD.

DIFFERENTIAL DIAGNOSIS

- Liver disease
 - Viral hepatitis
 - Autoimmune hepatitis/primary biliary cirrhosis
 - Menkes disease (low ceruloplasmin)
 - Cholestatic disease from parenteral nutrition (KF rings)
- Neurologic disease
 - Essential tremor
 - Sydenham or Huntington chorea
 - Hereditary dystonia
 - Other neurodegenerative diseases
- Psychiatric disease: depression, psychoses
- Protein loss from GI or renal abnormalities

TREATMENT

- Lifetime therapy aimed at treating copper overload
- Consists of two phases
 - (1) Removing or detoxifying the tissue copper (achieved by chelators)
 - (2) Preventing reaccumulation (low-dose chelators, dosages reduced by about 33% from original induction dose and/or by use of zinc salts)
- Successful therapy is measured in terms of a restoration of normal levels of free serum copper and its excretion in the urine.

MEDICATION (DRUGS)

- Penicillamine
 - Mode of action (MOA)
 - Chelates copper and promotes renal excretion
 - Also induces metallothionein (which forms a nontoxic combination with copper)
 - Efficacy: Improvement in clinical features noted after 2–3 months, continuing over a period of 1–2 years.
 - Dosages and monitoring:
 - Initial dose: 1–1.5 g/24 h in 2–4 divided doses PO, maximum total daily dose 20 mg/kg, taken 1 or 2 hours after food (absorption decreased by approximately 50% when taken with food).
 - May start at a lower dose (250–500 mg/day) with gradual escalation over a few weeks
 - Monitoring: clinical assessment + hematologic, biochemical (transaminases), and urinary parameters every week for 1 month, then every month for 6 months, and subsequently q6mo.
 - While on therapy, 24-hour urine copper exceeds $\geq 2,000$ mcg/day, with gradual decline over 6–12 months to values below ≤ 200 –500 mcg/day.
 - Once this level achieved and free serum copper < 15 mcg/dL, the maintenance dose can be lowered to 0.5–1 g/24 h in divided doses (usually after 4–6 months).
 - At this point, a zinc salt could be added to the treatment regimen, preferably before meals to avoid any interaction with penicillamine.
 - The goal of treatment is a 24-hour urine copper excretion of 50–100 mcg
 - Side effects in 20–30%
 - Acute neurologic deterioration caused by rapid mobilization of hepatic copper stores leading to increased brain copper deposition, or from the development of intracellular copper complexes
 - Reduce dose to 250 mg/24 h or switch to trientine or zinc.

- Pyridoxine deficiency, risk factors include intercurrent infection or a growth spurt. B₆ supplementation 25–50 mg/24 h
 - Skin complications due to interference with collagen and elastin formation
 - Hypersensitivity reactions (rash, fever, lymphadenopathy), bone marrow suppression, myasthenia gravis, optic neuritis, nephritis, lupuslike syndrome
 - Discontinue if the total white blood cell count <3,000 cells per mm³, neutrophils <2,000 cells per mm³, platelets <120,000 per mm³, or if a steady decline over three successive tests even if the values are above the earlier mentioned parameters for discontinuation.
 - Discontinue also if >2+ proteinuria on a dipstick, red cell or white casts or >10 red cells seen per high-power field on urine microscopy.
- Trientine
 - MOA: chelates copper/promotes renal excretion
 - Dosages and monitoring:
 - Has become initial drug of choice
 - Used in combination with zinc
 - Dosages: pediatric dose 20 mg/kg/24 h PO divided 2–3×/24 h up to a maximum of 1,500 mg/24 h. Round dose to the nearest 250 mg.
 - Maintenance therapy: 750–1,000 mg/24 2–3×/day, avoid taking with food.
 - Monitoring: same as penicillamine
 - Side effects: fewer than penicillamine
 - Risk of sideroblastic anemia (drug's effects on mitochondrial iron metabolism), hemorrhagic gastritis, nephritis, arthritis, worsened neurologic signs
 - Serum copper increases during treatment.
 - Also chelates iron, creating toxic complex; do not give supplemental Fe (if iron supplementation required, administer Fe in short courses, separated by trientine by at least 2 hours).
- Zinc
 - Routinely combined with trientine

- Also used alone as maintenance therapy
- Used successfully in asymptomatic or presymptomatic affected family members of individuals with Wilson disease
- MOA
 - Interferes with absorption from GI tract by inducing metallothionein in enterocytes, which chelates metals. Copper is bound within the enterocyte and not absorbed into the portal circulation. It is shed in stool along with normal shedding of enterocytes.
 - Also induces copper-binding metallothionein in the liver
 - May create a negative copper balance, removing all extra copper stores, resulting in improvement of hepatic and brain function, and loss of KF rings
- Dosage: 50 mg t.i.d. PO, empty stomach
- Side effects:
 - Few side effects: gastric irritation, nausea
 - Overtreatment may result in anemia, decreased wound healing, or neuromyelopathy from copper deficiency.
- No altered dose needed for surgery.
- Compliance with overall therapy monitored by urine zinc levels, which should be above 2 mg
- After chelation for 4–6 months, with normal labs, usually OK to change to zinc for maintenance
- Ammonium tetrathiomolybdate
 - Not FDA-approved
 - Complex with copper in the intestinal tract, preventing absorption.
 - Absorbed drug forms a complex with copper and albumin in blood, which is metabolized by liver and excreted in bile.
 - Particularly suited for treatment of neurologic manifestation in Wilson disease, as it is not associated with exacerbation on initiation of treatment.
 - S/E: bone marrow suppression, elevated aminotransferases
- Antioxidants and experimental therapies
 - Antioxidants (vitamin E/N-acetylcysteine) may protect against oxidative damage.

ADDITIONAL TREATMENT

General Measures

- Immunize for hepatitis A, B.
- Avoid excess alcohol.
- Well water or water via copper pipes needs to be tested: If >0.1 ppm Cu, find alternative source.

SURGERY/OTHER PROCEDURES

- Orthotopic liver transplant required for fulminant liver failure or end-stage liver cirrhosis, which is resistant to chelation therapy.
- Uncertain indication for therapy-resistant neurologic symptoms. Several case reports suggest improved neurologic symptoms after transplantation.
- 5% with WD need liver transplants.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients require lifelong dietary copper restriction and chelation therapy.
- Continual monitoring for compliance and side effects of medications is crucial.
- Sudden discontinuation of therapy may precipitate fulminant hepatic failure.
- 1st-degree relatives $>$ age 3 years should be screened with history, physical exam, LFTs, CBC, serum ceruloplasmin, 24-hour urine copper, and ophthalmologic examination for KF rings.
- Reproductive and genetic counseling for carriers should be offered.
Prenatal testing

DIET

Low-copper diet for life: Avoid liver and other organ meats, shellfish, nuts, mushrooms, and chocolate.

COMPLICATIONS

- Renal: Copper accumulation leads to Fanconi syndrome (tubular dysfunction, glycosuria, hypophosphatemia, and low uric acid).
- Hematologic: Coombs-negative hemolytic anemia, coagulopathy from liver failure
- Cardiac: cardiomyopathy/dysrhythmias
- Rare associations include renal stones, gallstones, osteomalacia, osteoporosis, arthralgias, pancreatitis, hypoparathyroidism, skin pigmentation, and a bluish discoloration at the base of the fingernails (azure lunulae)

PROGNOSIS

- If WD is recognized early and treated, most patients experience complete recovery.
- Progression to hepatocellular carcinoma is rare, unlike hemochromatosis.

WISKOTT-ALDRICH SYNDROME

Elena Elizabeth Perez

BASICS

DESCRIPTION

- An X-linked primary immunodeficiency caused by a mutation in the Wiskott-Aldrich syndrome (WAS) gene
- Originally described as clinical triad of thrombocytopenia with small platelets, eczema, and recurrent infections with opportunistic and pyogenic organisms
- Increased bleeding tendency secondary to thrombocytopenia likely results from impaired platelet production, increased turnover, and defective function.
- Disease variants also resulting from WAS gene mutations include X-linked thrombocytopenia (XLT) and X-linked neutropenia (XLN).
- Classic WAS is characterized by broad immunodeficiency, decreased number and function of T cells, disturbed marginal B-cell homeostasis, and skewed immunoglobulin isotypes, with defective antibody responses to vaccinations, impaired NK-cell cytotoxicity, and abnormal regulatory T-cell function as well as reduced phagocyte chemotaxis.

EPIDEMIOLOGY

- Presents in infancy with serious bleeding episodes secondary to thrombocytopenia (such as circumcision with increased bleeding, bloody diarrhea, ecchymoses)
- Recurrent infections usually start after 6 months of age:
 - Bacterial: otitis media, sinusitis, meningitis, sepsis, and pneumonia
 - Viral infections: herpes simplex virus, varicella with systemic complications
- Milder phenotypes may lack history of recurrent infections.
- Decline in T- and B-cell numbers with time
- Eczema is usually present by 1 year of age (may be resistant to therapy, sometimes requiring systemic antibiotics).

Incidence

- For WAS/XLT, estimate is 10 in 1 million live births.
- Prevalence of XLT equal to WAS

RISK FACTORS

Genetics

- X-linked recessive disease
- Defective Wiskott-Aldrich syndrome protein gene located on X p11.22p–11.23
- ~60% of cases will have a positive family history for WAS.
- XLT without the other findings is caused by mutations of the same gene.
- Genotype/phenotype correlation
 - Lack of Wiskott-Aldrich syndrome protein (WASP) expression: increased infections, severe eczema, intestinal hemorrhage, death from intracranial bleeding, and malignancies
 - Survival rate significantly lower in WASP-negative patients

ETIOLOGY

- Mutations in the gene for the WASP
- WASP is involved in the reorganization of the actin cytoskeleton in hematopoietic cells:
 - Following activation of WASP, reorganization of actin cytoskeleton results in polarization of cells (e.g., polarized actin mesh in platelets for clotting and in macrophages for phagocytosis, and polarization of T or B cells to form immunologic synapses).
- WASP is a cytoplasmic protein involved in cell mobility, immune regulation, cell signaling, cell-to-cell interactions, signaling, and cytotoxicity.
- Defects in WASP can lead to dysfunction in adaptive and innate immunity, immune surveillance, and platelet homeostasis and function as well as neutropenia.
- “Classic” WAS and XLT result from loss-of-function mutations.
- XLT can be misdiagnosed as idiopathic thrombocytopenic purpura (ITP) that does not carry increased risk of malignancy, so testing for WASP expression and WAS gene mutation is important in any male

with thrombocytopenia and small platelets.

- XLN results from “activating” mutations in WAS that lead to increased actin polymerization; profound neutropenia, with or without associated lymphopenia; decreased T-cell proliferation in vitro; and increased risk of myelodysplastic changes in bone marrow.
- WASP is also important for regulatory T-cell function.

COMMONLY ASSOCIATED CONDITIONS

Associated with IgA nephropathy, autoimmune disorders, and an increased incidence of B-cell lymphomas

DIAGNOSIS

- Diagnosis should be considered in any boy who has congenital or early-onset thrombocytopenia with small platelets.
- Definitive diagnosis
 - Male patient
 - Congenital thrombocytopenia ($<70,000/\text{mm}^3$)
 - Small platelets (mean platelet volume <0.5 fL)
 - Mutation in the WASP gene or absent WASP mRNA

HISTORY

- Persistent or severe bleeding in infancy due to thrombocytopenia
- Recurrent infections, especially by bacteria with capsular polysaccharides (e.g., pneumococcus)
- Eczema can be of variable severity:
 - “Acute or chronic”
 - 80% of cases associated with eczema
 - May result from imbalance of cytokines skewed toward Th2
- Older patients may report recurrent viral infections.
- Most common autoimmune features include autoimmune hemolytic anemia, cutaneous vasculitis, arthritis, and nephropathy.
- Less common autoimmune features include inflammatory bowel disease, ITP, and neutropenia.
- Autoimmune features are poor prognostic indicators and can occur simultaneously.

- Maternal family history of WAS or XLT

PHYSICAL EXAM

- Evaluation should focus on presence of infection.
- Dermatologic examination is significant for the extent of eczema and the presence of petechiae or ecchymoses.
- Splenomegaly

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential
- Small platelets, decreased mean platelet volume, decreased platelet count
- Normal IgG, decreased IgM, increased IgA and IgE (reflecting immune dysregulation)
- Reduced or absent responses to polysaccharide antigens and isohemagglutinins to ABO antigens
- T- and B-lymphocyte enumeration and mitogen stimulation studies may progressively deteriorate with increasing age.

Diagnostic Procedures/Other

- WAS disease scoring system useful for defining clinical phenotypes associated with WAS mutations (XLN, XLT vs. classic WAS)
- Sequencing of WAS gene
- Lymph node biopsy in suspected malignancy
- Bone marrow aspirate to evaluate thrombocytopenia

DIFFERENTIAL DIAGNOSIS

- Other causes of thrombocytopenia such as ITP
- In 1 cohort, approximately 7% of patients diagnosed as having ITP actually had WAS as an underlying cause of thrombocytopenia.
- Severe atopic disease with dermatitis and secondary skin infections
- HIV infection
- Hyper-IgE syndrome

TREATMENT

GENERAL MEASURES

- Antibiotics for acute infections and prophylactically in postsplenectomy patients
- Splenectomy may be helpful for persistent severe thrombocytopenia in select patients. However, this may greatly increase the risk of overwhelming infections with encapsulated organisms.
- Splenectomy should be reserved for emergencies in classic WAS patients who are candidates for hematopoietic stem cell transplantation (HSCT) because it is a risk factor for death. Splenectomy in XLT with severe bleeding may increase platelet counts, but risk of severe infection requires lifelong antibiotic prophylaxis.
- Thrombocytopenia precautions: No aspirin and avoidance of situations in which trauma (especially head trauma) is likely to occur, such as contact sports.
- Platelet transfusions may be necessary for severe bleeding. Use irradiated blood products to avoid graft versus host disease and cytomegalovirus-negative products in case of bone marrow transplantation.
- Immunoglobulin replacement therapy is helpful in managing recurrent infections in some patients:
 - HSCT is the treatment of choice for the classic WAS phenotype.
 - Allogeneic stem cell transplant from human leukocyte antigen (HLA) genotypically identical sibling or 9/10 or 10/10 allele matched unrelated donor for any WAS patient with disease score 3–5 (see “[Additional Reading](#)”) or with absent WASP expression
 - Outcomes are improving with 5-year survival rates >80% for matched sibling donors and similar for matched unrelated donor grafts <5 years of age. Transplant outcomes for patients >5 years of age with matched sibling or matched unrelated are also improving over time.
- Consider food allergy as exacerbating factor for eczema.
- First retroviral-based gene therapy trial in WAS recently completed in Germany with good immune reconstitution and increase in platelet counts in 9/10 patients. Lentiviral-based gene therapy trials are starting in the near future.

- XLT patients have excellent long-term survival with supportive treatment, but HLA-matched sibling transplant can be considered owing to morbidity.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Signs and symptoms of malignancy should be evaluated expeditiously.
- As patients age, a progressive increase in infectious and autoimmune complications may occur.

COMPLICATIONS

- Progressive decline in immunologic function with an increase in infections. Humoral and cellular immune systems are affected.
- Increased frequency of autoimmune phenomena such as arthritis and vasculitis. The most common is hemolytic anemia. Vasculitis, Henoch-Schönlein purpura, inflammatory polyarthritis, and inflammatory bowel disease are also observed.
- ~100-fold increased risk of malignancy compared with the general pediatric population. Malignancy is more common in adolescents. Associated with Epstein-Barr virus
- Bleeding episodes can be life threatening.
- Immune reconstitution via stem cell transplant or gene therapy needed to prevent autoimmune disorders, lymphoma, and other malignancy
- Success of bone marrow transplant in last 10 years significantly improved.
- Splenectomy not recommended for classic WAS but may have role in XLT.

D82.0 Wiskott-Aldrich syndrome

FAQ

- Q: What is the life expectancy for patients with Wiskott-Aldrich syndrome?
- A: Before currently available therapies, most affected patients died in childhood. Currently, many patients live into their 3rd and 4th decades, even without bone marrow transplantation. Major causes of mortality are infections (44%), bleeding (23%), and malignancies (26%). Incidence of malignancy increases in 3rd decade of life. Successfully transplanted patients have a prolonged life expectancy. Patients with no gene expression have a poorer outcome.
- Q: Should patients with Wiskott-Aldrich syndrome receive live viral vaccines?
- A: These vaccines should be avoided because of the variable cellular immune defects associated with Wiskott-Aldrich syndrome. In general, patients receiving IV immunoglobulin do not require vaccinations.
- Q: What is the chance of a sibling having Wiskott-Aldrich syndrome?
- A: As with any X-linked disease, there is a 50% chance of another affected male child or asymptomatic carrier female. Genetic counseling should be offered to carrier females.
- Q: Can Wiskott-Aldrich syndrome be diagnosed prenatally?
- A: In families with affected males, fetal blood sampling can be performed in male fetuses to assess the size of the platelets. Small platelet size and family history of Wiskott-Aldrich syndrome suggest an affected infant.

YERSINIA ENTEROCOLITICA

Julia Shaklee Sammons

BASICS

DESCRIPTION

Yersinia enterocolitica is a gram-negative bacillus that produces an enteric infection characterized by fever, diarrhea, and abdominal pain that may mimic acute appendicitis.

EPIDEMIOLOGY

- *Y. enterocolitica* is estimated to cause 116,716 infections in the United States annually.
 - According to surveillance by the Foodborne Diseases Active Surveillance Network (FoodNet) from 1996 to 2009, the overall annual incidence of *Y. enterocolitica* infections was 0.5 per 100,000 persons but significantly declined over the time period.
 - Most infections occurred in young children; 47% were in children <5 years, and 32% were in infants <1 year.
 - Among subgroups, the highest annual incidence was among infants <1 year at 12.3 per 100,000 persons.
- Transmission of *Y. enterocolitica*
 - Occurs through ingestion of contaminated food or water (particularly raw or undercooked pork or unpasteurized milk products) or contact with infected animals (swine are the principal reservoir)
 - Fecal–oral and person-to-person transmission are also possible.
 - In the United States, most epidemics have been related to the improper handling of raw pork intestine (chitterlings), most often during winter holiday festivities among African American households in the South.
 - Transmission to young children occurs through contact with adult caregivers preparing the chitterlings.
- Transmission through transfusion of contaminated blood products is also possible. The FDA has reported that contamination of the U.S.

blood supply by bacteria, although rare, is most frequently due to *Y. enterocolitica*.

- The incubation period is ~1–14 days (average 4–6). The mean duration of organism excretion is 42 days; however, asymptomatic carriage can persist even longer.
- Systemic disease or bacteremia occurs more commonly in young infants or those with predisposing conditions, including a clinical state of iron overload or deferoxamine therapy, immunosuppression, diabetes mellitus, malnutrition, and cirrhosis or other liver diseases.

GENERAL PREVENTION

- Infection control
 - Contact precautions are indicated for patients with enterocolitis until diarrhea resolves.
- General measures
 - Attempts to eliminate reservoirs and reduce frequency of ingesting contaminated foods and beverages are necessary.
 - Ingestion of undercooked meats, especially pork and unpasteurized milk, should be avoided.
 - Meticulous hand hygiene before and after handling uncooked meat products and avoidance of preparation of meats near or during preparation of infant bottles for feeding are essential.

PATHOPHYSIOLOGY

- The portal of entry for *Y. enterocolitica* is the gastrointestinal tract.
- *Y. enterocolitica* adheres to epithelial cells and mucus, producing heat-stable enterotoxins, which play a role in the development of watery diarrhea.
 - Another cytotoxin then directly injures the distal small and large bowel, producing stools characterized by blood and mucus.
 - Release of these toxins leads to the development of an enterocolitis, most commonly in younger age groups.
- Mesenteric adenitis and/or terminal ileitis may lead to a pseudoappendicitis syndrome, typically in the older child or young adult.
- Bacteremia may lead to focal abscesses in a variety of organs,

including the lung, liver, spleen, and kidney.

ETIOLOGY

- The genus *Yersinia* consists of 11 species, of which *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, and *Yersinia pestis* are the 3 most commonly encountered pathogens.
- *Y. enterocolitica* is a facultative, non–lactose-fermenting, urease-positive, gram-negative bacillus.
- Over 60 serotypes and 6 biotypes of *Y. enterocolitica* have been identified. Serotypes O:3, O:5.27, O:8, and O:9 and biotypes 2, 3, and 4 are most commonly isolated from patients. Serotype O:3 is the most common type in the United States.

DIAGNOSIS

Diagnosis depends on elucidation of the pertinent exposure history as well as recognition of typical symptoms and laboratory testing.

HISTORY

- Enterocolitis is the most common manifestation of *Y. enterocolitica* infection in young children and is characterized by fever, abdominal pain, and diarrhea with blood or mucus.
 - 25% of patients have hematochezia.
 - Typical duration of illness is 1–3 weeks but may be longer (up to several months).
 - The history taking should include questions regarding exposure to unpasteurized milk products and raw pork or poultry, especially the preparation of pork chitterlings.
- A pseudoappendicitis syndrome due to mesenteric adenitis and/or terminal ileitis predominates in older children and adults and is associated with fever, right lower quadrant abdominal pain, and leukocytosis.
- *Yersinia* bacteremia is found most commonly in infants <1 year of age or those with predisposing conditions, particularly states of iron overload (e.g., sickle cell disease, thalassemia).
- Extraintestinal manifestations of *Y. enterocolitica* infection are

uncommon and include pharyngitis, suppurative lymphadenitis, pyomyositis, osteomyelitis, abscess, UTI, pneumonia, endocarditis, meningitis, peritonitis, panophthalmitis, conjunctivitis, and septic arthritis.

PHYSICAL EXAM

Because of the wide range of clinical symptoms, including extraintestinal manifestations, the physical exam is nonspecific for this infection.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- *Y. enterocolitica* can be isolated from blood, sputum, CSF, urine, and bile; these specimens do not require selective culture media techniques.
 - Stool samples should be plated on selective media such as cefsulodin-triclosan-novobiocin agar.
 - If routine enteric media (MacConkey) are used, a cold enrichment technique will increase recovery of the organism.
 - The laboratory should be notified that *Yersinia* is suspected if not routinely sought.
- Serologic methods (tube agglutination assay, enzyme-linked immunosorbent assay [ELISA]) are available with a rise in titers noted 1 week after onset of symptoms and peak titers observed by the 2nd week of illness. These tests identify IgM, IgG, and IgA antibodies against *Y. enterocolitica*.
- Cross-reactivity between *Y. enterocolitica* and *Brucella abortus*, *Rickettsia* species, *Morganella morganii*, *Salmonella* species, and thyroid tissue antigen make serodiagnosis of limited usefulness.

Imaging

Abdominal ultrasound can be used to distinguish pseudoappendicitis from acute appendicitis through demonstration of bowel wall edema in the terminal ileum and cecum.

DIFFERENTIAL DIAGNOSIS

- *Y. enterocolitica* should be considered in all patients with fever, abdominal pain, and stools with blood or mucus as well as in patients with the extraintestinal manifestations described earlier.

- Pitfalls
 - Not all bacterial colitis presents with bloody or mucus-appearing diarrhea. Therefore, suspicion should exist if the diarrhea is prolonged or environmental exposures pose a risk for developing infection.
 - The possibility of *Y. enterocolitica* bacteremia should be considered in blood transfusion–related illnesses, thalassemia, or prior history of liver disease.

TREATMENT

GENERAL MEASURES

- The benefit of treatment of uncomplicated enterocolitis, mesenteric adenitis, or pseudoappendicitis has not been established in immunocompetent hosts.
- Antimicrobial therapy has been shown to benefit patients with systemic infections, focal extraintestinal infections, and enterocolitis in an immunocompromised host.
- For most isolates, trimethoprim/sulfamethoxazole, chloramphenicol, aminoglycosides, tetracycline or doxycycline, fluoroquinolones, and 3rd-generation cephalosporins are effective treatment options.
- *Y. enterocolitica* is usually resistant to most penicillins and 1st-generation cephalosporins.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Symptoms of enterocolitis usually abate within 2 weeks of the onset of illness.
- Shedding of the organism in stool can last more than 6 weeks after diagnosis.
- For extraintestinal manifestations, the expected course depends on the specific organ system involved.

PROGNOSIS

- The prognosis is usually quite good, as most infections are gastrointestinal.
- Systemic disease (i.e., septicemia with subsequent secondary spread) has higher morbidity and mortality. Mortality related to septicemia can be as high as 50%.

COMPLICATIONS

- Postinfectious sequelae may occur 1–2 weeks after gastrointestinal symptoms and include erythema nodosum as well as reactive arthritis involving weight-bearing joints. These complications are seen most often in adults, particularly those with HLA-B27 antigen.
- Reactive arthritis syndrome, myocarditis, glomerulonephritis, erysipelas, chronic diarrhea persisting for months, and hemolytic anemia have also been reported.
- Intestinal perforation and ileocolic intussusception are possible.

CODES

ICD10

- A04.6 Enteritis due to *Yersinia enterocolitica*
- A05.8 Other specified bacterial foodborne intoxications

FAQ

- Q: How long is a child considered infectious with *Y. enterocolitica*?
- A: Although the typical course of enterocolitis is ~14 days, shedding of the organism in the stool can last 6 weeks or longer. Strict adherence to hand hygiene should be discussed with the child's parent or caregiver, particularly for those with incontinent or diapered children, to ensure infection control.
- Q: If there is no history of stools with blood or mucus, can you exclude *Y. enterocolitica* as the likely infectious agent in a child with diarrhea?
- A: No. In fact, early in the course of illness, the diarrhea is more likely to be watery owing to the enterotoxins produced (see "[Pathophysiology](#)").
- Q: How is the diagnosis of *Y. enterocolitica* determined if you are unable to isolate the organism from a clinical specimen?
- A: When a diagnosis cannot be made during acute infection or in the clinical setting of postinfectious complications, a serologic titer of >1:128 is suggestive of previous infection of *Y. enterocolitica*. Keep in mind the possibility of cross-reactivity with *Brucella*, *Rickettsia*, *Morganella*, and *Salmonella* species as well as thyroid antigens.

Appendix I

The 5-Minute Educator

Terry Kind

- Part 1: Precepting**
- Part 2: Direct Observation**
- Part 3: Feedback**
- Part 4: Clinical Reasoning**

PART 1: PRECEPTING

Cara Lichtenstein

DESCRIPTION

Precepting is the education and teaching of learners in a clinical care setting.

TECHNIQUES USED BEFORE THE VISIT

Orient the learner at the start of the rotation:

- Gather information on background, strengths, and weaknesses of the learner.
- Communicate goals and set expectations for the rotation.
- Discuss your style of feedback and how frequently it will be given.
- Introduce trainee to office staff they will work with during the rotation.
- Familiarize trainee with recordkeeping (electronic medical record, paper charts).

Wave Scheduling

- Build in preceptor teaching time without reducing overall number of patients.

Time (a.m.)	Room 1	Room 2
8:30–8:50	Patient A seen by student	Patient B seen by preceptor
8:50–9:10	Patient A seen by preceptor and student	—
9:10–9:30	Student charts on patient A	Patient C seen by preceptor
9:30–9:50	Patient D seen by student	Patient E seen by preceptor
9:50–10:10	Patient D seen by preceptor and student	—
10:10–10:30	Student charts on patient D	Patient F seen by preceptor

Prime learners before they go in to room:

- Prompt learner to retrieve stored information and prepare for immediate use.
- Orient the learner to the patient or possible medical problem.
 - For example: cc ear tugging: What will help you determine what the

origin of the ear tugging is?

- For example: cc speech delay: What is the typical speech of a 2-year-old like?
- For example: cc 2-week well-child visit: What do you think the purpose(s) of this visit is?
- Give the learner a task and goal.
 - For example: cc “1st-time wheeze”: The task may be to gather a focused history, and the goal may be to formulate a broad differential diagnosis of causes of wheezing.
- Make a plan for when to meet back and discuss the case.

TECHNIQUES USED DURING THE VISIT

Reflective Modeling

- Allows learners to observe the preceptor interacting with and examining the patient
- Preceptor talks aloud during the visit explaining to patient AND to learner what’s going on, what they think the diagnosis or next steps are, and why they don’t think something else is going on.

Activated Demonstration

- Goal is for trainee to learn by observing preceptor’s interaction with a patient.
- Briefly prime them in advance for what to look for.
- Set up the observation.
 - Determine student’s relevant knowledge.
 - Identify what student should learn from observation.
 - Watch the technique the preceptor use for examining the ear, exposing the oropharynx, etc.
 - Watch how the preceptor enlist the help of the parent.
 - Watch how the preceptor navigates, excusing the parent from the room so the preceptor can talk with the teen (patient) privately.
 - Provide clear guidelines for what student should do while observing.
 - For example: Quietly observe; jot notes with what you are observing.

Student Clinical Observation of Preceptor (SCOOP)

- Allows learner to observe preceptor's interaction with patient and family
- Learner uses a tool or writes 3 things they observed.
- Items discussed together afterwards

Brief Structured Clinical Observation (SCO)

- Allows assessment of learners skill level through direct observation
- Preceptor spends short period of time (5 minutes) observing part of visit (can be history, physical, or information giving).
- Uses a tool to give immediate feedback to learner on directly observed performance

Presenting in the Room

- After confirming there are no sensitive issues, learner presents in front of family.
- Saves time, as preceptor can examine patient while learner is presenting
- Family can correct any misinformation or clarify questions on the spot.
- Patients perceive increased time spent with doctor, better care, and more adequate explanation of problems.

TECHNIQUES USED AFTER THE VISIT

One-Minute Preceptor

- A structure allowing preceptors to assess learners effectively, teach key points of a case, and provide feedback efficiently, using 5 “microskills”
 - **Get a commitment** about diagnosis or treatment.
 - **Probe for supporting evidence** for that diagnosis or treatment.
 - **Teach general rules** about the case or diagnosis.
 - **Reinforce what was correct** with positive feedback.
 - **Correct mistakes** with suggestions for future improvements.

SNAPPS

- Method of presentation that focuses on clinical reasoning and self-

directed learning that is learner-driven

- Preceptor sets expectation that learner will present using SNAPPS:
 - **Summarize** the history and findings.
 - **Narrow** the differential.
 - **Analyze** the differential diagnosis by comparing/contrasting possibilities.
 - **Probe** (student probes the preceptor) for further understanding, with questions about areas of uncertainty.
 - **Plan** for patient management.
 - **Self-directed learning: Select** an issue to learn more about.

GENERAL TEACHING TIPS

- Wait 3 seconds after asking a question.
- Focus only on 1–2 teaching points per encounter.
- If you don't know, say you don't know.
- Examples speak louder than words.

PITFALLS TO AVOID

- “Taking over” the case by providing answers instead of questions
- Inappropriately long, esoteric, or noninteractive lectures
- Not waiting long enough to get an answer
- Preprogrammed answers
- Not appreciating the level of the learners and teaching beyond their ability

PART 2: DIRECT OBSERVATION

Sandra Cuzzi

BASICS

- **Definition:** the process of observing a learner (e.g., student, resident) during an actual patient encounter for the purpose of assessing clinical skills
- **Aim:** to help preceptors gather accurate information about a learner's performance in real-life clinical scenarios
- **Assessment:** communication skills, history taking, physical exam techniques, information giving, professionalism, and evaluation of competence

GETTING STARTED

Primary Purpose

Defining the primary purpose of direct observation is important in choosing the tool, setting, scope, and skills to be observed.

- **Formative:** timely feedback given to initiate discussion and promote reflection, with the goal of improving clinical skills and modifying behavior
- **Summative:** scheduled summary evaluation to “grade” or rank, with the goal of assessing global performance
- **Documentation of competency:** Direct observation is required by the accrediting bodies for both medical student and resident education.

Using an Observation Tool

- Advantages of using a tool are that it:
 - Clarifies expectations for all involved
 - Standardizes what preceptors watch for
 - Guides feedback to make it more specific
 - Fulfills documentation requirements
- Formative assessment: Primary focus of tool is to facilitate feedback so proven reliability and validity is not as important.
- Summative assessment: critical for the tool to be well-studied, valid,

and reliable

- Use an existing tool for direct observation that fits the primary purpose.
- Mini-clinical evaluation exercise (mini-CEX)
 - Best studied tool with excellent validity
 - For formative or summative assessment
 - Requires observation over 10–20 minutes, which can make it difficult to incorporate into a busy clinical setting
- Structured clinical observation (SCO)
 - Most commonly used tool in pediatrics for formative assessment
 - Divided into 3–4 specific sections, 1 for each part of the clinical encounter, with a behavioral checklist to guide feedback
 - Used for 3–5-minute observations; complete only the section of patient encounter that is observed.

Determine Setting, Scope, and Skills

- Look for opportunities where an observer is already present during a clinical encounter.
- For example, a physician working in the newborn nursery may be present to observe learner's newborn physical exam skills or a social worker present at family meetings where learners are leading the discussion can engage in direct observation.
- Opportunities can lend themselves to shorter observation (e.g., inpatient or outpatient visit) or longer ones (e.g., counseling session).
- Shorter observations tend to work best as formative feedback; longer ones can be used for summative evaluations.

IMPLEMENTATION

Potential Barriers to Direct Observation

- Lack of time
- Inadequate training, discomfort, or difficulty in observation and/or feedback
- Hawthorne effect: Presence of observer changes behavior of those observed.
- Family perception regarding observation
- Logistical barriers (scheduling, patient flow, space configuration)

Orienting the Preceptor and Learner

- Clearly state expectations once setting, scope, and, skills are defined.
- Understand preceptor and learner attitudes, experience, and knowledge regarding direct observation.
- If setting up a direct observation program institution-wide, then determine what content areas need to be covered and provide preceptor faculty development.
- Orient all to the process and logistics.

Number of Observations

- When paired with feedback, every observation has value to the learner as formative assessment.
- 4–5 observations will probably identify an “outlier” in terms of minimal competency.
- Ideally, 10–12 observations are needed over time to be reliable in assessing competency for summative assessment.

Practical Tips

- Multiple short observations allow for less time commitment, observation in a variety of clinical scenarios, and can monitor improvement over time.
- A preceptor may want to routinely set up direct observation with the first patient in a clinical session (e.g., first afternoon patient).
- Set up the specific observation beforehand with the learner and family.
- Brief 3–5-minute observations
- Take notes while observing: Set up 2 columns, 1 for “things done well”, the other for “things to improve,” or consider filling out the tool’s checklist as you observe.
- Be a “fly on the wall”: Sit away from line of sight of the patient, avoid the temptation to interrupt.
- At times, the preceptor can get involved at a certain predetermined stage of the process (e.g., after physical exam, preceptor confirms findings and advises on technique).
- Provide timely focused feedback right after observing.

Creating a Culture of Observation

- Goal: Create a culture in which observation is understood, expected, nonthreatening, and routine for everyone including patients, parents, learners, and preceptors.
- Orient the participants and set expectations.
- Make it a joint responsibility between learner and preceptor to arrange.
- Observe at regular intervals so it becomes routine.
- Consistently give feedback after observing.
- Identify “champions” of direct observation as role models and mentors.
- Encourage opportunities for preceptors to be observed by learners too.

PART 3: FEEDBACK

Terry Kind • Dewesh Agrawal

BASICS

Description

Feedback

- Formative, nonevaluative, objective appraisal of performance aimed at modifying and improving clinical skills, correcting deficits, and improving future performance
- Targeted to specific (observed) behaviors the trainee already does well and those in need of improvement
- Immediate and formative, not summative
- Presents information, not judgment
- Can be positive (reinforcing) or negative (constructive or corrective) or both
- Feedback involves a specific event or occurrence versus compliment/criticism, which are more vague and general.
- Like evaluation, should ideally be based on objective observations

Evaluation

- Summative judgment
- Equivalent to grading and/or assigning a final grade for the rotation
- Intent is to tell learners how they performed.
- Like feedback, should ideally be based on objective observations

Compliment and Criticism

- COMPLIMENT: a polite expression of praise or admiration
- CRITICISM: an expression of disapproval based on perceived faults or mistakes
- These are typically general, judgmental, and are not goal-based or not based on specific observations.

BARRIERS

- Potential barriers to providing effective feedback:
 - Insufficient time; competing demands

- Insufficient observation; gathering essential information is difficult.
- Don't have the necessary skills; didn't have good role models
- Difficult to give negative feedback; want to be “popular”
- Fears of student reprisals or failure to recruit into specialty
- Not my responsibility; unimportant
- Don't know where to start
- Lack of sufficient structure
- Defensive learner or one who lacks insight into his or her deficiencies
- Lack of well-defined, mutually agreed upon goals established
- Conditions that promote appropriate feedback
 - Feedback is part of the institutional culture and is given frequently.
 - Adequate time and timing (promptly)
 - Private setting
 - Learner knows when/where it will happen.
 - Based on specific, observed, and potentially modifiable behaviors
 - Based on objective observations, not on interpretations of the learner's motives
 - Matches with well-defined learning goals
 - Nonjudgmental language

ALERT

Remember that the GOAL of feedback is to improve performance.

MODELS

Fast

- **F** = frequently given and in digestible chunks
- **A** = accurate, based on observation
- **S** = specific, focused on modifiable behaviors
- **T** = timely

Insight

- **I** = INQUIRY: How does the resident/student/learner think it went?
- **N** = NEEDS: What learning needs does the resident/student/learner identify?
- **S** = SPECIFIC: Was your feedback specific?

- **I = INTERCHANGE:** Was there a discussion?
- **G = GOALS:** What are the next steps?
- **H = HELP:** Are there ways you can help?
- **T = TIMING:** When will follow-up occur?

Feedback Grid (Walsh, 2006)

- **Continue:** Comment on aspects of performance that were effective and should be done in the future.
- **Start or do more:** Comment on behaviors that the student knows how to do and should start doing or do so more often.
- **Consider:** Comment on “doable challenges” for the future growth of the student.
- **Stop, or do less:** Comment on observed actions that were not helpful and/or could be harmful.

Pearls (Milan, 2006)

- **P** = partnership for joint problem solving
- **E** = empathic understanding
- **A** = apology for barriers to the learner’s success
- **R** = respect for learner’s values and choices
- **L** = legitimization of feelings and intentions
- **S** = support for efforts at correction

Sandwich

- Provide a compliment or some reinforcing feedback, then provide some constructive feedback, then close with another compliment or additional reinforcing feedback.
- The negative feedback is sandwiched between 2 positive statements.

SOAP Format

- **S** = subjective self-assessment by learner; ask learner how he or she thinks it went.
- **O** = objective balanced; descriptive feedback is provided.
- **A** = assess and summarize; ask learner to summarize 2 “take-home” points.
- **P** = plan for next steps incorporating new strategies.

FAQ

- Q: Is there anything wrong with just using the “feedback sandwich”?
- A: It can either confuse or dilute the real message. It may be perceived as insulting or condescending by the learner. Sometimes the learner only focuses on positives or negatives and fails to understand the big picture.
- Q: Is it ever okay to say “good job”?
- A: Compliments are best used when paired with reinforcing feedback that is more specific and based on observed behavior.

PART 4: CLINICAL REASONING

Mary Ottolini • Terry Kind

BASICS

Description

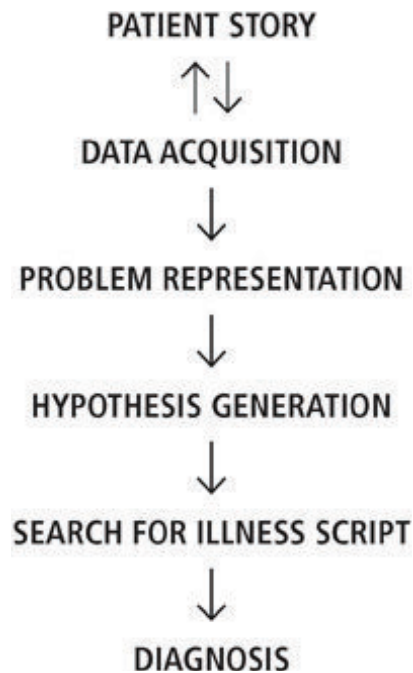

- The process of acquiring and interpreting clinical data to determine the etiology of a patient's presenting complaint
- Involves having a framework for storing and organizing medical knowledge effectively, which is critical for avoiding diagnostic error
- The experienced clinician uses problem representation, searches through "illness scripts" to make a diagnosis and employs strategies to avoid cognitive biases.

Developmental Progression

Clinical educators simultaneously diagnose the patient and diagnose the learner's developmental level of clinical reasoning.

- **Analytic reasoning:** Through basic pathophysiology, differential diagnoses are considered in "silos" or "disembodied" unrelated to patient's specific findings.
- **Development of illness scripts:** linking signs and symptoms of current patient to patterns of signs and symptoms seen in previous patients, filtering and grouping the data gathered into illness scripts
- **Problem representation:** creating a nuanced illness script for a current patient by synthesizing information into "semantic qualifiers," reflecting cognitive processing based on prior experience

The Clinical Reasoning Process

Problem Representation

SUMMARY statement of mental model of patient

- Key features of HPI/PE +
- Semantic qualifiers (adjectives)

Illness Scripts

Prototypical disease presentations based on the following:

- Epidemiology: Who gets the illness? (age, exposure, travel, etc.)
- Timing: onset and progression
- Classic/exclusionary findings
- Pathophysiology/anatomic explanation

Problem representation and illness scripts promote the “CHUNKING” of data or compiling information into a clinical syndrome, based on patterns and experience.

“Vertical Versus Horizontal Reading”

Deliberately compare/contrast illness scripts for 2–3 diagnoses for a clinical syndrome (vertically), rather than 1 diagnosis at a time (horizontally).

Type 1 Versus Type 2 Reasoning

Experts move back and forth between types (i.e., dual-processing)

depending on prior experience with illness presentation:

- **Type 1:** heuristics or “rules of thumb” as mental shortcuts if a pattern of signs and symptoms or illness script is recognized
- **Type 2:** analytical/deductive reasoning used when the presentation is unusual; slow and deliberate process

FACTORS LEADING TO DIAGNOSTIC ERRORS

Cognitive Biases

- Predictable errors in reasoning occurring particularly with TYPE 1 (heuristic) processing; can make gathering essential information and clinical reasoning difficult
- COMMON BIASES
 - Premature closure: relying on initial diagnostic impression despite subsequent information to the contrary
 - Anchoring bias: relying too heavily on 1 piece of information
 - Confirmation bias: searching for, interpreting, and remembering information in a way that confirms one’s preconceptions
 - Diagnostic momentum: sticking with one diagnostic label due to frequent repetition

ALERT

Diagnostic error is currently a leading cause of serious medical errors. Improved clinical reasoning can be taught as a strategy to decrease diagnostic errors.

- Availability bias: overreliance on what easily comes to mind
- Base-rate neglect: ignoring the true prevalence of a disease

Strategies to Overcome Biases

- Metacognition: deliberately reflecting “in-action” and thinking about thinking
 - Did the diagnosis come too easily?
 - Is there any data that doesn’t fit?
 - Am I investing too much in one finding?
 - Do I dislike the patient/parent?
- Take a “diagnostic time-out”

- Recognize when time pressure may lead to premature closure on the wrong diagnosis.

Oral Presentation Framework

Encourage students to include clinical reasoning in their presentations:

P: PROBLEM REPRESENTATION: assessment-driven presentation

BE: BACKGROUND EVIDENCE: Focus on pertinent positives and negatives.

A: ANALYSIS: Compare and contrast 2 likely illness scripts.

R: RECOMMENDATION: plan based on a problem rather than system

FAQ

- Q: Can the clinical reasoning process be taught?
- A: Yes, promoting “problem representation” and comparing and contrasting the differentiating features using illness scripts helps trainees to organize and store their patient experiences so that they can recall them in future similar situations.
- Q: Can one overcome cognitive errors?

- A: Yes. Using metacognition, or “thinking about your thinking,” a form of situational awareness, one can develop a habit of taking a “diagnostic time-out.”

Appendix II

Cardiology Laboratory

Gurumurthy Hiremath • Laura Robertson

BLOOD PRESSURE MEASUREMENT

- **All children >3 years old should have their blood pressure (BP) measured as part of their physical exam.**
- If <3 years old, measure BP if there are comorbidities present that predispose them to hypertension.
- **Measure BP in right upper arm** for purposes of consistency, comparability to standard tables and to avoid a spurious value in cases of coarctation.
- BP by auscultation is the preferred method.
- Abnormal BP obtained by oscillometry should be confirmed by auscultation.
- **Optimal BP cuff size (Table 1)**
 - Bladder length covers 80–100% of the circumference of the arm.
 - Bladder width covers 40% of the upper arm circumference.

Table 1. Recommended Dimensions for BP Cuff Bladders

Age Range	Width, cm	Length, cm	Maximum Arm Circumference, cm*
Newborn	4	8	10
Infant	6	12	15
Child	9	18	22
Small adult	10	24	26
Adult	13	30	34
Large adult	16	38	44
Thigh	20	42	52

BP, blood pressure.

* Calculated so that the largest arm would still allow the bladder to encircle arm by at least 80%.

From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114(2) (Suppl):555–576.

- **Refer to BP standards based on gender, age, and height** that now include 50th, 90th, 95th, and 99th percentiles (**Tables 2 and 3**).

Table 2. BP Levels for Boys by Age and Height Percentile

Age, y	BP Percentile	SBP, mm Hg					DBP, mm Hg				
		Percentile of Height					Percentile of Height				
		5th	10th	25th	50th	75th	5th	10th	25th	50th	75th

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure; y, year.
From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. Pediatrics. 2004;114(2):Suppl:555-576.

- **Hypertension** is defined as average systolic BP (SBP) and/or diastolic BP (DBP) that are ≥ 95 th percentile for gender, age, and height on 3 occasions.
- **Prehypertension:** If the SBP or DBP is ≥ 90 th percentile and < 95 th percentile, it is called “prehypertension.”
- **Aortic coarctation:** An upper extremity BP > 10 mm Hg higher than the lower extremity BP is pathologic and suggests the presence of

aortic coarctation, aortic arch hypoplasia, or interrupted aortic arch. If suspected, check BP in all 4 extremities.

PULSE OXIMETRY

Systemic arterial blood oxygen content is a combination of oxygen bound to hemoglobin (Hgb) plus dissolved oxygen. The calculation:

- **Oxygen Content** = (Hgb in gm/dL \times 1.36 in mL O₂/g of Hgb \times % O₂ saturation) + (PaO₂ \times 0.003 O₂/dL per mm Hg)
- Decreased arterial oxygen content is called “**hypoxemia**,” which can result in “**hypoxia**” which is failure to oxygenate at tissue level (manifesting as metabolic acidosis). “**Cyanosis**” is the clinical manifestation of bluish discoloration of skin or mucosa resulting from hypoxemia.
- **Etiologies of systemic arterial desaturation:**
 - Pulmonary venous desaturation (lung disease).
 - Right-to-left shunting (cardiac disease)
 - Hgb disorders

Visible central cyanosis occurs when the deoxygenated Hgb is >3 g/dL.

- **Polycythemic neonate** (Hgb = 20 g/dL) with an arterial saturation of 80% will have 4 g/dL of deoxygenated Hgb and will appear cyanotic.
- **Anemic neonate** (Hgb = 10 g/dL) with an arterial saturation of 80% will have only 2 g/dL of deoxygenated Hgb and will not appear cyanotic.

How to Measure Saturations Properly

- **Pulse oximetry is an established screening tool to detect critical congenital heart disease in newborns. See Figure 1.**
 - **Preductal:** Measure saturation in the right ear lobe or right arm.
 - **Postductal:** Measure saturation in either leg.

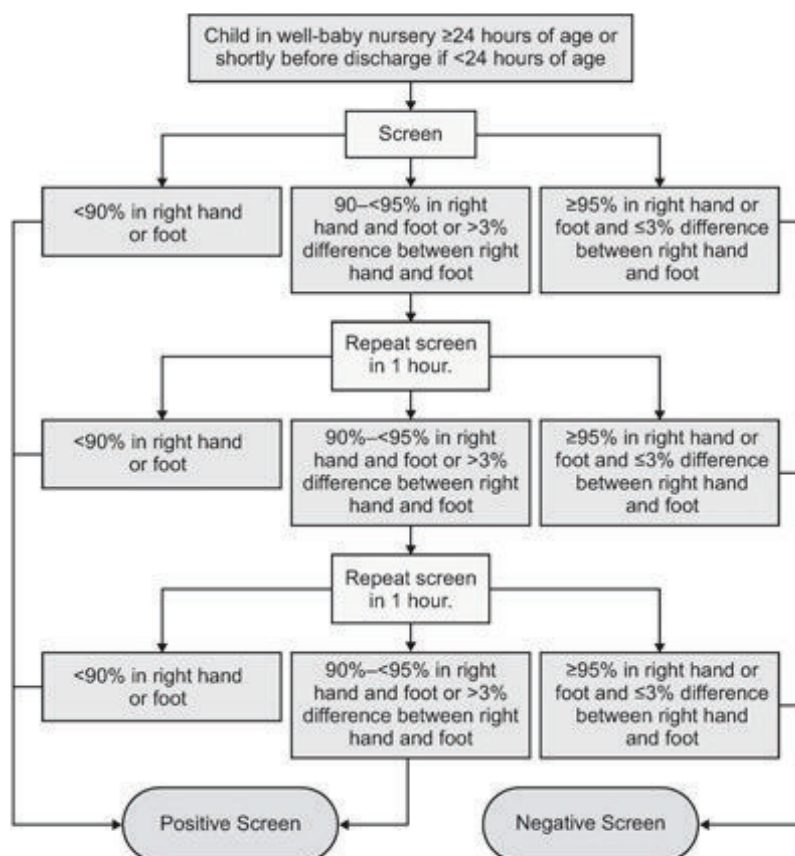

FIGURE 1. The proposed pulse-oximetry monitoring protocol based on results from the right hand and either foot. From Kemper AR, Mahle WT, Martin GR, et al. Strategies for implementing screening for critical congenital heart disease. *Pediatrics*. 2011;128(5):e1259–e1267.

Differential Saturation Interpretation

- **Lower postductal saturation** suggests coarctation of aorta, pulmonary hypertension, critical left-sided obstructive lesions, or infradiaphragmatic total anomalous pulmonary venous return.
- **Higher postductal saturation** suggests transposition or supracardiac total anomalous pulmonary venous return.

Hyperoxia Test

- In infants with cyanosis, a hyperoxia test using arterial blood gas is performed to differentiate cyanotic congenital heart disease from other etiologies of hypoxia. If a right radial arterial PaO_2 on 100% FiO_2 is <150 mm Hg, cyanotic congenital heart disease is likely (**Table 4**).

Table 4. Diagnostic Testing in Cyanosis					
Test	Pulmonary Parenchymal Disease	Intra- or Extrapulmonary Right to Left Shunt	Central Hypoventilation	Transposition Physiology	Hemoglobin Disorders
Respiratory distress	Present; may have fever	No	No; apnea/hypoventilation	Mild distress, usually tachypnea due to increased PBF	No
Cardiac exam	Normal	May have single S ₂ , RV heave, thrill and murmurs	Normal	Single S ₂ , flow murmur, RV heave	Normal
Chest x-ray	Pulmonary pathology	Variable cardiac silhouette; usually clear lung fields	Normal	Egg-on-end appearance, pulmonary venous congestion ±	Normal
Differential saturation (preductal vs. postductal)	Absent	Present if right-to-left shunt at ductus; postductal < preductal	Absent	Postductal > preductal	Absent
CBC	Elevated white cell count	Polycythemia if chronic	Normal	Polycythemia if chronic	Normal
Arterial blood gas on 100% FiO ₂	Pao ₂ > 150 mm Hg Paco ₂ variable	Pao ₂ < 150 mm Hg Normal Paco ₂	Pao ₂ > 150 mm Hg, usually much higher; elevated Paco ₂	Pao ₂ < 150 mm Hg, usually < 50 mm Hg; normal Paco ₂	Normal Pao ₂ and Paco ₂

CBC, complete blood count; FiO₂, fraction of inspired oxygen; PBF, pulmonary blood flow; RV, right ventricle.
Adapted from Hiremath G, Kamat D. Diagnostic considerations in infants and children with cyanosis. *Pediatr Ann.* 2015;44(2):76–80.

ELECTROCARDIOGRAPHY

- The standard ECG consists of 12 leads that include 3 limb leads (I, II, III), 3 augmented limb leads (aVR, aVL, aVF), and 6 precordial leads (V₁–V₆). In children, additional precordial leads are often used, making it a 15-lead ECG (V_{3R}, V_{4R}, and V₇).
- The standard ECG paper speed is 25 mm/s with amplitude of 0.1 mV/mm (**Fig. 2**). Each small box is 40 ms, and each large box is 200 ms.

FIGURE 2. A normal electrocardiogram showing waveforms and intervals. The standard paper speed is 25 mm/s; therefore, a single 1-mm box equals 0.04 seconds, and a large (5-mm) box equals 0.20 seconds.

- Pediatric ECG parameters are age-dependent.** See **Table 5** for

comprehensive standards of normal ECG in children.

d, days; ECG, electrocardiogram; mo, months; y, years.
From Van Hare GE, Dubin AM. The normal electrocardiogram. In: Allen HD, Discol DJ, Shaddy RE, et al, eds. *Mass & Adams' Heart Disease in Infants, Children, and Adolescents*. Philadelphia: Lippincott Williams & Wilkins; 2008:253-268.

Rate and Rhythm

- **Heart rate is calculated by dividing 60,000 ms/min by the measured cycle length.** The rhythm is considered sinus if each QRS is preceded by a P wave, and the P wave is upright in I, II, and aVF.

Axes

- Axes can be calculated in a hexaxial reference plane for all three waves of the ECG.
- **P-wave axis** indicates whether the rhythm begins in the sinus node or an alternative pacemaker.
- **QRS axis changes with age.** In the newborn period, the mean vector of depolarization is rightward, reflecting the dominance of the right ventricle in early infancy. As the left ventricular mass increases relative to the right side, the QRS axis shifts more leftward.
- **A superior QRS (northwest axis) suggests an endocardial cushion defect or tricuspid atresia.**
- The **T wave** represents ventricular repolarization. Within the first 72 hours of life, the T wave should invert in lead V₁. Persistence of upright T wave beyond 7 days of age until adolescence is a sensitive indicator of increased right ventricular pressure. As the left ventricle becomes progressively more dominant, the T-wave axis parallels the QRS axis. Thus, during adolescence, the T wave becomes upright in lead V₁ and the T-wave axis becomes leftward.
- The **QRS-T angle** should be ≤ 90 degrees. Abnormally wide QRS-T angle may be a result of ventricular hypertrophy with strain pattern or ventricular conduction disturbance.

Atrioventricular Conduction and Intervals

- The PR interval is measured from the onset of the P wave to the beginning of the QRS complex and reflects the time for atrial depolarization and delay through the AV node. In general, with age, the heart rate is slower and the PR interval is longer.
- A **short PR interval** occurs when there is Wolff-Parkinson-White syndrome, Lown-Ganong-Levine syndrome, glycogen storage disease, or low atrial pacemaker.

Abnormal Atrioventricular Conduction

- **First-degree AV block** is PR prolongation for age and heart rate.
- **Second-degree AV block** can be Mobitz Type I (Wenckebach), where there is progressive PR prolongation before a dropped beat or Mobitz

Type II, where there is abrupt failure of AV conduction without previous PR prolongation.

- **Third-degree AV block** involves no conduction of atrial impulses to the ventricle.
- **QRS widening** is seen with a bundle branch block, preexcitation (e.g., Wolff-Parkinson-White syndrome), intraventricular block, ventricular arrhythmias, and ventricular-paced rhythms.
- **Left bundle branch block** is diagnosed when there is slurred R wave in left precordial leads (V_6) and slurred S wave in right precordial leads (V_1).
- **Right bundle branch block** is diagnosed when there is a wide and slurred S wave in leads V_1 and V_6 , slurred R (rSR' pattern or M shaped QRS complex) in lead V_1 . Left anterior hemiblock can be diagnosed in the setting of left axis deviation associated with right bundle branch block.
- **QT interval** represents the time it takes for ventricular depolarization and repolarization and is measured from the onset of the Q wave to the termination of the T wave. Given that the QT interval should shorten with increasing heart rates, the QT measurement should be adjusted for heart rate using **Bazett formula**:

$$QTc = \frac{\text{measured QT}}{\text{square root of the R-R interval}}$$

- **The QTc interval is less than 0.45 seconds for infants younger than 6 months, and less than 0.44 seconds for children.**
- The QTc is prolonged in **long QT syndrome** wherein there are genetic abnormalities of either the cardiac potassium or sodium channels. Other conditions that prolong the QTc interval include head injury, myocarditis, medications (such as, procainamide, amiodarone, quinidine) and electrolyte abnormalities (e.g., hypocalcemia, hypomagnesemia, hypokalemia).

Waveforms

- When the P-wave amplitude is greater than 3 mm in lead II or lead V_1 , **right atrial enlargement** is present. If the P wave has duration greater

than 0.1 seconds in lead II or is biphasic with a prominent negative component in lead V₁, **left atrial enlargement** is present.

- Abnormally, tall R waves in lead V₁ or deep S waves in V₅ and V₆ represent **right ventricular hypertrophy**. Similarly, tall R waves in leads V₅ and V₆ or deep S waves in lead V₁ **represent left ventricular hypertrophy**.
- Low-voltage QRS complexes suggest myocarditis, pericarditis, pericardial effusion, or hypothyroidism.
- Tall, peaked T waves can be seen with ventricular hypertrophy associated with strain, myocardial infarction, or hyperkalemia.
- Low voltage, flat T waves are associated with electrolyte abnormalities (hypokalemia, hypoglycemia), hypothyroidism, myocarditis, pericarditis, ischemia, or medications (i.e., digitalis).

CHEST ROENTGENOGRAM

The plain chest roentgenogram is inexpensive, expedient, readily available, and continues to provide important information to the clinician when cardiac disease is suspected. The normal cardiac silhouette in the anteroposterior and lateral views are shown in **Figure 3**.

FIGURE 3. Normal cardiac silhouette. (Modified from Sapire DW. *Understanding and Diagnosing Pediatric Heart Disease*, East Norwalk, CT: Appleton & Lange; 1991:64, with permission.)

Heart Size

- **Cardiomegaly** can be due to dilated cardiac chambers or pericardial effusion. A quantitative assessment of cardiac size should be made on the inspiratory film, when 9–10 ribs are visualized above the level of the diaphragm.
- **The cardiothoracic ratio** is then determined by comparing the transverse dimension of the heart relative to the width of the thoracic cavity. **The heart is considered enlarged if the cardiothoracic ratio exceeds 60%.**

Pulmonary Vascularity

- When there is a suspicion of congenital heart disease, the appearance of the pulmonary vascular markings plays an important role in

understanding the pathophysiology.

- **Increased vascularity** is seen when a large left-to-right shunt is present (as in atrial septal defect, ventricular septal defect, patent ductus arteriosus). Increased pulmonary arterial flow makes the vessels appear sharp and prominent.
- **Decreased vascularity** is seen in right-sided obstructive lesion that result in decreased pulmonary blood flow or in Eisenmenger syndrome.
- **Pulmonary venous congestion** indicated by bronchial cuffing, and Kerley B lines (horizontal lines seen at periphery of lung fields suggesting fluid-filled interlobar septa), suggest pulmonary venous obstructive disease or congestive heart failure.

Specific Cardiac Lesions

- Distinctive radiographic configurations of the cardiac silhouette have been associated with specific cardiac lesions as listed below:
 - **Tetralogy of Fallot:** “boot-shaped” heart
 - **Total anomalous pulmonary venous return (supracardiac type):** “snowman” or “figure of 8”
 - **Coarctation of aorta:** “figure 3”
 - **D-transposition of great arteries:** “egg on a string”
 - **L-transposition of great arteries:** “box-shaped heart”
 - **Ebstein anomaly:** “wall-to-wall” heart

ECHOCARDIOGRAPHY

- Echocardiography involves the use of ultrasound technology to image the heart. It is an invaluable tool that provides details of the cardiac anatomy, function, and physiology.
- Echocardiography can be done bedside and is very valuable in emergently ruling out pericardial effusions and checking ventricular function.
- **Transesophageal echo** is done when more detailed information is needed or to guide cardiac surgery or catheterization procedures, using a probe inserted through the esophagus.
- **Normal values for valve and chamber dimensions vary with age/size and are available in the literature for comparison.**

- **Ejection fraction (EF)** is calculated by using left ventricular end-diastolic and end-systolic volumes in 2 planes. **Normal left ventricular EF: 56–75%**
- **Shortening fraction (SF)** is also a measure of left ventricular contractility and is measured in M-mode. **Normal left ventricular SF: 28–38%**

CARDIAC CATHETERIZATION

- **Diagnostic cardiac catheterization** measures direct oximetry and hemodynamics. In conjunction with angiography, it provides complete data on cardiac anatomy and physiology.
- **The normal pressures and oxygen saturations for children are shown in Figure 4.**

FIGURE 4. Normal pressures (systolic over diastolic, in mm Hg), mean pressures, and oxygen saturations for children during cardiac catheterization. The data are based on information compiled from healthy patients between the ages of 2 months and 20 years. AO, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

- **Interventional catheterization** has therapeutic applications including device closure of atrial septal defects, ventricular septal defects, and patent ductus arteriosus; performance of pulmonary artery angioplasty and stent placement; balloon dilation of valvar aortic and pulmonary stenosis; balloon angioplasty and stent repair of coarctation; and transcatheter replacement of pulmonary valves.

Calculation of Flows, Shunts, and Resistances

- **Cardiac output** can be calculated using thermodilution or Fick principle. When using Fick principle, oxygen is used as an indicator and blood flow can be calculated using oxygen consumption (measured or assumed) divided by the arteriovenous oxygen content difference.

$$Q_s \text{ (cardiac output)} = \frac{\text{(oxygen consumption)}}{\text{(systemic arterial oxygen content - systemic venous oxygen content)}}$$

- In most instances, the fraction of dissolved oxygen as a percentage of total oxygen content is negligible and can be ignored. That makes the equation for cardiac output simpler as shown below:

$$Q_s \text{ (systemic blood flow in L/min)} = \frac{O_2 \text{ consumption (L/min)}}{(1.36) \times (10) \times (\text{Hgb g/dL}) \times (\text{aorta sat} - \text{superior vena cava sat})}$$

Similarly,

$$Q_p \text{ (pulmonary blood flow in L/min)} = \frac{O_2 \text{ consumption (L/min)}}{(1.36) \times (10) \times (\text{Hgb in g/dL}) \times (\text{pulmonary vein sat} - \text{pulmonary artery sat})}$$

- **Normal cardiac output = 3–4.5 L/min/m²**
- Mathematically, the ratio of pulmonary blood flow to systemic blood flow is easier to calculate and is expressed as:

$$Q_p/Q_s = \frac{\text{aortic sat} - \text{SVC sat}}{\text{pulmonary venous sat} - \text{pulmonary arterial sat}}$$

- **Using the mixed venous saturation, systemic saturation, and Hgb, one can use the same principle to calculate cardiac output in any patient who has a central venous line.**

Resistance

- Systemic and pulmonary vascular resistance (SVR and PVR) can also be calculated using the catheterization data. This calculation is based on Ohm's law (resistance equals the pressure change across the

vascular bed divided by flow):

$$\text{SVR} = (\text{AO} - \text{RA})/\text{Qs}$$

$$\text{PVR} = (\text{PA} - \text{LA})/\text{Qp}$$

in which

AO = mean systemic (aorta) pressure

RA = mean right atrial pressure

PA = mean pulmonary artery pressure

LA = mean left atrial pressure

- **Normal pulmonary vascular resistance (PVR) = 1–3 Wood units/m²**

Appendix III

Syndromes Glossary

Angela Scheuerle

4p– syndrome (Wolf-Hirschhorn syndrome; deletion 4p; monosomy 4p)—characterized by growth failure of prenatal onset, microcephaly, “Greek helmet” facies (high forehead, prominent glabella, arched eyebrows, straight nose): hypertelorism, hypotonia, neurocognitive impairment, seizures; scoliosis

5p– syndrome (Cri du chat syndrome; deletion 5p; monosomy 5p)—characterized by catlike cry in infancy due to an abnormal larynx, growth failure of prenatal onset, microcephaly, neurocognitive impairment, hypotonia, round face, hypertelorism

13q– syndrome (deletion 13q; 13q monosomy)—characterized by growth deficiency of prenatal onset, microcephaly, and typically involves malformations of the brain, heart, kidneys, and digits; usually lethal, but severity varies with the size of the deletion. If the deletion involves the retinoblastoma gene, there is a high risk of cancer

22q11.2 deletion syndrome (microdeletion of 22q11.21)—phenotype varies widely from isolated mild learning disabilities and speech problems to complete DiGeorge syndrome. Common abnormalities include cleft soft palate or velopharyngeal incompetence, conotruncal heart defects, renal malformations, short stature, long fingers, and characteristic facies. Complete DiGeorge syndrome includes thymic aplasia, cellular immunodeficiency, parathyroid abnormalities, hypocalcemia, and interrupted aortic arch.

Aagenaes syndrome—autosomal recessive; characterized by recurrent intrahepatic cholestasis, which decreases with age and with lymphedema. Higher incidence in Norwegians

Aarskog syndrome—X-linked recessive; mutations in FGD1; characterized by short stature, mild to moderate mental deficiency in 1/3 of patients, musculoskeletal and genital anomalies; hypertelorism, small nose with anteverted nares, broad philtrum and nasal bridge, abnormal auricles and widow’s peak, brachyclinodactyly, broad thumbs, broad feet with bulbous toes, simian crease, ptosis, syndactyly, “shawl” scrotum

(penoscrotal transposition), cryptorchidism, inguinal hernia, hyperopic astigmatism, large corneas, ophthalmoplegia, strabismus, delayed puberty, mild pectus excavatum, prominent umbilicus; delayed bone age

Abetalipoproteinemia—autosomal recessive; mutations in MTTP; characterized by hypocholesterolemia and malabsorption of lipid-soluble vitamins. Secondary effects include retinal degeneration, neuropathy, and coagulopathy; early signs include failure to thrive, diarrhea, and acanthocytosis (star-shaped RBCs); childhood features include poor muscle control, ataxia, progressive pigmentary degeneration of the retina; by adulthood, there is significant cerebellar ataxia; absent or reduced lipoproteins and low carotene, vitamin A, and cholesterol levels. Higher incidence in Ashkenazi Jews

Achondroplasia—autosomal dominant; mutations in FGFR3; 90% of cases result from new mutations, usually paternal in origin; characterized by disproportionate short stature with rhizomelia, macrocephaly, small foramen magnum (risk of cord compression), caudal narrowing of spinal canal, mild hypotonia, normal intelligence, and relative glucose intolerance

Acrodermatitis enteropathica—autosomal recessive; mutations in SLC39A4; characterized by abnormal intestinal absorption of zinc, resulting in zinc deficiency. Secondary effects include vesicobullous and eczematous skin lesions in the perioral and perineal areas, cheeks, knees, and elbows; photophobia, conjunctivitis, and corneal dystrophy; chronic diarrhea; glossitis; nail dystrophy; growth retardation; superinfections and candidal infections; treatment requires lifelong zinc supplementation.

Agenesis of corpus callosum—multifactorial; complete or partial absence of the major tracts connecting the right and left hemispheres. Can be associated with hydrocephalus, seizures, developmental delay, spasticity, and hypertelorism; can be isolated or found with other brain malformations, and in many multiple anomaly and chromosomal syndromes

Aicardi syndrome—X-linked dominant, gene remains unknown; lethal in males; characterized by microcephaly, various brain malformations including cysts and heterotopias, infantile spasms, chorioretinal lacunae, and costovertebral skeletal abnormalities

Alagille syndrome (arteriohepatic dysplasia)—autosomal dominant; mutations in JAG1; characterized by paucity or absence of intrahepatic bile ducts with progressive destruction of bile ducts and 5 clinical abnormalities: cholestasis, cardiac disease characteristic facies (broad forehead, deep-set eyes that are widely spaced and underdeveloped, a small, pointed mandible), skeletal defects, and eye abnormalities. 39% of cases also have renal involvement.

Albright syndrome—see “[McCune-Albright syndrome](#).”

Alexander disease—autosomal dominant; mutations in GFAP; 3 subtypes: infantile, juvenile, adult; characterized by megalencephaly in infants, neurocognitive delay, and, spasticity; seizures in childhood; older patients show bulbar or pseudobulbar symptoms and spasticity. Subpial and subependymal astrocyte footplates have hyaline eosinophilic inclusions; progressive, degenerative disease with death with most patients dying within 10 years of onset; features similar to Canavan syndrome

Alport syndrome—X-linked, mutations in COL4A5: there are less common autosomal dominant and recessive forms; characterized by renal failure due to glomerulonephropathy, sensorineural hearing loss, and variable eye anomalies. Usually presents in infancy with hematuria, with proteinuria and hearing loss being later findings. Carrier mothers may show microscopic hematuria.

Andermann syndrome (Charlevoix disease)—autosomal recessive; mutations in SLC12A6; characterized by agenesis of the corpus callosum, progressive motor and sensory neuropathy, and neurocognitive defects. There are characteristic facies.

Andersen disease—see “[glycogen storage disease IV](#).”

Angelman syndrome—absence of maternal alleles of 15q11.2 that include the UBE3A gene. Mechanisms include deletion on the maternal chromosome, or paternal uniparental disomy. Rarely, mutations in the gene itself. Ataxic gait (wide-based, arms held upward) seizures, paroxysmal laughter, mental deficiency, absent or severely reduced speech, microcephaly; blonde hair and blue eyes in the deletion cases, characteristic facies with maxillary hypoplasia, large mouth, tongue protrusion and prognathia.

Apert syndrome (acrocephalosyndactyly type I)—autosomal dominant; mutations in FGFR2; characterized by craniosynostosis (typically coronal), turribrachycephaly, underdevelopment of the middle 3rd of the face, hypertelorism and proptosis; a narrow, high, arched palate; a short, beaked nose; variable but pronounced syndactyly. Other anomalies include malrotation and gastrointestinal atresias. Neurocognitive delays are present, but intelligence can be normal.

Ataxia telangiectasia syndrome—autosomal recessive; mutations in ATM; characterized by progressive ataxia within the first year, telangiectasias by age 8 years are a later finding. Degenerative central nervous system function, lymphopenia, immune deficit (low to absent IgA and IgE), growth deficiency, and mental deficits. Increased risk of lymphomas and leukemias in patients and carrier parents. Increased sensitivity to the effects of radiation exposure, including medical x-rays. Individuals have increased serum alpha-fetoprotein (AFP) levels.

Autosomal dominant epidermolysis bullosa dystrophica (Bart syndrome)—mutations in COL7A1; characterized by congenital aplasia of the skin on the lower legs and feet; nail defects and recurrent blistering of the skin and mucous membranes

Axenfeld-Rieger syndrome—autosomal dominant; mutations in PITX2; characterized by Rieger anomaly of the eye (anterior segment dysgenesis), glaucoma, hypodontia, maxillary hypoplasia, and umbilical abnormalities

Bardet-Biedl syndrome—autosomal recessive; mutations in various

genes; this is a condition caused by abnormalities in nonmotile cilia (the ciliopathies); characterized by mental retardation, retinitis pigmentosa, obesity, polydactyly, renal anomalies, hypogonadism, and neurocognitive impairments (presentation can resemble Prader-Willi syndrome with polydactyly)

Bart syndrome—see “[autosomal dominant epidermolysis bullosa dystrophica](#).”

Bartter syndrome—autosomal recessive group of disorders of impaired renal salt reabsorption, salt wasting, hypokalemic metabolic alkalosis and hypercalciuria. Multiple related genes. Patients have normal blood pressure, but the renin level is elevated; generalized muscle weakness

Basal cell nevus syndrome—autosomal dominant; mutations in PTCH1, PTCH2, or SUFU; characterized by basal cell carcinomas, macrocephaly, odontogenic keratocysts of jaws, bifid ribs, pits in the palms and soles, and calcification of the falx cerebri

Beckwith-Wiedemann syndrome (exomphalos-macroglossia-gigantism syndrome)—sporadic imprinting disorder of chromosome 11 or autosomal dominant due to mutations in CDKN1C; characterized by overgrowth of prenatal onset, omphalocele, macroglossia, hemihypertrophy, and characteristic facies. Significant increased risk of Wilms tumor and hepatoblastoma with higher risk in patients with hemihyperplasia. Neurocognitive impairment if neonatal hypoglycemia is unrecognized or uncontrolled

Behçet syndrome—presumed autosomal dominant; gene unidentified; disease mechanism unknown. Recurrent inflammatory lesions: oral and genital ulcers, various skin and eye lesions

Bloch-Sulzberger syndrome—see “[incontinentia pigmenti](#).”

Bloom syndrome—autosomal recessive; mutations in BLM; characterized by growth deficiency of prenatal onset, high risk of malignancy, microcephaly with dolichocephaly, facial telangiectatic erythema in a

butterfly pattern, skin pigmentation changes, mild neurocognitive impairment, and characteristic facies increased prevalence in Ashkenazi Jews; chromosome instability syndrome

Blue diaper syndrome—probably autosomal recessive; gene unidentified; defect in intestinal transport of tryptophan; bacterial degradation of the tryptophan form water-soluble metabolites that turn blue on exposure to oxygen. Only two brothers have been documented with the transport defect. Other causes of blue or discolored urine should be investigated.

Byler disease—see “[progressive familial intrahepatic cholestasis](#).”

Canavan syndrome—autosomal recessive; mutations in ASPA; progressive, degenerative demyelination and leukodystrophy. Usually beginning in infancy with macrocephaly, hypotonia, and developmental regression. Features similar to Alexander disease. Increased prevalence in Ashkenazi Jews

Caroli disease—inheritance pattern unclear; gene unidentified; overlaps significantly with the polycystic kidney syndromes and may not represent a separate entity; characterized by cystic dilatation of the intrahepatic bile ducts; recurrent bouts of cholangitis and biliary abscesses secondary to bile stasis and gallstones

Cat-eye syndrome (tetrasomy 22)—presence of an extra chromosome comprising two identical segments of chromosome 22 (i.e., the patient has 4 total copies of chromosome 22); characterized by coloboma of iris, down-slanting palpebral fissures, anal atresia, cardiac defects, renal agenesis; mild neurocognitive impairment. Growth is usually normal.

Charcot-Marie-Tooth disease (hereditary motor and sensory neuropathy [HMSN] or peroneal muscular atrophy)—a group of sensorineural peripheral polyneuropathies with various inheritance patterns and a wide range of clinical presentation; most common cause of chronic peripheral neuropathy; characterized by insidious onset and slowly progressive weakness and atrophy of distal limb muscles, impaired sensation

CHARGE syndrome—autosomal dominant; mutations in CHD7; characterized by Coloboma, Heart disease, choanal Atresia, Retarded growth and development and/or CNS anomalies, Genital anomalies and/or hypogonadism, and Ear anomalies and/or deafness. The ear malformation is a characteristic. Mondini defect and hypoplastic semicircular canals of the inner ear in the presence of other typical malformations is diagnostic for CHARGE.

Chédiak-Higashi syndrome—autosomal recessive; mutations in LYST; characterized by oculocutaneous albinism, lack of natural killer cells, decreased neutrophil and monocyte migration, anemia, neurodegeneration, hepatomegaly, and splenomegaly

Cockayne syndrome—autosomal recessive; mutations in ERCC6 and ERCC8; characterized by postnatal growth deficiency, microcephaly, neurocognitive impairment, ataxia, hearing loss, seizures, characteristic facies, hypertension, renal dysfunction, and photosensitivity

Congenital rubella syndrome—see “[fetal rubella syndrome](#).”

Cornelia de Lange syndrome (Brachmann-De Lange syndrome, de Lange syndrome)—autosomal dominant; mutations in NIPBL cause most cases; characterized by growth failure of prenatal onset microcephaly, hirsutism, limb reduction defects—particularly ulnar ray defects—gastroesophageal reflux, congenital heart defects, neurocognitive impairment, and characteristic facies

Crigler-Najjar syndrome, type I (glucuronyl transferase deficiency)—autosomal recessive; mutations in UGT1A1; absence of hepatic uridine 5'-diphospho-glucuronosyltransferase activity leading to unconjugated hyperbilirubinemia on 1st day of life without evidence of hemolysis; requires phototherapy to prevent kernicterus. Patients do not respond to phenobarbital treatment to lower serum bilirubin.

Crigler-Najjar syndrome, type II—autosomal recessive; mutations in UGT1A1; less severe unconjugated hyperbilirubinemia due to partial activity of uridine 5'-diphospho-glucuronosyltransferase; kernicterus is

less common than in type I. Patients respond to phenobarbital treatment to lower serum bilirubin.

Crouzon syndrome (craniofacial dysostosis)—autosomal dominant; mutations in FGFR2; characterized by craniosynostosis (most often coronal), exophthalmos due to shallow orbits, hypertelorism, high palate, and hypoplasia of maxilla; obstructive sleep apnea is common.

Cyclic neutropenia—autosomal dominant; mutations in ELANE; lack of granulocyte macrophage colony-stimulating factor (GM-CSF); characterized by fever, mouth lesions, cervical adenitis, and gastroenteritis; underlying regular 21-day cyclic fluctuation in number of blood leukocytes

De Sanctis-Cacchione syndrome—see “[xeroderma pigmentosum](#).”

Diamond-Blackfan syndrome (congenital pure red cell aplasia)—autosomal dominant; mutations in RPS19; failure of erythropoiesis; characterized by normochromic macrocytic anemia, postnatal growth retardation, craniofacial, limb heart, and urinary system malformations in 30–50%. One of the ribosomopathies

DiGeorge syndrome—see “[22q11.2 deletion syndrome](#).”

Down syndrome—see “[trisomy 21](#).”

Dubin-Johnson syndrome—autosomal recessive; mutations in ABCG2; characterized by elevated conjugated bilirubin, large amounts of coproporphyrin I in urine, and deposits of melanin like pigment in hepatocellular lysosomes, there is otherwise normal liver function.

Dubowitz syndrome—autosomal recessive; gene unidentified; growth failure of prenatal onset, microcephaly, eczema-like skin disorder, brachydactyly, various ocular abnormalities, neurocognitive impairment, characteristic facies that resemble fetal alcohol syndrome

Eagle-Barrett syndrome—see “[prune belly sequence](#).”

Ectodermal dysplasia—variable inheritance; a category of disease rather than a single condition; characterized by poor development or absence of teeth, nails, hair, and sweat glands

Edwards syndrome—see “[trisomy 18](#).”

Ehlers-Danlos syndrome—autosomal dominant group of conditions classified by type; hypermobile joints and hyperextensible or fragile skin are characteristic features across the types, but the specific phenotypes vary. Classic type (type I) is caused by mutations in COL5A1 or COL5A2. Abnormalities of the vasculature and hollow organs are characteristic of vascular type (type IV) caused by mutations in .

Fabry disease—X-linked; mutations in GLA; deficiency alpha-galactosidase A leading to lysosomal storage of glycosphingolipids; involvement of blood vessels leads to tingling and burning in the hands and feet; small, red maculopapular angiofibromata on the buttocks, inguinal area, fingernails, and lips; and an inability to perspire; renal involvement including proteinuria, progressing to renal failure; increased risk of cardiovascular disease and stroke; carrier females frequently manifest symptoms. Treated with replacement enzyme

Familial adenomatous polyposis—autosomal dominant; mutations in APC; characterized by multiple GI polyps with malignant transformation, skin cysts, supernumerary teeth, and multiple osteoma. Gardner syndrome is a variant in which desmoid tumors and other neoplasms occur along with the colon and rectum adenomata.

Familial dysautonomia (hereditary sensory and autonomic neuropathy)—autosomal recessive; mutations in IKBKAP; characterized by aberrant sensory and autonomic functions; progressive course of poor growth, alacrima, decreased taste sense, postural hypotension, episodic hyperhidrosis, hypotonia, and decreased pain sensation. Higher prevalence in Ashkenazi Jews

Farber lipogranulomatosis—autosomal recessive; mutations in ASAH1; deficiency of acid ceramidase; characterized by subcutaneous nodules,

painful and progressively deformed joints, and laryngeal involvement with hoarseness

Fetal alcohol spectrum disorder (FASD)—characterized by growth deficiency of prenatal onset, microcephaly, cardiac septal defect; delayed development; and neurocognitive impairment with a history of or suspicion for maternal alcohol use during pregnancy. Characteristic facies have been defined. Wide ranging effects that include neurocognitive problems (specifically abnormalities in executive function) even in the absence of physical features. The most severe end of the spectrum constitutes fetal alcohol syndrome. The CDC publishes specific diagnostic guidance.

Fetal alcohol syndrome—see “[fetal alcohol spectrum disorder](#).”

Fetal hydantoin syndrome—characterized by growth deficiency of prenatal onset; characteristic facies, neurocognitive impairment, and nail hypoplasia/aplasia may have cleft lip and palate, and cardiac defects

Fetal rubella syndrome—in utero rubella exposure (especially in the 1st trimester); characterized by mental deficiency, microcephaly, deafness, cataract, glaucoma, patent ductus arteriosus, cardiac septal defects, hepatosplenomegaly, anemia, and thrombocytopenia

Fetal valproate syndrome—characterized by neurocognitive impairments, neural tube defects, cardiovascular anomalies, and characteristic facies

Fetal warfarin syndrome—6–9 week exposure characterized by defects associated with aberrant cartilage: nasal hypoplasia, stippled epiphyses, hypoplastic distal phalanges. 14–20 week exposure characterized by central nervous system defects, eye anomalies, and intrauterine growth retardation. Exposure in the 3rd trimester is less concerning.

Fibrodysplasia ossificans progressiva (FOP)—autosomal dominant; mutations in ACVR1; characterized by short hallux, progressive ossification of muscles and subcutaneous tissues, and hearing loss; any

trauma (including iatrogenic) can cause ectopic ossification.

Focal dermal hypoplasia—X-linked dominant; mutations in PORCN; characterized by linear atrophy of the skin with fat herniation through the dermis, linear pigmentation abnormalities, and papillomata; may have eye, oral, or digit abnormalities

Fragile X syndrome—X-linked; triplet repeat mutations in FRM1; characterized by mental deficiency, autism spectrum disorders, macrocephaly, prognathism, large ears, mild connective tissue dysplasia, and macroorchidism after puberty. Female full mutation carriers can manifest the phenotype. Female carriers of premutations have increased risk of premature ovarian insufficiency. Male and female permutation carriers have increased risk of fragile X–associated tremor ataxia syndrome as adults.

Friedreich ataxia—autosomal recessive; triplet repeat mutations in FXN; progressive loss of large myelinated axons in peripheral nerves, with symptoms usually appearing in late childhood or adolescence; characterized by progressive cerebellar and spinal cord dysfunction; patients have high-arched foot, hammer toes, and cardiac failure

Gardner syndrome—see “[familial adenomatous polyposis](#).”

Gaucher disease—autosomal recessive; mutations in GBA; deficiency of glucocerebrosidase, leading to accumulation and storage of glucocerebroside in the reticuloendothelial system; 3 types: (a) adult, or chronic, (b) acute neuropathic, or infantile, (c) subacute neuropathic, or juvenile; characterized by splenomegaly, hepatomegaly, delayed development, strabismus, swallowing difficulties, laryngeal spasm, opisthotonos, and bone pain

Gilbert syndrome—typically autosomal recessive, but carriers can manifest symptoms; mutations in UGT1A1; reduced activity of glucuronyltransferase activity leading to mild unconjugated hyperbilirubinemia that worsens with stresses on the body, such as fasting

Gilles de la Tourette syndrome—Evidence suggests that mutations in one or more genes may be involved. Neurobehavioral disorder characterized by multiple motor and vocal tics that begin before the age of 18 years; difficulties, including obsessive-compulsive disorder, ADHD, anger control problems, and poor social skills

Glanzmann thrombasthenia—autosomal recessive; mutations in ITGA2B and ITGB3; involves defective primary platelet aggregation (size and survival of platelets is normal). Presents as bleeding dyscrasias

Glycogen storage disease 1A (GSD1A; von Gierke)—autosomal recessive; mutations in G6PC; inherited defect in glucose-6-phosphatase resulting in accumulation of glycogen and defective gluconeogenesis; characterized by fasting hypoglycemia, growth retardation, hepatomegaly, lactic acidosis, hyperlipidemia, and hyperuricemia

Glycogen storage disease IV (GSD4; Andersen disease)—autosomal recessive; mutations in GBE1; defect of glycogen branching enzyme; classic form characterized by hepatomegaly and failure to thrive in the 1st few months of life, progressing to liver cirrhosis and splenomegaly. Neuromuscular forms can present at any age.

Goldenhar syndrome—see “[oculo-auriculo-vertebral spectrum](#).”

Goltz syndrome—see “[focal dermal hypoplasia](#).”

Gorlin syndrome—see “[basal cell nevus syndrome](#).”

Hand-Schüller-Christian disease—see “[histiocytosis X](#).”

Hartnup disorder—autosomal recessive; mutations in SLC6A19; defect in transport of monoamine monocarboxylic amino acids by intestinal mucosa and renal tubules; characterized by photosensitivity and a pellagra-like skin rash, cerebellar ataxia, emotional instability, and amino aciduria

Hereditary fructose intolerance—autosomal recessive; mutations in ALDOB; involves deficiency of fructose-1-phosphate aldolase or fructose

1,6-diphosphatase; characterized by vomiting, diarrhea, hypoglycemic seizures, and jaundice upon exposure to fructose or sucrose

Holt-Oram syndrome—autosomal dominant; mutations in TBX5; characterized by upper limb defects, typically radial ray defects, and cardiac anomalies. Most common combination is a missing or hypoplastic thumb and atrial septal defect.

Homocystinuria—autosomal recessive; mutations in CBS; deficient cystathionine synthetase activity leading to marfanoid habitus and neurocognitive impairment, also thrombotic events, generalized hypopigmentation, and, with progression, seizures

Hunter syndrome—see “[mucopolysaccharidosis II](#).”

Hurler syndrome—see “[mucopolysaccharidosis I](#).”

Hutchinson-Gilford progeria syndrome—autosomal dominant; mutations in LMNA; all cases to date have been de novo mutations; characterized by the appearance of premature aging, severe growth failure, atherosclerosis, lipodystrophy, alopecia, and decreased joint mobility. Cognitive development is normal.

Hyper-IgE (Job syndrome)—autosomal dominant; mutations in STAT3; characterized by recurrent deep tissue and skin staphylococcal infections; patients have eosinophilia and IgE levels that are 10 times greater than normal.

Hypogonadotropic hypogonadism with or without anosmia—X-linked or autosomal dominant; some digenic inheritance; multiple genes involved; all have some degree of hypogonadism and altered or absent sense of smell due to olfactory lobe agenesis; bimanual synkinesis; not all affected persons are infertile.

Incontinentia pigmenti (IP)—X-linked dominant; mutations in IKBKG; characterized by 4-stage, evolving skin lesions and abnormalities of skin appendages; eosinophilia; high risk of neonatal stroke; neurocognitive

problems in patients with stroke or CNS anomalies, but majority of patients are neurocognitively normal. Malformations of internal organs are not characteristic of IP.

Jeune thoracic dystrophy—see “[short-rib thoracic dysplasia with or without polydactyly](#).”

Job syndrome—see “[Hyper-IgE](#).”

Kabuki syndrome—autosomal dominant; mutations in KMT2D; characterized by growth deficiency of postnatal onset, mental deficiency, hypotonia, characteristic facies resembling Kabuki dance makeup (long palpebral fissures with lateral ectropion, ptosis, arching eyebrows), skeletal anomalies, cardiac defects, and neurocognitive impairment

Kallmann syndrome—see “[hypogonadotropic hypogonadism with or without anosmia](#).”

Kartagener syndrome—see “[primary ciliary dyskinesia](#).”

Kleine-Levin hibernation syndrome—characterized by episodes of compulsive megaphagia, somnolence, and abnormal behavior predominantly in males

Klinefelter syndrome—47 XXY karyotype; paternal meiosis error; hypogonadism, tall stature with long limbs, mild neurocognitive impairments, although many are cognitively normal. Infertility is not universal.

Klippel-Feil anomaly—sporadic; multifactorial; cervical spine fusion of varying degrees; characterized by a short neck, limited neck motion, and low occipital hairline; isolated defect or can appear as part of a multisystem syndrome.

Krabbe leukodystrophy—autosomal recessive; mutations in GALC; deficiency in galactocerebrosidase; lysosomal storage disorder primarily affecting white matter of the central and peripheral nervous systems;

characterized classically by early, severe neurodegeneration leading, in the infantile form, to death by 2 years of age. There are late-onset forms.

Larsen syndrome—autosomal recessive; mutations in B3GAT3; characterized by hyperlaxity, multiple congenital dislocations, short stature, heart defects, and characteristic facies

Laurence-Moon-Biedl syndrome—see “[Bardet-Biedl syndrome](#).”

LEOPARD syndrome—autosomal dominant; mutations in PTPN11, RAF1, or BRAF; characterized by Lentigines, EKG abnormalities, Ocular hypertelorism, Pulmonic stenosis, Abnormalities of genitalia, Retardation of growth, and sensorineural Deafness

Lesch-Nyhan syndrome—X-linked recessive; mutations in HPRT1; defect in purine metabolism; diminished or absent hypoxanthine guanine phosphoribosyl transferase (HPRT) activity leading to hyperuricemia; spastic cerebral palsy, choreoathetosis, uric acid urinary stones; compulsive self-mutilation, and neurocognitive impairment

Letterer-Siwe disease—see “histiocytosis X.”

Lowe syndrome (oculocerebrorenal syndrome)—X-linked recessive; mutations in OCRL; characterized by congenital cataracts, and hydrophthalmia, vitamin D-resistant rickets, amino aciduria, hyporeflexia, hypotonia, renal Fanconi syndrome, and neurocognitive impairment

Lysosomal acid lipase deficiency (Wolman disease)—autosomal recessive; mutations in LIPA; lysosomal storage disease leading to cholesteryl ester and triglyceride deposition in visceral organs; fatal in infancy; characterized by intractable vomiting, failure to thrive, abdominal distention, steatorrhea, hepatosplenomegaly, and adrenal calcification

Maffucci syndrome—see “[multiple enchondromatosis, Maffucci type](#).”

Marfan syndrome—autosomal dominant; mutations in FBN1; characterized by ectopia lentis, dilatation of the aorta, scoliosis,

pneumothorax, pectus deformities, and long, thin extremities. Diagnostic criteria have been published.

McCune-Albright syndrome—autosomal dominant; mutations in GNAS; surviving cases are somatic mosaics as the nonmosaic state is presumed to be an embryonic lethal; characterized by polyostotic fibrous dysplasia; café au lait skin pigmentation, and peripheral precocious puberty. Note: Diagnosis requires biopsy of affected tissue.

MELAS syndrome—mitochondrial or autosomal recessive inheritance; mutations in any of a number of genes active in mitochondria most commonly MTTL1; characterized by Mitochondrial myopathy, Encephalopathy, Lactic Acidosis, and Strokelike episodes; causes seizures, hemiparesis, hemianopsia, or cortical blindness, and episodic vomiting

Menkes disease (kinky hair disease)—X-linked recessive; mutations in ATP7A; impaired GI transport of copper results in copper deficiency; characterized by low serum copper and ceruloplasmin, short, friable, colorless scalp hair, growth failure of postnatal onset, microcephaly, progressive neurocognitive impairment. Death usually by 3 years of age

Mismatch repair cancer syndrome—heritable cancer syndrome; dominant inheritance of one mutated allele, with somatic mutation of the other; mutations in any of 4 separate genes; characterized by adenomatous colonic polyposis associated with malignant brain tumors, especially medulloblastoma and glioblastoma

Möbius syndrome—sporadic; classically characterized by cranial nerve dysfunction causing bilateral facial weakness, feeding difficulties, and impairment of ocular abduction; the term has come to include any condition that includes congenital CN VII palsy.

Morquio syndrome—see “[mucopolysaccharidosis IV](#).”

Mucopolysaccharidosis I (Hurler, Scheie)—autosomal recessive; mutations in IDUA; involves an accumulation of heparan sulfate and dermatan sulfate, and enzyme deficiency of α -L-iduronidase; characterized

by coarse facial features, growth arrest, dysostosis multiplex, glaucoma, arthritis, cardiac valvular disease, and neurocognitive impairment. There is a spectrum of involvement from severe (Hurler phenotype) to mild (Sheie phenotype) and both may be found in the same family. Enzyme replacement therapy is available.

Mucopolysaccharidosis II (Hunter syndrome)—X-linked recessive; mutations in IDS; involves an accumulation of heparan sulfate and dermatan sulfate, and enzyme deficiency of l-iduronate sulfatase; characterized by macrocephaly, coarse facial features, hypertrophy of internal organs, dysostosis multiplex, and neurocognitive impairment. Enzyme replacement therapy is available.

Mucopolysaccharidosis III (Sanfilippo)—autosomal recessive; caused by a deficiency in 1 of 4 enzymes with clinically similar manifestations; lysosomal storage disease characterized by accumulation of heparan sulfate, and progressive neurocognitive impairment with mild somatic features.

Type A—mutations in SGSH and deficiency of heparin N-sulfatase

Type B—mutations in NAGLU and deficiency of alpha-N-acetylglucosaminidase

Type C—mutations in HGSNAT and deficiency of acetyl CoA:alpha-glucosaminide N-acetyltransferase

Type D—mutations in GNS and deficiency of N-acetylglucosamine-6-sulfatase

Mucopolysaccharidosis IV (Morquio syndrome)—autosomal recessive; mutations in GALNS; involves an accumulation of keratan sulfate and chondroitin-6-sulfate and enzyme deficiency of galactosamine-6-sulfate sulfatase; characterized by skeletal dysplasia with short-trunk dwarfism, corneal clouding, small joint hyperlaxity, and cardiac valve disease; patients have laxity of the odontoid processes and are at risk for life-threatening atlantoaxial subluxation. Enzyme replacement therapy is

available.

Multiple enchondromatosis, Maffucci type—all cases to date have been sporadic; presumed to be somatic mosaicism for mutations in currently unidentified gene; characterized by multiple enchondroma of the bone and soft tissue hemangiomas; patients have short stature, skeletal deformities, scoliosis, and high risk of malignant transformation.

Multiple exostoses, type I—autosomal dominant; mutations in EXT1; characterized by presence of multiple osteochondromas (exostosis) occurring most commonly on the metaphysis of long bones, but any bone can be involved, except the skull. Secondary deformity of legs, forearms, and hands typically occur.

Multiple hereditary exostosis—see “[multiple exostoses, type I](#).”

Nail-patella syndrome—autosomal dominant; mutations in LMX1B; characterized by dystrophic and hypoplastic nails, hypoplastic patellae, iliac horns, malformed radial heads, and nephrotic syndrome

Niemann-Pick disease—autosomal recessive; types A and B result from mutations in SMPD1; deficiency of acid sphingomyelinase resulting in accumulation of sphingomyelin in RES and other cells; characterized by failure to thrive, organomegaly, macular cherry red spot, and rapidly progressive neurodegeneration; in its most severe form, patients are normal at birth but by 6 months, experience delayed development and loss of developmental milestones with death by 3 years; increased prevalence in Ashkenazi Jews

Noonan syndrome—autosomal dominant; mutations in any of a number of genes, the most common is PTPN11; clinical features similar to Turner syndrome (but Noonan affects both sexes equally); characterized by short stature, heart defects (most commonly pulmonic stenosis and hypertrophic cardiomyopathy), bleeding diathesis, and characteristic facies. Neurocognitive function varies and is often average.

Oculo-Auriculo-Vertebral spectrum (OAV, Hemifacial microsomia,

Goldenhar)—sporadic; multifactorial; characterized by craniofacial malformations—typically unilateral—starting with microtia and involving ipsilateral skull and face bones, eyeball, and facial soft tissue structures. Severe cases may also involve vertebrae. Cognitive function tends to be normal.

Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia)—autosomal dominant; mutations in ENG; vascular dysplasia; characterized by telangiectases and arteriovenous malformation of the skin, mucosa, and viscera (lung, liver, brain)

Osteogenesis imperfecta—autosomal dominant; types I–IV caused by mutations in COL1A1 or COL1A2; types differentiated by clinical presentation, all involving soft or fragile bones and consequences thereof; other features are conductive hearing loss (due to ossicle fracture), thin sclerae (which appear blue or grey), and dentinogenesis imperfecta.

Type I—frequent fractures with secondary deformation; normal lifespan

Type II—all new mutation or born to unaffected mosaic parent; severe prenatal-onset fractures; typically lethal in infancy

Type III—intermediate between types I and II

Type IV—bone deformation with less tendency to frank fractures

Osteopetrosis—various inheritance patterns. Multiple genes involved. Widely varying phenotypes. Patients have dense bones that are prone to fractures and have mild anemia and craniofacial disproportion; radiologic changes include increased cortical bone density, longitudinal and transverse dense striations at the ends of the long bones, lucent and dense bands in the vertebrae, and thickening at the base of the skull.

Patau syndrome—see “[trisomy 13](#).”

Pelizaeus-Merzbacher disease—X-linked recessive; mutations in PLP1;

characterized by failure of normal CNS myelination; nystagmus, spastic quadriplegia, ataxia and neurocognitive impairment; patients may also have optic atrophy and seizures; infantile and adult onset subtypes

Peutz-Jeghers syndrome—autosomal dominant; mutations in *STK11*; characterized by melanotic macules on the lips and mucous membranes, intestinal polyposis, and increased risk of malignancy

Pierre Robin sequence—characterized by micrognathia, glossoptosis, and cleft soft palate. May be found as an isolated entity or a component of multisystem syndromes, most commonly 22q11.2 deletion syndrome and Stickler syndrome

Poland anomaly—characterized by a unilateral absence or hypoplasia of the pectoralis muscle with ipsilateral breast hypoplasia and sometimes associated upper limb abnormalities. May be found as an isolated entity or a component of multisystem syndromes

Prader-Willi syndrome—absence of paternal alleles of 15q11.2 that include the *SNRPN* gene. Mechanisms include deletion on the paternal chromosome, or maternal uniparental disomy. Rarely, mutations in the gene itself; characterized by hypotonia and initial failure to thrive, followed by marked obesity due to an insatiable appetite; other features include mental retardation, hypogonadism, small hands and feet, and short stature. Appropriate treatment with growth hormone and diet control ameliorates the obesity, increased lean muscle mass, and raises height.

Primary ciliary dyskinesia—autosomal recessive; multiple genes involved; characterized by mucociliary function abnormalities in the respiratory tract, male infertility due to immotile sperm, and hydrocephalus. Kartagener syndrome includes heterotaxy and is caused by mutations in *DNAI1*.

Progeria syndrome—see “[Hutchinson-Gilford progeria syndrome](#).”

Progressive Familial Intrahepatic Cholestasis (Byler disease)
—autosomal recessive; mutations in *ATP8B1*, *PFIC2*, and *PFIC3*;

characterized by intrahepatic cholestasis leading to cirrhosis and end-stage liver disease before adulthood and anticipated secondary effects of liver failure; short stature, failure to thrive, splenomegaly

Prune belly sequence—characterized by deficiency of the abdominal musculature; most commonly in association with a grossly distended urinary system due to bladder outlet obstruction. The primary defect is variable, even within the urinary system. Obstruction and dilation of other viscera, or presence of a mass can lead to prune belly as a secondary feature. There are some cases described that appear to be primary failure of the muscle to form.

Rieger syndrome—see “[Axenfeld-Rieger syndrome](#).”

Riley-Day syndrome—see “[familial dysautonomia](#).”

Rotor syndrome—autosomal recessive; digenic inheritance of homozygous mutations in *SLCO1B1* and *SLCO1B3*; characterized by mild conjugated bilirubinemia and jaundice that may be exacerbated by infection, surgery, pregnancy, or drugs; usually asymptomatic with normal life expectancy; clinically, similar to Dubin-Johnson; however, patients with Rotor have normal-appearing hepatocytes.

Rubinstein-Taybi syndrome—autosomal dominant; mutations in *CREBBP*; characterized by growth deficiency of postnatal onset, microcephaly, broad thumbs and halluces, neurocognitive impairment, and characteristic facies; increased risk of neoplasia

Russell-Silver syndrome—20–60% caused by imprinting abnormalities of chromosome 11, 10% by maternal uniparental disomy of chromosome 7; characterized by growth failure and short stature of prenatal onset with head sparing (relative but not absolute macrocephaly) and characteristic facies. Can have 5th finger clinodactyly, hemihypertrophy, and hyperpigmented macules

Sandhoff disease (GM2-gangliosidosis type II)—autosomal recessive; mutations in *HEXB*; deficiency of hexosaminidase B leading to

accumulation of GM2 gangliosides, particularly in neurons; progressive neurodegenerative disorder; hypotonia in the first 6 months of life, startle reaction, macular cherry-red spots, macrocephaly, organomegaly, and progressive neurocognitive impairment; manifestations similar to Tay-Sachs disease. No ethnic predilection

Sanfilippo syndrome, types A, B, C, and D—see “**mucopolysaccharidosis III.**”

Scheie syndrome—see “**mucopolysaccharidosis I.**”

Seckel syndrome—autosomal recessive; multiple subtypes differentiated by gene involved; characterized by growth failure of prenatal onset, extreme short stature, microcephaly, neurocognitive impairment, and characteristic facies

Short-rib thoracic dysplasia with or without polydactyly—autosomal recessive; mutations in various genes; this is a set of conditions caused by abnormalities in nonmotile cilia (the ciliopathies); characterized by skeletal dysplasia; short ribs; polydactyly; orofacial clefts; and abnormalities of the brain, eye, heart, kidneys, liver, pancreas, intestines, and genitalia. Includes Jeune, Ellis-van Creveld, Hydrolethrus, and others

Shwachman-Diamond syndrome—autosomal recessive; mutations in SBDS; characterized by exocrine pancreatic dysfunction, bone marrow dysfunction with risk of malignant transformation, and skeletal abnormalities with disproportionate short stature

Smith-Lemli-Opitz syndrome—autosomal recessive; mutations in DHCR7; disorder of cholesterol synthesis; characterized by growth retardation, microcephaly, hypospadias with cryptorchidism, characteristic 2–3 toe Y-shaped syndactyly, photosensitivity, neurocognitive impairment, and characteristic facies. Dietary cholesterol supplementation may result in clinical improvement of neurocognitive status.

Sotos syndrome (cerebral gigantism)—autosomal dominant; mutations in NSD1; characterized by macrocephaly, rapid somatic growth (final

height is usually the average for the family) large hands and feet, neurocognitive impairment that may be mild, and characteristic facies.

Stickler syndrome—autosomal dominant; mutations in COL2A1, COL11A1, or COL11A2; characterized by Pierre Robin anomaly at birth and mild skeletal features with more obvious problems later; characteristic vitreous and retinal abnormalities, high-frequency hearing loss, osteoarthritis before age 40 years; cognition usually normal

Sturge-Weber syndrome—multifactorial, can be caused by autosomal dominant somatic mutation of GNAQ; characterized by a port-wine stain on the face at the 1st branch of the trigeminal nerve; patients have ipsilateral leptomeningeal angiomas with intracranial calcifications leading to seizures and mental retardation and may also have ocular complications, such as glaucoma.

Tay-Sachs disease (GM2-gangliosidosis type I)—autosomal recessive; mutations in HEXA; characterized by deficient hexosaminidase activity which leads to accumulation of GM2 gangliosides in the CNS; patients have loss of motor milestones, seizures, macular cherry-red spot, and progressive neurodegeneration leading to blindness, paralysis, and death within the 2nd or 3rd year of life. Highest prevalence in Ashkenazi Jews

Testicular regression syndrome—characterized by bilateral gonadal absence in a person with 46 XY karyotype; phenotype depends on the amount of early testicular tissue present and active; ranges from phenotypic female to anorchic phenotypic male

Tetrasomy 22—see “[cat eye syndrome](#).”

Tourette syndrome—see “[Gilles de la Tourette syndrome](#).”

Treacher Collins syndrome—autosomal dominant; mutations in TCOF1; characterized by mandibulofacial dysostosis; characteristic finding of hypoplastic zygomatic arches and mandibles, micrognathia, downward slanting palpebral fissures, coloboma of the lower eyelid, microtia with associated conductive hearing deficits, and a cleft palate with or without

cleft lip; cognitive function is normal.

Trisomy 13 (Patau syndrome)—characterized by holoprosencephaly, aplasia cutis congenita, cleft lip and/or cleft palate, microphthalmia, postaxial polydactyly; cardiovascular anomalies in 80%; majority abort spontaneously; median survival is 7 days.

Trisomy 18 (Edwards syndrome)—characterized by severe neurocognitive impairment, growth failure of prenatal onset, and characteristic facies with prominent occiput, micrognathia; other common features are clenched hands with overriding fingers, a short sternum, and rocker bottom feet; cardiac and renal anomalies in up to 50% of cases; the majority abort spontaneously; median survival is 2 weeks.

Trisomy 21 (Down syndrome)—characterized by neurocognitive impairment and characteristic facies; 40% have congenital heart disease (particularly atrioventricular canal defects); other common findings are GI disorders (Hirschsprung disease, duodenal atresia), musculoskeletal abnormalities, leukemia, hearing loss, and thyroid disease. The majority of cases abort spontaneously. Survival past infancy depends on the specific defect(s) present.

Tuberous sclerosis—autosomal dominant; mutations in TSC1 or TSC2, also a contiguous gene deletion syndrome involving TSC2; characterized by hamartoma in brain, skin, heart, kidneys, and lung with secondary effects; seizures, neurocognitive impairment, renal and pulmonary compromise; pathognomonic skin lesions include hypopigmented macules (ash leaf spots), connective tissue nevi (shagreen patch), adenoma sebaceum, and subungual or periungual fibromas.

Turcot syndrome—see “[mismatch repair cancer syndrome](#).”

Turner syndrome (monosomy X)—45 X karyotype; paternal meiosis error; characterized by gonadal dysgenesis with sterility and primary amenorrhea, and short stature; may have cardiac malformations, congenital lymphedema of the extremities, and characteristic facial and body features

Usher syndrome—autosomal recessive; mutations in any of a number of genes; characterized by early retinitis pigmentosa, vestibular dysfunction, and sensorineural deafness

Vanishing testes syndrome—see “[testicular regression syndrome](#).”

VATER association—characterized by Vertebral defects, Anal atresia, Tracheoesophageal fistula with Esophageal atresia, and Radial and/or renal anomalies; may be expanded to VACTERL to include Congenital heart defects or other Limb defects; at least two noncardiac components must be present for the diagnosis; overlaps with diagnosable genetic conditions which must be considered; VATER is a diagnosis of exclusion rather than a primary diagnosis.

von Gierke disease—see “[glycogen storage disease](#).”

von Hippel—Lindau disease—autosomal dominant; mutations in VHL or CCND1; familial cancer syndrome; benign and malignant tumors, most frequently retinal, cerebellar and spinal hemangioblastoma, renal cell carcinoma, pheochromocytoma, and pancreatic tumors

Waardenburg syndrome—autosomal dominant; multiple types and subtypes; mutations most commonly in PAX3; pigmentary abnormalities of the hair, skin, and eyes (white forelock, heterochromia iridis, premature graying of hair) congenital sensorineural hearing loss, and characteristic facies

Wegener granulomatosis—complex genetics; necrotizing granulomatous vasculitis involving (a) the airways, leading to rhinorrhea, chronic sinusitis, nasal ulceration; (b) the lungs, causing hemoptysis, dyspnea, and cough; (c) the kidneys, manifested as hematuria and/or proteinuria due to glomerulonephritis; other symptoms include fever, malaise, weight loss, myalgias, arthralgias, ophthalmic involvement, neuropathies, and cutaneous nodules or ulcers.

Werner syndrome—autosomal recessive; mutations in RECQL2; characterized by scleroderma-like skin changes, premature arteriosclerosis,

diabetes mellitus, and an appearance of premature aging; short stature, slender limbs, and a stocky trunk

Williams syndrome—autosomal dominant; deletion in 7q11.23; characterized by hypercalcemia in infants, supraaortic stenosis, peripheral pulmonary artery stenosis, short stature, neurocognitive impairment, particularly in math, hypersocial with affinity for music, hyperacusis, characteristic facies

Wiskott-Aldrich syndrome—X-linked recessive; mutations in WAS; characterized by immunodeficiency, thrombocytopenia, severe eczema, and recurrent infections

Wolff-Parkinson-White syndrome—accessory conduction pathway found in 25% of patients with supraventricular tachycardia; typical electrocardiographic findings include a short PR interval and slow upstroke of the QRS (delta wave); may be an isolated finding, or related to structural cardiac defects; genetic or acquired

Wolman disease—see “[lysosomal acid lipase deficiency](#).”

Xeroderma pigmentosum—autosomal recessive; characterized by extreme sunlight sensitivity, slowly progressive neurocognitive impairment, photophobia, and cutaneous and ocular malignancies; skin is unable to repair itself after exposure to ultraviolet light; patients may have freckling, progressive skin atrophy, erythema, scaling bullae and crusting, telangiectasia.

Zellweger syndrome (cerebrohepato-renal syndrome)—autosomal recessive; mutations in PEX1; disorder of peroxisome biogenesis (absence of peroxisomes); characterized by severe neurologic dysfunction, hepatic cirrhosis and characteristic facies. The vast majority of patients die within the 1st year of life.

Appendix IV

Tables and Figures

Michael D. Cabana

DEVELOPMENTAL DISABILITIES

Table 1. Developmental Milestones from Birth to 5 Years				
Age (mo)	Adaptive/Fine Motor	Language	Gross Motor	Personal-Social
1	Grasp reflex (hands fisted)	Facial response to sounds	Lifts head in prone position	Stares at face
2	Follows object with eyes past midline	Coos (vowel sounds)	Lifts head in prone position to 45 degrees	Smiles in response to others
4	Hands open	Laughs and squeals	Sits: head steady	Smiles spontaneously
	Brings objects to mouth	Turns toward voice	Rolls to supine	
6	Palmar grasp of objects	Babbles (consonant sounds)	Sits independently	Reaches for toys
			Stands, hands held	Recognizes strangers
9	Pincer grasp	Says "mama," "dada" nonspecifically, comprehends "no"	Pulls to stand	Feeds self
				Waves bye-bye
12	Helps turn pages of book	2–4 words	Stands independently	Points to indicate wants
		Follows command with gesture	Walks, one hand held	
15	Scribbles	4–6 words	Walks independently	Drinks from cup
		Follows command no gesture		Imitates activities
18	Turns pages of book	10–20 words	Walks up steps	Feeds self with spoon
		Points to 4 body parts		
24	Solves single-piece puzzles	Combines 2–3 words	Jumps	Removes coat
		Uses "I" and "you"	Kicks ball	Verbalizes wants
30	Imitates horizontal and vertical lines	Names all body parts	Rides tricycle using pedals	Pulls up pants
				Washes, dries hands
36	Copies circle	Gives full name, age, and sex	Throws ball overhand	Toilet-trained
	Draws person with 3 parts	Names 2 colors	Walks up stairs (alternating feet)	Puts on shirt, knows front from back
42	Copies cross	Understands "cold," "tired," "hungry"	Stands on 1 foot for 2–3 s	Engages in associative play
48	Counts 4 objects	Understands prepositions (under, on, behind, in front of)	Hops on 1 foot	Dresses with little assistance
	Identifies some numbers and letters	Asks "how" and "why"		Shoes on correct feet
54	Copies square	Understands opposites	Broad-jumps 24 inches	Bosses and criticizes
	Draws person with 6 parts			Shows off
60	Prints first name	Asks meaning of words	Skips (alternating feet)	Ties shoes
	Counts 10 objects			

REFRACTIVE ERROR

A EMMETROPIA

B HYPEROPIA

C MYOPIA

D ASTIGMATISM

FIGURE 1. The normally refractive eye, common refractive errors, and their corrections. **A:** In a normal (emmetropic) eye, light rays from a near or far object are adequately refracted so that the rays converge directly on the retina, enabling formation of a clear image. **B:** In a farsighted (hypermetropic, hyperopic) eye, an image from a near point is focused behind the retina. The resulting condition can be corrected with convex lenses. **C:** In a nearsighted (myopic) eye, an image from a far point is focused in front of the retina. This refractive condition can be corrected with concave lenses. **D:** Refractive errors of astigmatism result from irregular curvatures of the cornea, lens, or both. Consequently, horizontal and vertical points from various visual fields are focused at two different focal points on the retina, resulting in distorted vision. (From Bhatnagar SC. *Neuroscience for the Study of Communicative Disorders*, 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2012.)

PRIMARY AND PERMANENT DENTITION

FIGURE 2. The Universal Numbering System. **A:** Primary teeth. **B:** Permanent teeth. (From Lippincott Williams & Wilkins. *Lippincott Williams & Wilkins' Comprehensive Dental Assisting*. Philadelphia: Lippincott Williams & Wilkins; 2011.)

PERIODONTAL STRUCTURES

FIGURE 3. The various types of trauma to the periodontal structures: concussion/subluxation (A), lateral luxation (B), intrusion (if primary tooth is intruded note location of developing permanent tooth bud) (C), extrusion (D), and avulsion (E). Refer emergencies B through E to the dental staff as soon as possible. (From Fleisher GR, Ludwig S, Henretig FM, et al. *Textbook of Pediatric Emergency Medicine*, 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2005.)

DEHYDRATION

Table 2. Clinical Signs of Dehydration in Children

Parameter	Mild	Moderate	Severe
Activity	Normal	Lethargic	Lethargic to comatose
Color	Pale	Gray	Mottled
Urine output	Decreased (<2–3 mL/kg/hr)	Oliguric (<1 mL/kg/hr)	Anuric
Fontanelle	Flat	Depressed	Sunken
Mucous membranes	Dry	Very dry	Cracked
Skin turgor	Slightly decreased	Markedly decreased	Tenting
Pulse	Normal to increased	Increased	Grossly tachycardic
Blood pressure	Normal	Normal	Decreased
Weight loss	5%	10%	15%

Hypernatremic dehydration may be accompanied by moderate clinical signs.
Reprinted with permission from Rogers MC. Shock. In: Rogers MC, Heliaer MA, eds. *Handbook of Pediatric Intensive Care*. 2nd ed. Baltimore: Williams Wilkins; 1994:140.

PLEURAL EFFUSION

Table 3. Characteristics of the Three Stages of Parapneumonic Pleural Effusions

	Exudative Stage	Fibrinolytic Stage	Organizing Stage (Empyema)
Appearance	Nonpurulent, not turbid	Nonpurulent, not turbid	Purulent, turbid
Fluid consistency	Free-flowing	Loculated	Organized
Gram stain and culture results	Negative	Transitional	Positive (before antibiotic treatment)
Glucose	>100 mg/dL	<50 mg/dL	<50 mg/dL
Protein	<3 g/dL	>3 g/dL	>3 g/dL
pH	>7.30	<7.30	<7.30
WBCs	Few	PMNs	PMNs

PMNs, polymorphonuclear neutrophils; WBCs, white blood cells.

Table 4. Pleural Fluid Diagnostic Studies

Study	Transudate	Exudate
Biochemical		
Pleural LDH	<200 IU	≥200 IU
Pleural fluid/serum LDH ratio ^a	<0.6	≥0.6
Pleural fluid/serum protein ratio ^a	<0.5	≥0.5
Specific gravity	<1.016	≥1.016
Protein level	<3.0 g/dL	≥3.0 g/dL
Other studies		
Glucose	Usually >40 mg/dL	Typically <40 mg/dL
Amylase	May be elevated in some neoplasms, GI trauma, or surgery	
Rheumatoid factor, LE prep, ANA	Are occasionally helpful if collagen vascular disorders are within the differential	
Hematologic		
WBC count	Although high counts (>100/mm ³) are suggestive of an exudate, the results are quite variable	
WBC differential	May actually provide more useful information	
Lymphocyte count	May be elevated in neoplasms, tuberculosis, and some fungal infections	
Segmented neutrophils	May be elevated in bacterial infections, connective tissue disease, pancreatitis, or pulmonary infarction	
Eosinophil count	May be elevated in bacterial infections, neoplasms, and connective tissue diseases	
RBC count	If >100,000/mm ³ , is suggestive of trauma, neoplasms, or pulmonary infarction	
Cytology and chromosomal studies	May show evidence of malignant cells or chromosomal abnormalities	
Microbiology		
Gram stain		
Fluid culture for aerobes and anaerobes		
Acid-fast stain (if tuberculosis is in the differential)		
Fungal culture		
Viral culture		
Counterimmune electrophoresis may aid in the detection of a bacterial infection)		

ANA, antinuclear antibody; LDH, lactate dehydrogenase; LE prep, lupus erythematosus cell preparation; WBC, white blood cell.

^aThese tests are more reliable in differentiating transudate from exudate than specific gravity or protein level.

COMA

Table 5. Glasgow Coma Scale

Eyes open		Best motor response	
Spontaneously	4	Obey commands	6
To speech	3	Localize pain	5
To pain	2	Withdrawal	4
None	1	Flexion to pain	3
Best verbal response		Extension to pain	2
Oriented	5	None	1
Confused	4		
Inappropriate	3		
Incomprehensible	2		
None	1		

Adapted from Fleisher G, Ludwig S, eds. *Textbook of Pediatric Emergency Medicine*. 3rd ed. Baltimore: Williams Wilkins; 1993:272.

Table 6. Glasgow Coma Scale for Adults and Children and Modified Score for Infants

	Glasgow Coma Scale (Adults/Older Children)		Modified Glasgow Coma Score (Infants)	
Eye opening	Spontaneous	4	Spontaneous	
	To verbal stimuli	3	To speech	
	To pain	2	To pain	
	None	1	None	
Best verbal response	Oriented	5	Coos and babbles	
	Confused speech	4	Irritable, cries	
	Inappropriate words	3	Cries to pain	
	Nonspecific sounds	2	Moans to pain	
	None	1	None	
Best motor response	Follows commands	6	Normal spontaneous movements	
	Localizes pain	5	Withdraws to touch	
	Withdraws to pain	4	Withdraws to pain	
	Flexes to pain	3	Abnormal flexion	
	Extends to pain	2	Abnormal extension	
	None	1	None	

VAGINITIS: PHYSICAL EXAM

Table 7. Key Characteristics of Vaginal Discharges

	Presenting Symptoms	Discharge	Nonmenstrual pH	Amine/Whiff Test	Vaginal Smear	Treatment
Nonspecific vaginitis	Foul-smelling discharge Itching	Scant to copious Brown to green in color	Variable	Negative	Leukocytes Bacteria and other debris	Improved perineal hygiene
Physiologic leukorrhea	None	Variable Scant to moderate Clear to white	<4.5	Negative	Normal epithelial cells Lactobacilli predominate	None
Bacterial vaginosis	Foul-smelling discharge	Gray-white	>4.7	Positive	Epithelial cells with bacteria ("clue cells") Gram-negative rods	Metronidazole Clindamycin
Candidiasis	Severe itching Vulvar inflammation	White, "curd-like"	<4.5	Negative	Fungal hyphae and buds	Topical or intra-vaginal imidazoles, triazoles Oral ketoconazole Metronidazole
Trichomonal vaginitis	Copious discharge Itching	Profuse Yellow to green	5.0–6.0	Occasionally present	Motile flagellated organisms	
Foreign body	Foul-smelling discharge	Purulent Dark brown	Variable (usually >4.7)	Occasionally present	Leukocytes Epithelial cells with bacteria and debris	Remove foreign body. Irrigate vagina.
Contact vulvovaginitis	Vulvar inflammation Itching Edema	Scant White to yellow	Variable (usually <4.5)	Negative	Leukocytes Epithelial cells	Remove irritant. Topical steroids

FOOD POISONING OR FOODBORNE ILLNESS

Table 8. Epidemiologic Aspects of Food Poisoning

Organism	Pathogenesis	Source	Prevention
<i>Salmonella</i>	Infection	Meats, poultry, eggs, dairy products	Proper cooking and food handling, pasteurization
<i>Staphylococcus</i>	Preformed enterotoxin	Meats, poultry, potato salad, cream-filled pastry, cheese, sausage	Careful food handling, rapid refrigeration
<i>Clostridium perfringens</i>	Enterotoxin	Meats, poultry	Avoid delay in serving foods, avoid cooling and rewarming foods
<i>Clostridium botulinum</i>	Preformed neurotoxin	Honey, home-canned foods, uncooked foods	Proper refrigeration (see text)
<i>Vibrio parahaemolyticus</i>	Infection enterotoxin	Sea fish, seawater, shellfish	Proper refrigeration
<i>Bacillus cereus</i>	Sporulation enterotoxin	Many prepared foods	Proper refrigeration
Diarheal type			Proper refrigeration of cooked rice and other foods
Vomiting type	Preformed toxin	Cooked or fried rice, vegetables, meats, cereal, puddings	
Enterohemorrhagic including STEC O157:H7	Cytotoxins	Milk, beef	Thorough cooking of beef, consumption of pasteurized milk products
Enterotoxigenic <i>Escherichia coli</i> (traveler's diarrhea)	Enterotoxin	Food or water	Travelers should drink only bottled or canned beverages and water, and avoid ice, raw produce including salads, and peeled fruit. Cooked foods should be eaten hot.

STEC, Shiga toxin-producing *Escherichia coli*.

Table 9. Clinical Aspects of Food Poisoning

Organism	Incubation	Symptoms	Duration
<i>Bacillus cereus</i>	Vomiting toxin 1–6 h Diarrhea toxin 6–24 h	Vomiting ± diarrhea; fever uncommon	8–24 h
<i>Brucella</i>	Several days to months; usually >30 d	Weakness, fever, headache, chills, arthralgia, weight loss, splenomegaly	
<i>Campylobacter</i>	2–10 d; usually 2–5 d	Diarrhea (often bloody), abdominal pain, fever	
<i>Clostridium botulinum</i>	2 h to 8 d; usually 12–48 h	Poor feeding, weak cry, constipation, diplopia, blurred vision, respiratory weakness; symmetric descending paralysis	
<i>Clostridium perfringens</i>	6–24 h	Diarrhea, abdominal cramps, vomiting and fever uncommon	<24 h
<i>Escherichia coli</i>	→	→	→
<i>E. coli</i> O157:H7	1–10 d; usually 3–4 d	Diarrhea (often bloody), abdominal cramps, little or no fever. Can cause HUS	5–10 d
ETEC	6–48 h	Diarrhea, abdominal cramps, nausea, fever, and vomiting; uncommon	5–10 d
<i>Listeria monocytogenes</i>	2–6 wk	Meningitis, neonatal sepsis, fever	Variable
Nontyphoidal <i>Salmonella</i>	6–72 h	Diarrhea often with fever and abdominal cramps	<7 d
<i>Salmonella typhi</i>	3–60 d; usually 7–14 d	Fever, anorexia, malaise, headache, myalgias ± diarrhea or constipation	3–4 wk
<i>Shigella</i>	12 h to 6 d; usually 2–4 d	Diarrhea (often bloody), frequently fever, abdominal cramps	1 d to 1 mo
<i>Staphylococcus aureus</i>	30 min to 8 h; usually 2–4 h	Vomiting, diarrhea	<24 h
<i>Vibrio</i>	4–30 h	Diarrhea, cramps, nausea, vomiting	Self-limited
<i>Yersinia enterocolitica</i>	1–10 d; usually 4–6 d	Diarrhea, abdominal pain (often severe), mesenteric adenitis, pseudoappendicular syndrome	1–3 wk

ETEC, enterotoxigenic *Escherichia coli*; HUS, hemolytic uremic syndrome.

ACNE: PREGNANCY CLASS

Table 10. U.S. Food and Drug Administration Pharmaceutical Pregnancy Categories

Pregnancy Category A	Adequate and well-controlled human studies have failed to demonstrate a risk to the fetus in the 1st trimester of pregnancy (and there is no evidence of risk in later trimesters).
Pregnancy Category B	Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.
Pregnancy Category C	Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
Pregnancy Category D	There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
Pregnancy Category X	Studies in animals or humans have demonstrated fetal abnormalities and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

RICKETS

Table 11. Assessment of Etiology of Rickets Based on Laboratory Results

	Ca	Phos	Alk phos	iPTH	25-(OH)D	1,25-(OH) ₂ D	Urine Ca/ Cr	TRP
Nutritional/insufficient sunlight	N or ↓	↓	↑	↑	↓	↑	↓	↑
Malabsorption	N or ↓	↓	↑	↑	↓	↑	↓	↑
Renal tubular defects	N or ↓	↓	↑	↑	N	↑	↑	N or ↓
Altered vitamin D metabolism	N or ↓	↓	↑	↑	↓	↑	↓	↑
Genetic forms of rickets								
X-linked, AD, and AR hypophosphatemic rickets	N	↓	↑	N or ↑	N	N or ↑	N or ↓	↓
1α-hydroxylase deficiency	↓	↓	↑	↑	N	↓	↓	↑
Vitamin D receptor mutations (vitamin D resistance)	↓	↓	↑	↑	N	↑	↓	↑
Hereditary hypophosphatemic rickets with hypercalciuria	N or ↓	↓	↑	↑	N	↑	↑	↓
Hypophosphatasia	N or ↑	N or ↑	↓	N or ↓	N	N or ↓	N or ↑	N

AD, autosomal dominant; alk phos, alkaline phosphatase; AR, autosomal recessive; Ca, calcium; Ca/Cr, calcium/creatinine ratio; iPTH, intact parathyroid hormone; N, normal; 1,25-(OH)₂-D, 1,25-dihydroxy vitamin D; phos, phosphorus; TRP, tubular reabsorption of phosphorus [(1 - (U phos × P Cr)/(U Cr × S Phos)) × 100, normal 85–95%]; 25-(OH)-D, 25-hydroxy vitamin D.

Table 12. Dietary Reference Intake for Calcium and Vitamin D

Age	Calcium			Vitamin D		
	Estimated Average Requirement (mg/d)	Recommended Dietary Allowance (mg/d)	Upper Level Intake (mg/d)	Estimated Average Requirement (IU/d)	Recommended Dietary Allowance (IU/d)	Upper Level Intake (IU/d)
0–6 mo	200	200	1,000	400	400	1,000
6–12 mo	260	260	1,500	400	400	1,500
1–3 y	500	700	2,500	400	600	2,500
4–8 y	800	1,000	2,500	400	600	3,000
9–18 y	1,100	1,300	3,000	400	600	4,000
19–30 y	800	1,000	2,500	400	600	4,000

Adapted from Ross AC, Abrams SA, Aloia JF, et al. Dietary reference intakes for calcium and vitamin D. <http://www.iom.edu/~media/Files/Report%20Files/2010/Dietary-Reference-Intakes-for-Calcium-and-Vitamin-D/Vitamin%20D%20and%20Calcium%202010%20Report%20Brief.pdf>. Accessed March 1, 2015.

CONGENITAL ADRENAL HYPERPLASIA

Table 13. Clinical and Biochemical Features of Congenital Adrenal Hyperplasia

Enzyme Defect	Sexual Ambiguity		Additional Clinical Manifestations	Predominant Steroids
	Female	Male		
Desmolase	—	+	Salt wasting	—
3 β -hydroxysteroid dehydrogenase	+	+	Salt wasting	17-OH-pregnenolone, DHEA
21-hydroxylase	+	—	Salt wasting	17-OH-progesterone, androstenedione
11-hydroxylase	+	—	Hypertension	11-deoxycortisol
17-hydroxylase	—	+	Hypertension	DOC, corticosterone

DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone.

ACETAMINOPHEN POISONING

ASTHMA

STEPWISE APPROACH FOR MANAGING ASTHMA LONG TERM

The stepwise approach tailors the selection of medication to the level of asthma severity (see page 5) or asthma control (see page 6). The stepwise approach is meant to help, not replace, the clinical decisionmaking needed to meet individual patient needs.

ASSESS CONTROL:		STEP UP IF NEEDED (first, check medication adherence, inhaler technique, environmental control, and comorbidities)					
		STEP DOWN IF POSSIBLE (and asthma is well controlled for at least 3 months)					
		STEP 1	STEP 2	STEP 3	STEP 4	STEP 5	STEP 6
		At each step: Patient education, environmental control, and management of comorbidities					
0-4 years of age		Intermittent Asthma	Persistent Asthma: Daily Medication				
	Preferred Treatment ^a	SABA ^a as needed	Consult with asthma specialist if step 3 care or higher is required. Consider consultation at step 2.				
	Alternative Treatment ^{a,†}		low-dose ICS ^a	medium-dose ICS ^a	medium-dose ICS ^a + either LABA ^a or montelukast	high-dose ICS ^a + either LABA ^a or montelukast	high-dose ICS ^a + either LABA ^a or montelukast + oral corticosteroids
		If clear benefit is not observed in 4-6 weeks, and medication technique and adherence are satisfactory, consider adjusting therapy or alternate diagnoses.					
Quick-Relief Medication		<ul style="list-style-type: none"> SABA^a as needed for symptoms. Intensity of treatment depends on severity of symptoms. With viral respiratory symptoms: SABA every 4-6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if asthma exacerbation is severe or patient has history of severe exacerbations. Caution: Frequent use of SABA may indicate the need to step up treatment. 					
5-11 years of age		Intermittent Asthma	Persistent Asthma: Daily Medication				
	Preferred Treatment ^a	SABA ^a as needed	Consult with asthma specialist if step 4 care or higher is required. Consider consultation at step 3.				
	Alternative Treatment ^{a,†}		low-dose ICS ^a	low-dose ICS ^a + either LABA ^a , LTRA ^a , or theophylline [§]	medium-dose ICS ^a + LABA ^a	high-dose ICS ^a + LABA ^a	high-dose ICS ^a + LABA ^a + oral corticosteroids
			cromolyn, LTRA ^a , or theophylline [§]	OR medium-dose ICS	medium-dose ICS ^a + either LTRA ^a or theophylline [§]	high-dose ICS ^a + either LTRA ^a or theophylline [§]	high-dose ICS ^a + either LTRA ^a or theophylline [§] + oral corticosteroids
		Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma. ^{¶¶}					
Quick-Relief Medication		<ul style="list-style-type: none"> SABA^a as needed for symptoms. The intensity of treatment depends on severity of symptoms: up to 3 treatments every 20 minutes as needed. Short course of oral systemic corticosteroids may be needed. Caution: Increasing use of SABA or use >2 days/week for symptom relief (not to prevent EIB[§]) generally indicates inadequate control and the need to step up treatment. 					
≥12 years of age		Intermittent Asthma	Persistent Asthma: Daily Medication				
	Preferred Treatment ^a	SABA ^a as needed	Consult with asthma specialist if step 4 care or higher is required. Consider consultation at step 3.				
	Alternative Treatment ^{a,†}		low-dose ICS ^a	low-dose ICS ^a + LABA ^a OR medium-dose ICS ^a	medium-dose ICS ^a + LABA ^a	high-dose ICS ^a + LABA ^a AND consider omalizumab for patients who have allergies [¶]	high-dose ICS ^a + LABA ^a + oral corticosteroid ^{¶¶} AND consider omalizumab for patients who have allergies [¶]
			cromolyn, LTRA ^a , or theophylline [§]	low-dose ICS ^a + either LTRA ^a , theophylline [§] , or zileuton	medium-dose ICS ^a + either LTRA ^a , theophylline [§] , or zileuton		
		Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma. ^{¶¶}					
Quick-Relief Medication		<ul style="list-style-type: none"> SABA^a as needed for symptoms. The intensity of treatment depends on severity of symptoms: up to 3 treatments every 20 minutes as needed. Short course of oral systemic corticosteroids may be needed. Caution: Use of SABA >2 days/week for symptom relief (not to prevent EIB[§]) generally indicates inadequate control and the need to step up treatment. 					

^a Abbreviations: EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, inhaled long-acting beta₂-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta₂-agonist.

[†] Treatment options are listed in alphabetical order, if more than one.

[‡] If alternative treatment is used and response is inadequate, discontinue and use preferred treatment before stepping up.

[§] Theophylline is a less desirable alternative because of the need to monitor serum concentration levels.

[¶] Based on evidence for dust mites, animal dander, and pollen, evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.

^{¶¶} Clinicians who administer immunotherapy or omalizumab should be prepared to treat anaphylaxis that may occur.

^{||} Zileuton is less desirable because of limited studies as adjunctive therapy and the need to monitor liver function.

^{|||} Before oral corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.

 Umbilical cord knot, 425
 Umbilical hernia, 2
 Umbilical stump infection, 642–643
 Umbilical vein thrombosis, 425

- Unconjugated hyperbilirubinemia, 524
- Upper airway resistance syndrome, 847
- Upper gastrointestinal bleeding (UGIB), 962–963
- Upper respiratory infection (URI), 238–239
- Urachal cyst, 2
- Urachus, patent, 642
- Urea cycle defects, 585
- Ureaplasma urealyticum, 183, 666
- Ureter, ectopic, 310, 462, 463
- Ureteral obstruction, 965
- Ureterocele, 462, 463, 596, 836
- Ureteropelvic junction obstruction, 2, 256, 462, 463, 596, 964–965, 968
- Ureterovesical junction obstruction, 463, 984
- Urethral atresia, 742
- Urethral prolapse, 836
- Urethral stricture, 318
- Urethral valves, posterior, 264, 462, 463, 720–721
- Urethritis, 318
- Urethromeatoplasty, 485
- Urinary incontinence
 - daytime, 264–265 (see also Dysfunctional elimination syndrome [DES])
 - nocturnal, 264, 332–333
- Urinary tract infections (UTIs), 264, 288, 581, 667, 743, 758, 966–967, 968, 984
- Urinary tract obstruction, 968, 969
- Urination
 - blood with, 420–421
 - painful, 318–319
 - with posterior urethral valves, 720–721
 - in proteinuria, 740–741
- Urine output, in diabetes insipidus, 286
- Urolithiasis, 462, 968–969
- Ursodeoxycholic acid (UDCA), 401, 619
 - for alpha-1 antitrypsin deficiency, 37
 - for biliary atresia, 111
 - for cholelithiasis, 187
 - for congenital hepatic fibrosis, 221
 - for hepatitis, 195
- Urticaria, 32, 146, 343, 436, 811, 970–971
- Urticaria, solar, 694
- Urticaria multiforme, 343

Uterine adhesion, 315
Uterine bleeding, dysfunctional, 312–313
Uterine duplication, 498
Uterine fibroids, 315
Uterine polyps, 313, 315
Uterus, bicornuate, 742
Uveitis, 158, 224, 390
Uvulitis, 338

V

Vaccine(s)
 22q11.2 deletion syndrome and, 268
 adenovirus, 8, 28
 adverse events with, 972–973
 anthrax, 60
 in asplenia, 77
 contraindications for, 972
 diphtheria, 300
 DTaP, 972
 febrile seizures and, 820
 hepatitis, 973, 986
 human papillomavirus, 457, 973
 influenza, 338, 504, 505, 973
 live virus, 972
 measles, 384, 566, 973
 MMR, 384, 973
 mumps, 598
 rabies, 783
 recommendations, 356
 rotavirus, 973
 in severe combined immunodeficiency, 835
 in sickle cell disease, 842
 smallpox, 850
 tetanus, 372, 973
 tuberculosis, 952
 varicella, 178, 973
VACTERL, 498, 918, 934
Vagal maneuvers, 894
Vaginal atresia, 498, 742
Vaginal candidiasis, 152, 153

Vaginal reflux, 264
 Vaginitis, 312, 398, 974–975
 Vaginosis, 172
 Valacyclovir, 107, 173
 Valproate, 194, 355, 582, 821, 823
 Valproic acid, 415, 444, 503, 658, 770, 871
 Valsalva maneuver
 for barotitis, 102, 103
 for supraventricular tachycardia, 894
 Valvular aortic stenosis, 607
 Vancomycin, 49, 129, 169, 193, 327, 577, 643, 647, 783, 845, 869, 879, 929, 933
 Van der Woude syndrome, 200
 Vanishing bile duct syndrome, 198
 Vanishing testes syndrome, 249, 751
 Variant Creutzfeldt-Jakob disease (vCJD), 734–735
 Varicella, 34, 178–179, 225, 318, 320, 338, 343, 500, 670, 851, 875
 Varicella vaccine, 178, 973
 Varicocele, 459, 507, 976–977
 Variola virus, 850–851
 Vascular brain lesions, 978–979
 Vascular endothelial growth factor (VEGF), 781
 Vascular lesions, 418–419
 Vascular ring, 934, 936
 Vasculitis, 433, 708, 880, 948, 999
 Vasodilators, 755. See also specific agents
 for cor pulmonale, 235
 for hemolytic uremic syndrome, 426
 Vasomotor rhinitis, 844
 Vasopressin, 287
 VATER, 964
 Vedolizumab, 961
 Vegetarian diet, 574
 Veillonella, 48
 Vein of Galen malformations (VOGMs), 978, 979
 Velocardiofacial syndrome, 200, 268–269, 536. See also DiGeorge syndrome;
 22q11 Microdeletion syndrome
 Venlafaxine, 609, 855
 Veno-occlusive disease (VOD), in bone marrow transplantation, 117
 Venous sinus thrombosis, 650
 Ventilation

- in congenital diaphragmatic hernia, 297
 - high-frequency, 570
 - mechanical, 775
 - for meconium aspiration, 570
 - in tracheoesophageal fistula, 935
- Ventral hernia, 2
- Ventricular inversion, 945
- Ventricular septal defect (VSD), 222, 306, 665, 742, 754, 914, 944, 980–981
- Ventricular tachycardia (VT), 898, 982–983
- Verapamil, 894, 983
- Verbal auditory agnosia, 858
- Verbal dyspraxia, 858
- Verrucae, 994–995
- Vertebral osteomyelitis, 302
- Vesicoureteral reflux (VUR), 151, 264, 310, 462, 463, 596, 965, 966, 984–985
- Vesicovaginal fistula, 318, 742
- Vestibular neuronitis, 82, 881
- Vibrio cholerae, 188
- Vigabatrin, 503, 955
- Vinblastine, 150, 453
- Vincent angina, 301
- Vincent curtsy, 264
- Vincristine
 - for acute lymphoblastic leukemia, 25
 - for brain tumors, 125
 - effects of, 150
 - for Hodgkin lymphoma, 453
 - for non-Hodgkin lymphoma, 633
 - for rhabdomyosarcoma, 789
 - syndrome of inappropriate antidiuretic hormone secretion with, 900
 - for Wilms tumor, 1003
- Viral hepatitis, 22–23, 986–987, 1004
- Viral meningitis, 576–577
- Viral myocarditis, 606–607
- Vision
 - in amblyopia, 42–43
 - in cataract, 158–159
 - refractive errors and, 766–767
 - in strabismus, 876
- Vitamin A

- deficiency, 691
- for measles, 567
- Vitamin A supplementation
 - for bronchopulmonary dysplasia, 138
 - for cholera, 189
- Vitamin A toxicity, 244, 272
- Vitamin B₁₂ deficiency, 490, 575, 655, 907
- Vitamin C deficiency, 140, 389
- Vitamin D
 - for 22q11.2 deletion syndrome, 268
 - for chronic kidney disease, 197
 - deficiency, 100, 476, 480, 794
 - in diet, 795
 - intoxication, 227
 - supplementation, 794–795
- Vitamin E deficiency, 557
- Vitamin K, for liver failure, 23
- Vitamin K deficiency, 140, 305
- Vitamin supplementation, in short-bowel syndrome, 840
- Vitiligo, 694
- Vocal cord dysfunction, 32, 436, 936
- Volvulus, 3, 446, 510, 516, 544, 613, 827, 840, 889, 988–989
- Vomiting, 990–991. See also Cyclic vomiting syndrome (CVS)
- Von Hippel-Lindau disease, 657
- Von Willebrand disease, 9, 140, 141, 313, 428, 636, 992–993
- Von Willebrand factor, 992, 993
- Voriconazole
 - for aspergillosis, 75
 - for blastomycosis, 113
 - for cryptococcal infections, 247
- Vulvar carcinoma, 994
- Vulvovaginitis, 696, 759, 974–975

W

- WAGR syndrome, 1002
- Walker-Warburg syndrome, 460
- Walled-off necrosis (WON), 656
- Warfarin, 140, 921
- Warfarin-induced skin necrosis, 757
- Warts, 994–995. See also Human papillomavirus (HPV)

Wasp stings, 852
Water deprivation test, 286
Waterhouse-Friderichsen syndrome, 732
Water intoxication, 332, 900
Weakness, 83–84, 106, 280, 316, 602
Webbed penis, 668
Wegener granulomatosis, 430, 433, 700, 708, 830
Weight faltering, 350–351
Weight loss, 195, 291, 639, 996–997
Werdnig-Hoffmann disease, 119
Westley Croup Score, 242
West Nile virus (WNV), 326, 783, 939, 946, 998–999
West syndrome, 502
Wet cough, 238
Wheezing, 1000–1001
Whooping cough, 140, 183, 239, 688–689
Wide-complex tachycardia, 894
Williams syndrome, 166, 355, 464
Wilms tumor, 2, 420, 597, 627, 632, 772, 1002–1003
Wilson disease (WD), 22, 82, 194, 198, 199, 435, 525, 741, 790, 865, 1004–1005
Winged scapula, 672
Wiskott-Aldrich syndrome (WAS), 86, 94, 466, 490, 492, 614, 632, 1006–1007
Withdrawal, acute drug, 18–19
Wolf-Hirschhorn syndrome, 664
Wolff-Parkinson-White syndrome (WPW), 617, 894, 895, 898
Wolman disease, 435, 865
Wound botulism, 118, 119

X

Xeroderma pigmentosa, 694
Xerosis, 86
Xerostomia, 151
X-linked agammaglobulinemia (XLA), 212, 478, 492, 834, 972
X-linked hypophosphatemia (XLH), 480
X-linked lymphoproliferative syndrome (XLP), 340, 492, 554, 555, 632
X-linked neutropenia (XLN), 1006
X-linked thrombocytopenia (XLT), 1006, 1007
Xylitol chewing gum, 273

Y

Yellow nail, 552
Yersinia, 44
Yersinia enterocolitica, 67, 1008–1009
Yersinia pestis, 698–699

Z

Zanamivir, 505
Zellweger syndrome, 199, 361, 561, 711
Zinc
 for cholera, 189
 for Wilson disease, 1005
Zinc deficiency, 34
Zollinger-Ellison syndrome, 574
Zonisamide, 503, 823

Table of Contents

Title Page	4
Copyright	8
Dedication	10
Preface	12
Contributing Authors	16
Sixth Edition Author Acknowledgments	128
Abdominal Mass	149
Abdominal Migraine	158
Abdominal Pain	165
Abnormal Bleeding	175
Acetaminophen Poisoning	184
Acne	192
Acquired Hypothyroidism	206
Acute Drug Withdrawal	214
Acute Kidney Injury	223
Acute Liver Failure	231
Acute Lymphoblastic Leukemia	241
Acute Myeloid Leukemia	250
Adenovirus Infection	259
Alcohol (Ethanol) Intoxication	267
Allergic Child	275
Alopecia (Hair Loss)	284
Alpha-1 Antitrypsin Deficiency	294
Altitude Illness	302
Ambiguous Genitalia	311
Amblyopia	320
Amebiasis	328

Amenorrhea	336
Anaerobic Infections	344
Anaphylaxis	352
Anemia of Chronic Disease (Anemia of Inflammation)	361
Ankyloglossia	367
Anomalous Left Coronary Artery From the Pulmonary Artery (ALCAPA)	373
Anorexia Nervosa	379
Anthrax	388
Aplastic Anemia	397
Apparent Life-Threatening Event	407
Appendicitis	416
Arthritis, Juvenile Idiopathic (Rheumatoid)	422
Ascaris Lumbricoides (Ascariasis)	431
Ascites	437
Aspergillosis	446
Asplenia/Hyposplenia	454
Asthma	461
Ataxia	476
Atelectasis	484
Atopic Dermatitis	492
Atrial Septal Defect	500
Attention-Deficit/Hyperactivity Disorder (ADHD)	506
Autism Spectrum Disorder	516
Autoimmune Hemolytic Anemia	524
Avascular (Aseptic) Necrosis of the Femoral Head (Hip)	533
Babesiosis	539
Back Pain	548

Barotitis	557
Bartter Syndrome	564
Bell Palsy	570
Bezoars	580
Biliary Atresia	585
Blastomycosis	593
Blepharitis	600
Bone Marrow and Stem Cell Transplant	607
Botulism and Infant Botulism	617
Brain Abscess	627
Brain Injury, Traumatic	634
Brain Tumor	643
Branchial Cleft Malformations	651
Breast Abscess	657
Breast Milk and Breastfeeding Jaundice	665
Breastfeeding	674
Breath-Holding Spells	683
Bronchiolitis (See Also: Respiratory Syncytial Virus)	691
Bronchopulmonary Dysplasia (BPD)	700
Bruising	709
Bruxism	718
Bulimia	725
C1 Esterase Inhibitor Deficiency	735
Campylobacter Infections	742
Cancer Therapy Late Effects	750
Candidiasis	761
Carbon Monoxide Poisoning	769
Cardiomyopathy	776
Cataract	786

Cat-Scratch Disease	795
Cavernous Sinus Syndrome	803
Cavernous Transformation and Portal Vein Obstruction	810
Celiac Disease	818
Cellulitis	827
Cerebral Palsy	836
Cervicitis	845
Chancroid	852
Chest Pain	857
Chickenpox (Varicella, Herpes Zoster)	866
Child Abuse, Physical	875
Chlamydia Trachomatis Infection	884
Chlamydophila (Formerly Chlamydia) Pneumoniae Infection	891
Cholelithiasis	895
Cholera	903
Chronic Diarrhea	912
Chronic Granulomatous Disease	922
Chronic Hepatitis	931
Chronic Kidney Disease	940
Cirrhosis	948
Cleft Lip and Palate	956
Clubfoot	966
Coarctation of Aorta	973
Coccidioidomycosis	981
Colic	991
Coma	999
Common Variable Immunodeficiency	1008
Complement Deficiency	1017

Concussion	1022
Congenital Adrenal Hyperplasia	1030
Congenital Hepatic Fibrosis	1039
Congestive Heart Failure	1046
Conjunctivitis	1056
Constipation	1066
Contact Dermatitis	1075
Contraception	1084
Cor Pulmonale	1099
Costochondritis	1107
Cough	1114
Crohn Disease	1124
Croup (Laryngotracheobronchitis)	1134
Crying	1145
Cryptococcal Infections	1154
Cryptorchidism	1163
Cryptosporidiosis	1171
Cushing Syndrome	1177
Cutaneous Larva Migrans	1185
Cyclic Vomiting Syndrome	1190
Cyclospora	1199
Cystic Fibrosis	1205
Cytomegalovirus Infection	1215
Daytime Incontinence	1224
Dehydration	1231
22Q11.2 Deletion Syndrome (DiGeorge Syndrome, Velocardiofacial Syndrome)	1238
Dental Caries	1245
Dental Health and Prevention	1250

Dental Infections	1258
Dental Trauma	1265
Depression	1272
Dermatomyositis/Polymyositis	1282
Developmental Delay	1293
Developmental Dysplasia of the Hip	1301
Diabetes Insipidus	1310
Diabetes Mellitus, Type 1	1319
Diabetes Mellitus, Type 2	1328
Diabetic Ketoacidosis	1338
Diaper Rash	1346
Diaphragmatic Hernia (Congenital)	1354
Diarrhea	1363
Diphtheria	1373
Diskitis	1381
Disseminated Intravascular Coagulation	1386
Down Syndrome (Trisomy 21)	1392
Drowning	1402
Dysfunctional Elimination Syndrome	1412
Dysfunctional Uterine Bleeding	1418
Dysmenorrhea	1427
Dyspnea	1436
Dysuria	1445
Earache	1451
Edema	1460
Ehrlichiosis and Anaplasmosis	1466
Encephalitis	1474
Encopresis	1482
Endocarditis	1491

Enuresis	1500
Eosinophilic Esophagitis	1509
Epididymitis	1517
Epiglottitis	1522
Epstein-Barr Virus (Infectious Mononucleosis)	1530
Erythema Multiforme	1539
Erythema Nodosum	1545
Ewing Sarcoma	1551
Exstrophy–Epispadias Complex	1560
Failure to Thrive (Weight Faltering)	1568
Feeding Disorders	1577
Fetal Alcohol Syndrome	1586
Fever and Petechiae	1594
Fever of Unknown Origin	1602
Floppy Infant Syndrome	1610
Food Allergy	1621
Food Hypersensitivity (Non–IgE-Mediated, Gastrointestinal)	1631
Food Poisoning or Foodborne Illness	1639
Fragile X Syndrome	1648
Frostbite	1657
Functional Diarrhea of Infancy (Toddler’s Diarrhea)	1667
Fungal Skin Infections (Dermatophyte Infections, Candidiasis, and Tinea Versicolor)	1675
Gastritis	1684
Gastroesophageal Reflux	1691
Germ Cell Tumors	1702
German Measles (Third Disease, Rubella)	1709
Giardiasis	1715

Gingivitis	1723
Glaucoma–Congenital	1732
Glomerulonephritis	1741
Glucose-6-Phosphate Dehydrogenase Deficiency	1749
Goiter	1757
Gonococcal Infections	1767
Graft-Versus-Host Disease	1776
Graves Disease	1785
Growth Hormone Deficiency	1794
Guillain-Barré Syndrome	1802
Gynecomastia	1810
Hand, Foot, and Mouth Disease	1819
Head Banging	1826
Headache and Migraine	1830
Heat Stroke and Related Illness	1839
Hemangiomas and Other Vascular Lesions	1848
Hematuria	1857
Hemolysis	1867
Hemolytic Disease of the Newborn	1876
Hemolytic Uremic Syndrome	1884
Hemophilia	1893
Hemoptysis	1902
Henoch-Schönlein Purpura	1909
Hepatomegaly	1918
Hereditary Angioedema	1928
Hereditary Spherocytosis	1936
Heroin Intoxication	1944
Herpes Simplex Virus	1954
Hiccups (Singultus)	1965

Hirschsprung Disease	1974
Histiocytosis	1982
Histoplasmosis	1992
Hodgkin Lymphoma	2002
Human Immunodeficiency Virus Infection	2011
Human Papilloma Virus	2021
Hydrocele	2028
Hydrocephalus	2035
Hydronephrosis	2044
Hypercalcemia	2054
Hyperimmunoglobulinemia E Syndrome	2062
Hyperinsulinism	2067
Hyperleukocytosis	2075
Hyperlipidemia	2083
Hypertension	2092
Hypocalcemia	2101
Hypogammaglobulinemia	2111
Hypophosphatemic Disorders	2117
Hypoplastic Left Heart Syndrome	2127
Hypospadias	2135
Hypothyroidism, Congenital	2141
Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)	2150
Idiopathic Thrombocytopenic Purpura	2157
Immune Deficiency	2166
Immunoglobulin A Deficiency	2176
Immunoglobulin A Nephropathy	2183
Imperforate Anus	2191
Impetigo	2198

Infantile Spasms	2205
Influenza	2214
Inguinal Hernia	2224
Intellectual Disability	2231
Intestinal Obstruction	2240
Intoeing–Tibial Torsion	2249
Intracranial Hemorrhage	2256
Intussusception	2265
Iron Deficiency Anemia	2272
Iron Poisoning	2282
Irritable Bowel Syndrome	2289
Jaundice	2297
Kawasaki Disease	2306
Knee Pain, Anterior/Patellofemoral Malalignment Syndrome	2316
Lacrimal Duct Obstruction	2321
Lactose Intolerance	2329
Lead Poisoning	2336
Learning Disabilities	2346
Leukocytosis	2355
Lice (Pediculosis)	2363
Long QT Syndrome	2372
Lower GI Bleeding	2380
Lupus Erythematosus	2391
Lyme Disease	2399
Lymphadenopathy	2406
Lymphedema	2415
Lymphoproliferative Disorders	2423
Malabsorption	2433

Malaria	2440
Malformations of Cortical Development	2449
Mammalian Bites	2457
Mastoiditis	2464
Measles (Rubeola)	2472
Meckel Diverticulum	2480
Meconium Aspiration Syndrome	2487
Mediastinal Mass	2496
Megaloblastic Anemia	2503
Meningitis	2511
Meningococemia	2521
Mesenteric Adenitis	2528
Metabolic Diseases in Acidotic Newborns	2535
Metabolic Diseases in Hyperammonemic Newborns	2544
Metabolic Diseases in Hypoglycemic Newborns	2552
Metabolic Syndrome	2560
Methemoglobinemia	2570
Microcytic Anemia	2577
Milia	2585
Multicystic Dysplastic Kidney	2589
Mumps/Parotitis	2594
Munchausen Syndrome by Proxy (Child Abuse in the Medical Setting)	2603
Muscular Dystrophies	2609
Myasthenia Gravis	2618
Myocarditis	2628
Narcolepsy	2637
Neck Masses	2644
Necrotizing Enterocolitis	2653

Neonatal Alloimmune Thrombocytopenia	2663
Neonatal Apnea	2671
Neonatal Cholestasis	2680
Neonatal Encephalopathy	2688
Nephrotic Syndrome	2695
Neural Tube Defects	2703
Neuroblastoma	2713
Neurofibromatosis-1	2721
Neutropenia	2729
Non-Hodgkin Lymphoma	2737
Nontuberculous Mycobacterial Infections (Atypical Mycobacterial Infections)	2747
Nosebleeds (Epistaxis)	2753
Obesity	2760
Obsessive-Compulsive Disorder	2770
Omphalitis	2776
Osteogenesis Imperfecta	2785
Osteomyelitis	2794
Osteosarcoma	2802
Otitis Externa	2810
Otitis Media	2819
Pallor	2827
Pancreatic Pseudocyst	2835
Pancreatitis	2842
Panhypopituitarism	2852
Parvovirus B19 (Erythema Infectiosum, Fifth Disease)	2861
Patent Ductus Arteriosus	2868
Pelvic Inflammatory Disease (PID)	2876
Penile and Foreskin Problems	2886

Pericarditis	2894
Perinatal Brachial Plexus Palsy	2903
Periodic Breathing	2911
Periorbital Cellulitis	2917
Perirectal Abscess	2923
Peritonitis	2929
Peritonsillar Abscess	2937
Persistent Pulmonary Hypertension of the Newborn	2944
Perthes Disease	2953
Pertussis	2961
Pharyngitis	2969
Phimosis and Paraphimosis	2978
Photosensitivity	2983
Pinworms	2991
Plague	2998
Pleural Effusion	3006
Pneumocystis Jiroveci (Previously Known as Pneumocystis Carinii Pneumonia)	3015
Pneumonia—Bacterial	3024
Pneumothorax	3034
Polyarteritis Nodosa	3043
Polycystic Kidney Disease	3049
Polycystic Ovary Syndrome	3057
Polycythemia	3065
Polyps, Intestinal	3074
Portal Hypertension	3082
Posterior Urethral Valves	3091
Prebiotics	3100
Precocious Puberty	3105

Premature Adrenarche	3113
Premature Thelarche	3119
Premenstrual Syndrome	3125
Primary Adrenal Insufficiency	3134
Prion Diseases (Transmissible Spongiform Encephalopathies)	3143
Probiotics	3151
Protein-Energy Malnutrition	3157
Proteinuria	3167
Prune Belly Syndrome	3175
Pruritus	3182
Psittacosis	3190
Psoriasis	3196
Pubertal Delay	3205
Pulmonary Embolism	3214
Pulmonary Hypertension	3223
Purpura Fulminans	3231
Pyelonephritis	3240
Pyloric Stenosis	3249
Rabies	3255
Rectal Prolapse	3263
Refractive Error	3272
Renal Artery Stenosis	3281
Renal Tubular Acidosis	3290
Renal Venous Thrombosis	3297
Respiratory Distress Syndrome	3305
Respiratory Syncytial Virus (See Also: Bronchiolitis)	3314
Retinoblastoma	3323
Retinopathy of Prematurity	3331

Retropharyngeal Abscess	3339
Reye Syndrome	3345
Rhabdomyolysis	3351
Rhabdomyosarcoma	3359
Rheumatic Fever	3368
Rhinitis, Allergic	3377
Rickets/Osteomalacia	3387
Rickettsial Disease	3395
Rocky Mountain Spotted Fever	3402
Roseola	3412
Rotavirus	3416
Salicylate Poisoning (Aspirin)	3422
Salmonella Infections	3428
Sarcoidosis	3438
Scabies	3444
Scarlet Fever	3451
Scleroderma	3459
Scoliosis (Idiopathic)	3469
Seborrheic Dermatitis	3477
Seizures—Febrile	3484
Seizures, Partial and Generalized	3493
Separation Anxiety Disorder	3502
Sepsis	3509
Septic Arthritis	3519
Serum Sickness	3528
Severe Acute Respiratory Syndrome (SARS)	3536
Severe Combined Immunodeficiency	3544
Sexual Abuse	3550
Short Stature	3560

Short-Bowel Syndrome	3570
Sickle Cell Disease	3579
Sinusitis	3587
Sleep Apnea—Obstructive Sleep Apnea Syndrome	3597
Slipped Capital Femoral Epiphysis	3606
Smallpox (Variola Virus)	3611
Snake and Insect Bites	3620
Social Anxiety Disorder	3630
Sore Throat	3636
Speech Delay	3644
Speech Problems	3653
Spinal Muscular Atrophy	3663
Splenomegaly	3672
Spondyloarthropathy	3680
Staphylococcal Scalded Skin Syndrome	3686
Status Epilepticus	3693
Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis	3701
Stomatitis	3709
Strabismus	3718
Strep Infection: Invasive Group A β -Hemolytic Streptococcus	3726
Stroke	3735
Stuttering	3744
Subdural Hematoma	3752
Substance Use Disorders	3761
Sudden Infant Death Syndrome	3769
Suicide	3778
Superior Mesenteric Artery Syndrome	3787

Supraventricular Tachycardia	3793
Sympathomimetic Poisoning	3801
Syncope	3810
Syndrome of Inappropriate Antidiuretic Hormone Secretion	3817
Synovitis–Transient	3825
Syphilis	3830
Tapeworm	3840
Teething	3850
Tendonitis	3857
Tetanus	3861
Tetralogy of Fallot	3870
Thalassemia	3876
Thoracic Insufficiency Syndrome	3885
Thrombosis	3893
Tick Fever	3902
Tics	3911
Toxic Alcohols	3920
Toxic Shock Syndrome	3929
Toxoplasmosis	3938
Tracheitis	3945
Tracheoesophageal Fistula and Esophageal Atresia	3953
Tracheomalacia/Laryngomalacia	3961
Transfusion Reaction	3968
Transient Erythroblastopenia of Childhood	3977
Transient Tachypnea of the Newborn	3983
Transposition of the Great Arteries	3991
Transverse Myelitis	4000
Trichinosis	4008

Trichotillomania	4017
Tuberculosis	4023
Tuberous Sclerosis Complex	4032
Tularemia	4040
Turner Syndrome	4048
Ulcerative Colitis	4055
Upper Gastrointestinal Bleeding	4065
Ureteropelvic Junction Obstruction	4074
Urinary Tract Infection	4082
Urolithiasis	4091
Urticaria	4096
Vaccine Adverse Events	4105
Vaginitis	4114
Varicocele	4123
Vascular Brain Lesions (Congenital)	4129
Ventricular Septal Defect	4137
Ventricular Tachycardia	4145
Vesicoureteral Reflux	4152
Viral Hepatitis	4161
Volvulus	4171
Vomiting	4178
Von Willebrand Disease	4187
Warts	4195
Weight Loss	4204
West Nile Virus (and Other Arbovirus Encephalitis)	4213
Wheezing	4222
Wilms Tumor	4231
Wilson Disease	4237
Wiskott-Aldrich Syndrome	4247

Yersinia Enterocolitica	4255
